The use of an absorbent of this kind would, therefore, reduce the amount of material to be brought into the city to less than one-third, or to an amount equal to the excreta to be removed; or 5,000,000 cubic feet brought in, and 10,000,000 cubic feet taken out, annually, the daily removal being 385 tons in, and 770 tons out. This is not more than the present daily removal of ashes, while there would be no greater nuisance, and the value, exclusive of the value of the charcoal, would be about 15s. per ton. Viewed in this light, the dry closet system presents strong claims to notice, and, in a sanitary sense, its arrangements are perfect.

Air Carriage.

Carriage by atmospheric pressure possesses several advantages afforded by neither of the former systems, both of which add a large bulk of valueless, but costly, material to the excreta to be removed. Considering the great value, and easy application, of pneumatic pressure, it is remarkable that so little attention has been directed to it as a means of dealing with excreta; it has been entirely overlooked by those great authorities who have professed to look into all the bearings of this difficult question.

The principal effort in this direction is due to Captain Tiernur. I will briefly describe the main features of this proposition, referring to "The Sewage Question," by Krepp, for further details. Captain Tiernur proposes to place in houses a simple open-pan closet of a particular form, in connection with a vertical soil-pipe, and so shaped that the total excreta fall at once to the bottom of this pipe in the basement storey of the house, where it collects in a small syphon bend. The soil-pipe is made of earthenware, 14 to 16 inches in diameter, and is continued to the top of the house, where it is open to the air, and covered with a wind-guard for ventilation. The syphon bend and bottom of the pipe are of cast-iron narrowed from the soil-pipe to a 5-inch cast-iron pipe. This is continued to a central receiver, sunk in the public street. This reservoir has about 20 cubic feet capacity; and allowing 1 cubic foot to every thirty-six individuals, each serves about 700 persons and a number of houses. Each house has a so-called house-valve, which is accessible from the street, and closes the connection with the sewage reservoir. This reservoir may be placed in any central position in the public street, sunk under the ground, and surmounted by an ornamental lamp-post, within which the two communicating pipes are concealed. It is of a nearly spherical shape, or quite spherical top and bottom, with cylindrical sides. It receives the drain-pipes from a number of houses, collected in four main branches, which enter it with a slight bend at the top; the house pipes and main pipes are all about 5 inch bore, the former entering the latter horizontally at an angle of 30°, and a curve of 2 feet radius. The main pipes have a gentle downward inclination towards the reservoir, but enter it by a sudden bend upwards. There are two vertical pipes concealed within the lamp-post—one, the air-pipe, about 3 inch bore, fixed to the top of the reservoir; and the other the exit soil pipe, about 6 inch bore, continued nearly to the bottom of the reservoir.

The mode of filling and emptying these receivers is by a "locomotive engine and pneumatic tender," which is drawn by one horse, assisted by the steam power of the engine, to the several reservoirs during the night. The process is simple; the engine works a powerful air-pump, which is placed in connection with the reservoir and the tender; in about three minutes the gauge indicates a vacuum of about 10 lbs. to the square inch, or about 20 in. barometer pressure, and both are sufficiently exhausted. The several house-valves are then opened and closed consecutively, and the contents of the syphons instantly shot into the receiver by the downward pressure of air in the soil-pipe, the vertical ventilating shaft acting like a pea-shooter. When all the house-traps are discharged, the air-pipe of the receiver is disconnected, the exit soil-pipe connected with the exhausted tender, the contents thus transferred to it, and the whole machine is driven off to the next reservoir; the foul gas from the air-pump is blown into the engine furnace. The tenders have each 100 cubic feet capacity, 10 cubic feet of which is used as a water-tank to the engine. When full, these are taken to "decanting houses," where the contents are transferred to barrels. These barrels are 28 inches in diameter, 32 inches long, about 5 cubic feet capacity, and made of strong oak staves bound with iron hoops; they form the stores for the manure, and for its transport, and are to be sold direct to farmers. For applying the contents directly to the soil, which is Captain Tiernur's special object, he proposes plans of ingenious manure ploughs and meadow manurers, which support the barrel and empty its contents at once into the furrow, where it is covered over and kept at once from decomposition. During frost, he proposes keeping these barrels in store.

The method of collecting, and particularly of applying, the excreta in these barrels, seems to me a most unnecessary complication. Glasgow would collect at the rate of 2,740 barrels a day, and a month's frost would accumulate an explosive store of 82,000 barrels; while in the summer I fear the barrels could not be used fast enough to prevent decomposition. There is also this great objection to this method, which applies, also, to irrigation, that we are compelled to sell our manure constantly to get it off our hands, and by making the farmer take it when he does not want it, and cannot advantageously apply it, we are entirely at his mercy, and must accept his prices; but if we could store it, make it into good manure, and sell it when he wants it, then, and not till then, can we expect to realise its value. If the other parts of this plan work well, a modification would make this feasible.

* Read before the Glasgow Sewage Association, March 30th, 1869.

We have a material to deal with in chemical works which presents some analogy with that under consideration; it must be kept from the air, it cannot be handled; but it is nearly double the weight of the excreta, and very corrosive. Yet this is lifted, without any difficulty, to great heights, and carried long distances, with no trouble and little expense, by atmospheric pressure; and could not the excreta be dealt with in the same way? The drain-pipes from the houses should be led into iron reservoirs, the size and number of these to be determined; the total daily removal being only 13,700 cubic feet, twelve cylindrical boilers with egg-shaped ends, about 10′ × 10′, by 15 to 20 feet long, sunk vertically, would be sufficient for Glasgow. It might, however, be advisable to have smaller vessels in larger number; that is a matter of detail.

These reservoirs are all to be connected, by a small air-pipe, to one or more central pumping stations, where a powerful air-pump is fixed; each, also, to be furnished with an exit soil pipe, passing to the bottom, and continued up into a main pipe leading to one or two manure works situated some miles out of town.

This would, then, be the process of removal; at a fixed hour at night the air-pump would be set to exhaust a large iron reservoir at the pumping station, and communicating with the air pipes attached to the soil reservoirs. Two men for each district would then be sent round, and, opening the air-pipe valve, would place each receiver in connection with the exhausting pump, and then open, consecutively, the house-valves, by which means the soil-pipes would be nightly discharged, and the whole closet ventilated by a powerful blast of air. This is one operation. During the day, at a certain hour, the engine and air-pump would be reversed, and pump air into the air-vessel at the pumping station; the several soil reservoirs would then be placed in connection, and the contents lifted, by the atmospheric pressure, away to the manure works.

When we consider that a pressure of 50 lbs. on the square inch can be thus easily applied, there is merely the friction and some little weight to overcome; the plan seems quite practicable, and is, at any rate, worth a trial. The piping required would be an arterial system of small cast-iron piping; its cost, compared to sewers, would be little, and the cost for pumping must be insignificant, compared to that for lifting sewage in such enormous quantities.

The Abbey Mills pumping station has eight engines, 142 horse power each, or 11·36 horse power; and these lift 15,000 cubic feet a minute 36 feet high. We have only to lift 385 tons, or 13,700 cubic feet, and the whole day's produce of Glasgow may be contained in a tank 30 feet square and 16 feet deep. These pumps, therefore, would do our day's work in fifty-four seconds.

When engineer's talk of intercepting sewers for our sewage, they mean immense culverts of brick, which leak in all directions, and are full of noxious gases, to carry off 137,000 tons of sewage a day, containing 385 tons, or 1-355th of excreta, and only 38½ tons, or 1-3550th of its weight, of solid excreta. My notion of a true intercepting sewer is a perfectly tight and cheap cast-iron pipe, which will really intercept this excreta, and deal with it alone. It is, to all intents and purposes, a fluid, and subject to all the laws of fluid pressure; to add 355 times its weight of water to *make it fluid*, is not only "carting coals to Newcastle," but it is paying very heavily for the pleasure of doing so.

Engineers should consider the possibility of removing, without nuisance, the excreta, as it is, from where it is to where it should be; because, if it can be so delivered, the further disposal of it can be safely left to chemists, who may, then, be fairly asked to turn it to account. We have not hitherto had a fair chance; engineers are allowed to mix the excreta with much water, and then to turn round and ask chemists to separate it again, forgetting that the "*reductio ad absurdum*" is *not* a chemica process.

Dickens, in his preface to the last edition of "Pickwick Papers," after referring to the great improvements which have taken place since he wrote the work, ventures a hope that "it may some day be discovered that the universal diffusion of common decency and health is as much the right of the poorest of the poor as it is indispensable to the safety of the rich and of the state; that a few petty boards and bodies—less than drops in the great ocean of humanity which roars around them—are not for ever to let loose fever and consumption on God's creatures at their will, or always to keep their jobbing little fiddles going for a dance of death."

DECOMPOSITION OF REFRACTORY SILICATES BY FLUORIDES IN THE WET WAY.

By CHARLES E. AVERY,
Student in the Massachusetts Institute of Technology.

I FIND that silica and silicates, such as felspar and glass, may be completely dissolved in the cold by a mixture of some normal fluoride with almost any of the stronger acids, whether concentrated or dilute.

When mixed with the fluorides of sodium, barium, aluminum, lead, or the double fluorides of these metals, the silicates in question can be readily decomposed by nitric, chlorhydric and sulphuric acids, either concentrated or diluted with four volumes of water.

If strong sulphuric acid is used, a part of the silicon passes off as gas; if the dilute acid is used, portions of many silicates remain undissolved as insoluble sulphates.

The same decomposition of the silicates is effected, though less easily by the action of oxalic, acetic, tartaric, and like acids, on the mixed fluoride and silicate. Carbonic acid, even as dilute as in the air, does the same thing, but less rapidly.

Strong nitric acid gives a perfect solution and acts rapidly, dissolving a moderately fine powder of felspar or quartz in a few hours even in the cold. The loss of silica is very slight if the experiment is properly conducted; hence, all the constituents of a siliceous mineral can be estimated in the solution produced.

In analysing the silicates in this way, it is best to use the fluoride of some metal which is not to be estimated in the analysis; since, if we use a fluoride whose metal is present in the mineral, we must know the weight of fluoride taken. Of the various fluorides those of barium and lead seem to me the most promising.

An objection to the use of fluoride of ammonium is that, as usually made, it contains sulphate of ammonium, so that insoluble sulphates might be formed and solution retarded.

If fluoride of sodium, as made from cryolite, were not so hard to purify, it would be well fitted for the analysis of silicates free from sodium.

It has long been known that acid fluorides attack the silicates, and that even acetic acid can change normal into acid fluorides; but, so far as I know, no one has before shown that the action of acids is sufficiently rapid and complete, in the cold, to be useful in analysis. In another paper, I shall give the details of the process of solution, the method of analysis, and the means of making the fluorides.

Boston, February, 1869.

Quantitative Estimation of Sulphocyanides.—According to experiments instituted by Dr. Rüdorff, the estimation of the aforenamed salts, when neutral and soluble in water, is perfectly reliable when executed by means of titration with a neutral soluble silver salt. Experiments made by the author with properly re-crystallised sulphocyanides of ammonium and potassium yielded exactly the theoretical quantity; the salts experimented with had been purified by re-crystallisation from alcohol and afterwards drying.—*Poggendorff's Annalen.*

NOTICES OF BOOKS.

More Light: A Dream in Science. Wyman and Sons, Great Queen Street, Lincoln's Inn Fields.

IN the so-called "scientific world" we find a large number of men who do not work. The reasons why they do not work are not always so obvious as one would imagine. Some, including among them many of our most influential and successful men, do not work simply because they find it unnecessary. Fluent, strong in voice and in nerve; ambitious, and, perhaps, just the least thing in the world intriguing, they find it far more easy to acquire a position in scientific societies by criticising the researches of others than by working themselves. It is men like these who so mercilessly cross-examine the laborious workers who venture to read their papers before scientific bodies. These cross-examinations are, moreover, often carried on in a semi-bantering tone, as if the student had taken a liberty in bringing his results before a body, some of whose most august members found work unnecessary. And how often, in all countries, do we find the mantles of the greatest workers placed on the shoulders of these very men!

On the other hand, a vast number of those we meet in scientific circles do not work, simply because they prefer to dream. As there are people (even in this our day) who buy works on witchcraft and alchemy, not as curiosities, to be laid on the shelf until wanted as illustrations of the history of a past age, but to read them with reverence and faith, so there are men who revel in any darkness that has a savour of mystery. They have an instinctive repugnance of those physical truths which can be demonstrated by an appeal to the balance; as we have said, they prefer to dream; but we must do them the justice to say they generally keep their dreams to themselves. The author of the pamphlet before us is a man of a different stamp; he publishes his dreams, charges one-and-sixpence for them, and, fearful that his just rights and property in his dreams will be infringed, he carefully reserves the right of translating them. This is wrong. When a great prophet comes to give us "more light" (and we confess that we need it), he should rather encourage than repress those who would disseminate it.

But, to proceed—It was on a winter's evening, in December, 1866, that our author sat by the fire reading, to relax what he is pleased to term "his mind," which had been for several hours absorbed in "abstruse scientific speculations." The book that he read was George Henry Lewes's "Life of Goethe." As he read his last memorable words, "More light!" and pondered upon their depth of meaning, he fell asleep. What then happened he does not tell us; but a mysterious line of asterisks at once informs us that it was something very awful. Soon there appeared at his right hand a man, "beautiful of countenance." On his brow was a band, on which appeared, in sparkling gems, the name "Oriel," "Light of God;" and in his right hand he held a rod. Our author here pathetically tells us that he "trembled." This was but natural; he probably feared that Oriel was about to lay it on. Oriel, however (who, althongh a highly rectified spirit, appears to disagree with the stomach or brain of the eminently dyspeptic dreamer), bids him not be afraid, and, good-naturedly taking him by the hand, places him on a "Pinnacle of the Universe."

Oriel then tells him the destiny of the sun, and explains a few other astronomical phenomena, in language which shows distinctly that he has read Herschel's "Astronomy," and that his reading has been for edification. Our author (doubtless because Oriel has laid aside his rod) now not only ceases to "tremble," or to be "afraid," but even summons up courage enough to put a regular poser to Oriel in these startling words—"What is matter?" Oriel, evidently at a nonplus for the moment, does exactly what we all do under similar circumstances, and, instead of answering the question, proposes another, namely, "What is mind?" If our author had been sharp, here was a capital opportunity for a repartee. He should have answered "It is *no matter*;" but, instead of this, he somewhat feebly gives the views of Newton and Bishop Berkeley. Afterwards, feeling that he is expected to quote some more modern philosopher, he states "matter to be nothing but force, thus depriving it of that grossness generally supposed to belong to it." This, he says, "was the opinion of Faraday, who could not prove it, but yet believed it not impossible."

Poor Oriel, feeling himself unable to oppose the views of Faraday, without losing the confidence of our Dreamer, then states his own views to be the same. We would here most respectfully put the following difficulty which occurs to us, to Oriel. If you say that matter is force, we hope you will admit that force is matter; and, therefore, if, by out-flanking the question, in endeavouring to *take* grossness from matter, do you not at the same time *give* grossness to force? We do not insist upon this argument, because we feel, with Sir Roger de Coverley, "that much may be said on both sides."

Oriel then goes on to show our Dreamer (let us here confess that we had very nearly omitted the capital D) the "original element," and to prove that "this original element" is, "paradoxical as it may seem, *nothing*."

Up to this point we had travelled in all faith with our author; but when we find him gravely state that Oriel's next step was to make this "original element" (which he admits to be Nothing) revolve on its axis, we gave it up. We do not wonder, then, that after a few more feats, which Robert Houdin might have studied with advantage, our author says, "Despair took hold of me; my brain began to whirl, my feet to slip from under me, when—oh! relief!—I awoke; and it was a dream." At this point, we made a great discovery. "More light" is an allegory. Oriel means spirit; as we said before, highly rectified spirit; and thus we see that, under the influence of too strong a dose of "Oriel," we may expect our brains to whirl, and our feet to slip from under us.

Pharmacopœæ Recentiores, Anglica, Gallica, Germaniæ, Helvetica, Russiæ, inter se collatæ. Scripsit, præfatus est et indicem triplicem adjecit, H. HAGER, Phil. Dr., Vratislaviæ. Günther, 1869.

THIS work will, undoubtedly, be appreciated by all really scientific medical men, as well as by pharmaceutists everywhere, and Dr. Hager deserves the greatest possible credit, and the sincere thanks of the profession for this publication. As the title indicates, he has compared, *inter se*, the pharmacopœias recently published in Great Britain, France, Germany (not to be confused with the Pharmacopœæ Borussica (Prussian), for the work here alluded to is in use in Central Germany, in dominions not as yet Prussianised), Switzerland, and, lastly, the immense Russian empire.

Throughout this work, the rule of most continental pharmacopœias, that weighing shal almost always be resorted to, instead of measuring, has been rigidly adhered to, and the measures of the British pharmacopœia have been reduced to weights as far as possible. The book is alphabetically arranged, and is, therefore, easy for reference.

Taking a couple of instances, almost at random, we observe, in the Russian codex only, a very excellent prescription for making magnesia sulphurosa (sulfis magnesiæ), a salt now used internally in this country. The French codex has syrupus chinini sulphurici (sirop de sulfate de quinine), a useful preparation to give to young children, if required.

There are added to the work (1st) very useful tabulated forms, taken from the Swiss and German codices, wherein are indicated the single doses of the more active preparations and compounds, *above* which the substances named should not be dispensed, *unless* the medical man who pre-

scribes *distinctly* requires higher doses to be given; (2nd) indices for reference in the French, English, and Latin languages.

The book is well printed, in clear type, by M. Günther, at Breslau.

Labels for Chemical Substances. In paper wrapper, price 6d. London: John J. Griffin and Sons, 22, Garrick Street, W.C.

In a recent number, we noticed several editions of chemical labels. We have since received another book, containing 195 labels, admirably arranged by A. Vernon Harcourt, M.A., F.R.S., Secretary to the Chemical Society, and H. G. Madan. The nomenclature is similar to that adopted in "Fownes" and "Roscoe." The labels for solutions contain an indication of the strength of the solution, and an explanation of the expressions used is also given. We are told that a book on laboratory practice, by the same authors, will shortly be issued.

CORRESPONDENCE.

EQUIVALENCE AND QUANTIVALENCE.

To the Editor of the Chemical News.

Sir,—No better proof can be wanted of the truth of Professor Williamson's remarks, upon the conflicting views held by chemists on the theories of equivalence and quantivalence, than a comparison of the opinions which those remarks have called forth.

Mr. Ward regards atomicity and quantivalence, equivalent and atomic weight, as synonymous terms. Mr. Orme describes the equivalent of an element as a varying quantity, from which the atomic weight is deduced by theoretical considerations, and from which it differs, being, of course, constant. Mr. Attfield tells us that the term equivalent is correctly used with "distinct meanings," that the equivalents of Cl, O, N, C, are 1, 2, 3, 4, "in regard to the exchangeable values of atoms" but 35½, 8, 4⅔, 3, "in displacing one part by weight of hydrogen." "Chemicus" seems to follow Wurtz in considering the term equivalence a substitute for atomicity.

Doubtless these conflicting ideas would be reconciled, and much vagueness overcome, by accepting the definitions given by Mr. Ward, but unfortunately for our peace of mind, we cannot adopt them, unless we shut our eyes to chemical phenomena and our minds to the reasoning of not less able chemists. Equivalence may justly be considered *ponderal*, but equivalent weight can scarcely be taken as synonymous with atomic weight, as Mr. Ward seems to think. Let it be for a moment considered that atoms represent forces—as may be done upon the supposition that saturated compounds are in a state of equilibrium—then we may suppose that the atom of phosphorus in such a compound as the pentachloride (PCl_5) exerts a force five times as great as one atom of chlorine, consequently $\frac{1}{5}$ will represent a force equal to that exerted by 35·5 parts by weight of chlorine, and may reasonably be said to be equivalent to it. No such equivalent relation, however, exists between 1 part by weight of hydrogen and 16 of oxygen.

The numerical nature of quantivalence or atomicity is, of course, universally granted; a difference has, however, already arisen with regard to the use of these two terms, which Mr. Ward considers as synonymous. Naquet, in his excellent "Handbook of Chemistry," has preferred using the term atomicity for the maximum amount of saturation of which an element is capable, while he reserves the term quantivalence to express its varying saturating power. Thus he speaks of lead as being tetratomic, but forming a series of compounds in which it is bivalent. If atoms represent forces, they must be definite forces, which sometimes become latent, and it seems desirable to have a special nomenclature by which the degree of latency may be expressed.

Since, then, the word atomicity is objected to by chemists (not, I think, without cause), and the expression quantivalence has a special significance, I would suggest that the term equivalent *number* be used to express the *fixed* saturating power of polyatomic bodies. If this course were adopted, we should speak of an element, such as phosphorus, as having for its

Atomic weight	31
Equivalent weight	$\frac{31}{5}$
Equivalent number	5

And as forming compounds, such as PCl_3, in which it is trivalent, and others, such as PCl_5, in which its quantivalence and equivalent number are the same.—I am, &c.,

C. H.

MISCELLANEOUS.

The Chemical Society, wishing to honour the memory of its late distinguished Fellow, Professor Faraday, and at the same time to promote the personal intercourse of the Society with eminent foreign chemists, has decided upon instituting a Faraday Medal, to be awarded, from time to time, to some foreign chemist of distinction, upon his accepting the invitation of the President and Council of the Chemical Society to deliver a lecture to its Fellows. The inaugural lecture will be delivered on June 17th by M. Dumas, Master of the French Mint, a personal friend of Professor Faraday's, and well known to chemists all over the world as the author of many important investigations in organic chemistry, and especially as the introducer of the doctrine of chlorine substitutions. By permission of the managers, M. Dumas's lecture will be delivered in the theatre of the Royal Institution, associated for so many years with Professor Faraday's own expositions. The Fellows of the Society and their friends will dine together at Willis's Rooms on June 18th, on which occasion M. Dumas is expected to be present as a guest.

Collodion for Protecting Silver Wares.—The loss of silver which results from the impregnation of our atmosphere with sulphur compounds, especially where gas is burned, is very great. It has been said that many thousands of pounds' worth go down our sewers annually in the form of dirt from plate cleaning, and the loss of one large house on Cornhill from this source has been described to us as serious. Silversmiths may, then, thank one of their confraternity—Herr Strolberger, of Munich—for a happy thought. He seems to have tried various plans to save his silver, if possible. He covered his goods with a clear white varnish, but found that it soon turned yellow in the window, and spoilt the look of his wares. Then he tried water glass (solution of silicate of potash), but this did not answer. He tried some other solutions, to no purpose; but at last he hit upon the expedient of doing his goods over with a thin coating of collodion, which he finds to answer perfectly. No more loss of silver, and no longer incessant labour in keeping it clean. The plan he adopts is this:—He first warms the articles to be coated, and then pays them carefully over with a thinnish collodion diluted with alcohol, using a wide, soft brush for the purpose. Generally, he says, it is not advisable to do them over more than once. Silver goods, he tells us, protected in this way, have been exposed in his window more than a year, and are as bright as ever, while others unprotected have become perfectly black in a few months.—*Mechanic's Magazine.*

Depth of some Recently-Bored Wells.—As an evident proof of the greatly advanced desire to procure for domestic purposes good and pure water and a plentiful supply thereof, it is interesting to learn that within the last five years the undermentioned wells have been bored, some of them at very great expense. At Antwerp, to a depth of 165 metres below the surface; at Ostend, 300 metres; at Oeynhausen, Prussia, 696 metres; at Mondorff, Grand Duchy of Luxemburg, 730 metres; at Passy, Paris, 624 metres; at Rochefort, Charente Inférieure, France, 816 metres (this is the deepest bored well now existing in Europe). At Grissee, Soerabaya, Java, a well has been bored to a depth of 549 metres through hard rock. The deepest boring in Holland has been carried to a depth of 182 metres below sea level at Gorkum, at which depth in that locality, the tertiary formation has been reached, but water only of very indifferent quality; with this exception all the above-named wells yield water in abundance, and of great purity.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

In accordance with the generally expressed wishes of our friends and readers, we are endeavouring to effect arrangements to enable us to give, under the above heading, notices of EVERY CHEMICAL PAPER IN THE WORLD, *as soon as possible after publication. Whenever possible, these notices will appear in the form of carefully prepared, although necessarily brief, abstracts; as respects papers either too long or too abstruse to render condensation possible, their titles will be chronicled; and in all cases accurate reference will be made to the original publication. The two half-yearly volumes of the* CHEMICAL NEWS, *with their copious indices, will therefore be equivalent to an English edition of the "Jahresberichte," with the additional advantage of keeping the readers week by week on a level with the latest advances of science.*

Annales des Mines, vol. 14, sixth series, No. 6.

The greater portion of this valuable periodical is filled with information of use only to the officials and officers of the Corps Impérial des Ingénieurs des Mines. We meet, however, with a large number of results of analyses of waters, among which is one, very recently made, by M. Péligot, of—

The Water of the Grenelle Artesian Well.—The author calls attention to the remarkable fact that this water does not contain any dissolved oxygen, but only nitrogen, the quantity of which amounts to 14 c.c. to the litre of the water at 10° C. The total saline residue to the litre amounts to 0·142 grm.; the percentage composition of this saline matter is:—Carbonate of lime, 40·8; carbonate of magnesia, 11·5; carbonate of potassa, 14·4; carbonate of protoxide of iron, 2·2; sulphate of soda, 11·3; hyposulphite of soda, 6·4; chloride of sodium, 6·4; silica, 7·0. The same author has estimated the quantity, and determined the quality of the gases contained in rain water fallen and collected in the neighbourhood of Paris; 1 litre of this water gave off 23 c.c. of gas composed, in 100 parts, of 2·4 parts of carbonic acid; the remainder was a mixture of oxygen and nitrogen, in the proportion of 32 parts of the former to 68 of the latter. M. Stoelet has discovered that the water brought up from the coal-pits contains a greasy matter, soluble in ether, and no doubt derived from the coal; from his observations at and about collieries, he draws the conclusion that this greasy or fatty matter makes the water unsuitable, and, at times, even dangerous, for the use of steam boilers, since it may cause explosions.

It being impossible to quote all, or even the larger portion, of the results of mineral water analysis contained in the above-named periodical, we conclude this brief notice with—

Analysis of the Water of Villa Salice, near Voghéra, Piédmont.—M. Tissandier.—The dry residue for 1 litre weighs 65·532 grms., composed of—Chloride of sodium, 61·544 grms.; chloride of calcium, 1·031; iodide of magnesium, 1·338; sulphate of lime, 0·144; carbonate of lime, 0·811; carbonate of magnesia, 0·165; silica, alumina, oxide of iron, and organic matter, 0·499; total, 65·532 grms. This water is remarkable on account of the large quantity of iodine it contains.

This number of the *Annales* contains, moreover, a valuable collection of the results of recently-made analyses of minerals and rocks from divers parts of the globe.

Bulletin Mensuel de la Société Chimique de Paris, May, 1869.

This number opens with the *extraits des procès-verbaux des séances*, from which we abstract the following:—

Urea.—M. Bouchardat communicated that he had studied the conditions which accompany the production of urea by the action of ammonia upon chloroxycarbonic acid; besides urea, cyanic amides, melanuric acid, and other substances are formed. Hydrogen, in the nascent state, attacks nitrate of urea, thereby producing divers gases, consisting of hydrogen compounds, nitrogen, and carbonic acid. This reaction may be applied to the quantitative estimation of urea, by weighing the quantity of carbonic acid given off.

Oxysulphide of Carbon.—M. Ladenburg gave an oral account of his researches on oxysulphide of carbon. This substance, first obtained by M. Than, by means of the decomposition of sulphocyanate of potassium with dilute sulphuric acid, is also the product of the action of sulphuretted hydrogen upon cyanic ether, and of the action of heat upon thiacetic acid; it is also formed when sulphide of carbon acts upon urea.

Hydrates of Hydrocyanic Acid.—M. Gautier made a few observations on the question of the existence of well-defined hydrates of hydrocyanic acid. The experiments of MM. Bussy and Buignet, on the contraction of mixtures of water and hydrocyanic acid, led to a maximum contraction, corresponding to a mixture expressed by the formula $2CNH+3H_2O$; if, M. Gautier says, there do exist hydrates, their fusing point must be constant. In order to test this, the author made several experiments on this subject, with mixtures made up of variable quantities of hydrocyanic acid and water taken in definite proportions; not one of these mixtures had a constant melting point (*point de fusion constant*). From his experiments, the author draws the conclusion that two definite hydrates may be said to exist expressed by the formulæ CNH,H_2O and $CNH,2H_2O$; these, by combining together, produce the hydrate $2CNH,3H_2O$.

Iodide of Silicium.—M. Friedel made a brief communication relating to the iodide of silicium, Si_2I_6, which is formed by the action of silver upon the tetraiodide. The first-mentioned substance is decomposed, by heat, into tetraiodide and diniodide; water decomposes this iodide, first forming an unstable hydrate, $Si_2(OH)_6$, which is soon split up, giving rise to the formation of water and silici-oxalic acid, $Si_2H_2O_4$.

Vapour Density of Perchloride of Phosphorus.—M. Wurtz stated that he had repeated experiments on the vapour density of perchloride of phosphorus; his experiments have been conducted at a lower temperature than 160° C., and he has followed the process of Wanklyn, by causing the vapour of the perchloride to diffuse in a known bulk of air. The result of his (Wurtz's) experiments is that 7·2 expresses the vapour density of the perchloride of phosphorus.

The present number of the *Bulletin* contains the following original papers:—

Theory of the Carbides of Hydrogen.—M. Berthelot.—Too lengthy for abstraction.

Formation of Bromide of Acetylen.—M. Berthelot.—The author relates, somewhat circumstantially, how atmospheric influences affect the ready combination of those substances (bromine and acetylen) when in contact; bright sunlight appears to be an essential, but not an exclusive, condition. Since the absorption of acetylen by bromine does not always take place readily, Berthelot advises that when mixtures of gases containing acetylen have to be analysed, subchloride of copper should be used, when no gases but acetylen, absorbable by that substance, are present; subchloride of copper may also be applied as a qualitative test to ascertain whether or not acetylen, when present in a mixture of gases, is being absorbed by bromine, added to the mixture for that purpose. Fuming sulphuric acid was found always to act well, and its action is unaffected by light, a foggy day, or other atmospheric influence.

New Synthesis of Phenol.—M. Berthelot.—This paper is too abstruse for proper abstraction.

Oxidation of the Carbides of Hydrogen.—M. Berthelot.—The author finds that several carbides of hydrogen can be oxidised directly, and without loss of carbon, by the agency of chromic acid dissolved in a small quantity of water. Pure ethylen, free from vapour of ether, is slowly transformed, at a temperature of 120° C., into aldehyd. Propylen is far more readily oxidised, even at the ordinary temperature of the air, aceton being the result of the oxidation; amylen is very violently acted upon by chromic acid, so that no definite products are readily obtained; acetylen is converted into formic and carbonic acids.

Formation of Substances Homologous with Benzin by the Reciprocal Action of more simply composed Carbides taken in Free State, by M. Berthelot; Pyrogenic Formation of the Acetylen of the Benzol Series, by M. Berthelot; Toluidine and Pseudotoluidine, by M. Berthelot; Researches on the Constitution of Toluen and the Alkaloids derived therefrom, by M. Rosenstiehl; New Mode of Preparing Allylic Alcohol, by MM. Tollens and Henninger; Bromide of Allyl and the Essential Oil of Mustard, by M. B. Tollens; Boiling Points of the Allylic Compounds, by M. B. Tollens; Electrolysis of Tartaric Acid and Tartrates, by M. Edm. Bourgoin. These memoirs, evidently concisely written abstracts of longer papers, embodying an enormous mass of scientific research, cannot be properly abstracted, so as to do justice to the authors and their labours.

The remaining pages of this periodical are filled with abstracts taken from papers published in English, German, and French scientific journals, and also scientific books; but the contents of these abstracts are known to our readers, and are frequently taken from works published some years ago.

Journal fur Gasbeleuchtung, April, 1869.

As may be inferred from its title, this periodical is more especially devoted to the interests of gas lighting; occasionally, however, it contains papers of interest to scientific readers, and when this is the case, as in the present instance, we shall make a brief abstract of such paper.

Influence of Heat upon the Regeneration of Sulphide of Iron.—It is well known that, according to theory, only oxide of iron and sulphur should result from the exposure to air of the oxide of iron applied for the purposes of purifying coal gas; in practice, however, it has been found that peroxide of iron, protoxide of iron, and sulphuric acid are also formed, but in variable quantities. Dr. A. Wagner has instituted a series of experiments, in order to ascertain the influence of heat and moisture upon the regeneration process. One sample of sulphide of iron, prepared by the moist way, was kept for three weeks at nearly 100° C., damp, and exposed to air; another portion was kept cold and damp, and exposed, for the same time as the foregoing, to air; while a third portion, under otherwise the same circumstances as No. 2, was kept dry. The result of these experiments is, that heat favours the production of sulphuric acid, while water or moisture does not exert any influence; that moisture and cold (ordinary temperature) produces less sulphuric acid than dryness and cold, since, in the former instance, the occasional watering with cold water, to keep the mass moist, favours a lowering of temperature which, when no moisture is present, is raised, in consequence of the chemical action; water is, however, absolutely required, in order to re-produce the peroxide of iron, since sample 3 was found to have been only very imperfectly converted into peroxide, more than half of the oxide being found as protoxide. The quantities, as deduced from the experiments, are the following:—Sample 1 (hot and moist)—Upon 1 part of S, 0·319 part

of SO_3; and upon 1 part of Fe_2O_3, 0·1 part of FeO. Sample 2 (cold and moist)—Upon 1 part of S, 0·034 part of SO_3; and upon 1 part of Fe_2O_3, 0·151 part of FeO. Sample 3 (cold and dry)—Upon 1 part of S, 0·085 part of SO_3; and upon 1 part of Fe_2O_3, 0·5 part of FeO.

Moniteur Scientifique, No. 298, 1869.

This number does not contain any original articles; a portion of its pages are devoted to the description of the specification of patents, the subject matter of which is already known to our readers. Among the miscellaneous matter we observe the following:—

Improved Preparation of Neutral Acetate of Copper.—Five kilos. of sulphate of copper are ground to a fine powder; this having been done, the powder is placed in a suitable vessel, and 7·5 kilos. of liquid ammonia added thereto. After the solution is effected, 10 kilos. of acetic acid are added, and the vessel containing the copper solution placed on a water-bath; as soon as crystals are observed on the top of the liquid, the latter is strongly stirred, which promotes the formation of crystals. By this process, about 4 kilos. of neutral acetate of copper are obtained from the above quantity of sulphate, while the mother liquor yields some sub-acetate of copper afterwards.

Silicium contained in Aluminium.—It is well known that the aluminium of commerce is always contaminated with silicium and iron; a sample of aluminium recently analysed by Prof. Rammelsberg gave as much as 10·46 per cent of silicium, and another sample even 13·9 per cent. The quantity of iron varies from 2·94 to 7·5 per cent.

Silvering Cast-Iron.—M. Bœttger recommends the use of a bath prepared in the following manner:—15 grms. of nitrate of silver are dissolved in 250 grms. of water, and 30 grms of cyanide of potassium are added; when the solution is complete, the liquid is poured into 750 grms. of water wherein 15 grms. of common salt have been previously dissolved. The cast-iron intended to be silvered by this solution should, after having been well cleaned, be placed for a few minutes in a bath of nitric acid of 1·2 sp. gr., just previous to being placed in the silvering fluid.

Les Mondes, May 20, 1869.

We only notice the following from this paper:—MM. Wurtz, Bouchardat, Gübler, and Bergeron have been appointed to study the not altogether easy, but important question, Whether the addition of alcohol to wine, after its fermentation has entirely ceased, is injurious to the health of the consumer.

The title of the following work, from the eminent *savant's* well-known reputation, will not, we think, be unacceptable to many of our readers:—"L'Unité des Forces Physiques, Essai de Philosophie Naturelle," par le R. P. Secchi, Membre Correspondant de l'Institut de France, Directeur de l'Observatoire de Rome, Officier de la Légion d'Honneur, &c. Edition originale Française, grand 8vo., xx. and 700 pages; 56 woodcuts. Paris, 1869.

May 27, 1869.

This number does not contain any original communications or papers.

Berichte der Deutschen Chemischen Gesellschaft zu Berlin, No. 7, April 24, 1869.

This periodical contains the following original papers:—

On the Toluylen Group.—MM. Limpricht and Schwanert.—The authors begin this paper with an introduction, wherein they state that the reader of their present paper is referred back to memoirs of theirs published some years ago; next, they give a review of chief combinations of the toluylen group, being a series of some thirty chemical formulæ and names (too many to quote here); and they wind up with theoretical considerations on the relations existing between benzin, benzoin, toluol, benzil, and toluylen.

History of the Aldehyde of Salicyl.—M. L. Henry.—Since salicylic alcohol—

$$C_6H_4\begin{matrix}HO\\CHO,\end{matrix}$$

is an aldehyde, as well as a phenol, the author argues that it must be possible to obtain, from the salicylic alcohol, doubly chloruretted cresol, triply chloruretted toluol, and chloruretted aldehyde of salicyl. The author has succeeded in obtaining these compounds from the salicylic alcohol, and in this paper he describes, at length, the processes applied. Doubly-chloruretted cresol—

$$C_6H_4\begin{matrix}HO\\CHCl_2,\end{matrix}$$

is a solid substance, crystallising in prisms, fusing at 82° C.; its alcoholic solution yields, with chloride of iron, a dark red colour. Triply-chloruretted toluol—

$$C_6H_4\begin{matrix}Cl\\CHCl_2,\end{matrix}$$

is an oily liquid insoluble in water; specific gravity, 1·4; boils at 227° C. Chloruretted aldehyde of salicyl—

$$C_6H_4\begin{matrix}Cl\\CHO,\end{matrix}$$

is a colourless liquid, boiling at 210°.

Tension of Vapour, and Heat of Volatilisation of Chloride of Ammonium, by Aug. Horstman, and **Observations on the Aromatic Theory**, by A. Ladenburg, are both too abstruse for translation, an observation which equally applies to M. Buff's paper, **On the Doctrine of Affinity**, a most erudite essay on a difficult subject. Next follow two papers, by two different authors, on the same subject:—C. Rammelsberg's essay, **On the Formation of Periodates from Iodides, by means of Superoxides**; and J. Phillipp's paper, **On the Formation of Periodates**. Contributions to our Knowledge of Methyl-Aldehyde, by A. W. Hoffmann. All these papers being concisely-written and purposely-condensed abstracts made for this periodical, cannot be further condensed.

Polymeric Cyanobromide.—A. Eghis.—When freshly-prepared cyano-bromide is placed in a sealed tube, and exposed therein for from eight to ten hours, to a temperature of from 130° to 140° C., the at first crystalline cyanobromide is converted into an amorphous, yellowish-coloured mass, this colouration being due to free bromine, while, at the same time, at the moment of the unsealing of the tube, cyanogen gas escapes. The author found that, with the product prepared in the manner just briefly described, he could not obtain the results he desired to have; he therefore placed freshly-prepared cyanobromide into anhydrous ether, and digested these substances for some time; he thus obtained a perfectly white amorphous powder, insoluble in benzol and absolute alcohol, and fusing at 300°. By analysis, this substance was proved to be a cyanobromide of the formula Cy_2Br_2, containing 74·89 per cent of bromine.

Zeitschrift für Chemie, von Beilstein, No. 8, 1869.

There are no original articles contained in this number, which is entirely filled with translations, chiefly from French papers of older date, the contents of which have already been recorded in the Chemical News.

Comptes Rendus des Séances de l'Académie des Sciences, Monday, May 24, 1869 (No. 21).

Improvement of the Health of Workpeople, by an Improved System of Ventilation and Better Supply of Fresh Air to the Manufactories, illustrated by the good effects obtained at the Weaving Factory of Orival, near Lisieux.—General Morin.—Although, in the strictest sense, the subject matter of this paper does not belong to our department, we briefly notice that, in a factory wherein 400 people are daily employed, it becomes a matter of great importance to see to their health, especially in respect of fresh air. The General having been consulted on this subject by the owner of the factory, the former advised that at least 300 cubic metres per head, per hour, should be allowed for fresh air, provision being made to supply it so as to have a proper degree of moisture, as well as a proper degree of heat; into the minute details of the mode of supply, and carrying off the foul air, we do not enter, as this is a matter very much dependent on local conditions of buildings. The good results are proved by the fact (in this instance) that the yearly outlay for medicines had been reduced from 5,000, to less than so many hundreds of francs; while the consumption of bread had largely increased, as compared with the period previous to the making of the above-named improvements.

Distribution of Heat, and Work of the Induction Apparatus.—M. Le Roux.—This is a physico-mathematical essay, too abstruse for condensation.

Means of Ascertaining the Age of any Writing made with Ink containing an Iron Salt.—M. Carré.—The author states that, as long as writing is not very old, it admits of being copied, when moistened with water only, by means of the well-known copying press; further, that when writing has once attained a certain age, an alteration has taken place in the ink, which prevents the ordinary process of copying being successful; but, in that case, moistening with water acidulated with hydrochloric acid effectually aids the copying process. When, however, writing is some eighty years old, this contrivance also fails to aid the copying process; M. Carré found that writing, made in 1787, could not be reproduced by copying press, even when previously moistened with acidulated water.

Experiments on the Quantity of Mud and Slime carried down by Rivers.—M. Hervé-Mangon.—The author finds that the river Var carries from 9·15 to 36·61 grms. to the litre of water, of mud, amounting in one year, on an average, to 18,000,000 kilos., a quantity sufficient to raise a surface of 5,500 hectares (1 hectare = 2·471 acres), 20 centimetres in height. The rivers Marne and Seine carry down far smaller quantities of solid materials.

Second Note on Saturation, Surfusion, and Solution.—M. Dubrunfaut.—This is an abstract too concisely written and too long to admit of further condensation.

New Source of the First Terms of Acids belonging to the Fatty Acid Series, and especially on Propionic Acid.—M. Barré.—We hope to return to this paper, and give it in full, at a future time.

Climate of the Isthmus of Suez.—Referring to this subject, M. Le Verrier read an abstract of a letter from Prof. Buijs-Ballot, the Director of the Royal Netherlands Meteorological Institute at Utrecht, wherein that gentleman states that the draining of the Haarlem lake, in Holland, a surface of 19,000 hectares, has had the effect of increasing the average summer temperature of that locality, and adjacent country, by ½°, and of decreasing the average winter temperature, also, by ½° C.

Cosmos, 22nd livraison, May 29, 1869.

The present number of this periodical does not contain anything fit for abstraction for these columns, though, as usual, the periodical is very cosmopolitan and entertaining to general scientific readers.

Annalen der Chemie und Pharmacie, vi., Supplementband, Heft 3, 1868.

As usual, this supplement appears rather late in the present year. It contains the following original essays:—

Combinations of Phosphorus.—M. H. Wichelhaus.—The tendency of this essay, for it is that rather than a paper, may be inferred from the title and introduction, wherein the author says, "It is my aim to prove that it is unnecessary to assume anything else for phosphorus than triatomicity." The author, before entering upon his subject, discusses the word and meaning of quantivalence, and next writes an essay, filling some thirty closely-printed octavo pages, too concisely constructed for further abstraction.

Isomerism of Bicarbonate of Ethylen and Ethyliden, by M. H. Wichelhaus.—**Development of Heat of Chemical Reactions, as dependent on the Change of the Number of the Molecules of Substances**, by Dr. A. Naumann.—**Vapour Tension of Formiate of Ethyl and Acetate of Methyl**, by M. C. W. Dittmar.—**Relation Existing between the Chemical Composition of Arable Soil, and its Property of Yielding a Good Harvest**, by M. Schultze.—**Ammonium-Amalgam**, by M. Laudolt.—**Isomeric Derivatives of Allyl and Propylen**, by M. Alphonso Oppenheim.—**New Method of Formation of Resorcin**, by MM. Oppenheim and Vogt.

Journal fur Praktische Chemie, No. 4, 1869.

This periodical contains the following original papers:—

On Patellaric Acid, a New Lichen Acid, and its Existence in the Parmelia scruposa.—M. H. Weigelt.—The author has written a lengthy essay on this subject. Patellaric acid is a solid, exhibiting crystalline form and snow-white colour; its taste is exceedingly bitter; it is soluble in water, alcohol, and ether; and these solutions redden blue litmus paper. The percentage composition of this acid is:—C, 53·1; H, 5·2; O, 41·66. Space forbids us to quote any more from this paper, which contains the records of a long series of researches, not only on this acid, but on lichens generally, and the *Parmelia scruposa* especially.

Methintrisulphonic Acid.—M. Theilkuhl.—This acid is obtained when methyloxysulphate of lime is treated with a large excess of fuming sulphuric acid. The lime-salt of this new acid has the following percentage composition:—C, 3·62; H, 0·91; S, 29·00; Ca, 26·13; O, 43·34. The formula is:—

$$(C_2H)\left[\begin{matrix}S_2O_4\\S_2O_4\\S_2O_4\end{matrix}\right]O_9Ca_3+2H.$$

The author has also studied the baryta, potassa, and lead salts of this acid.

Amylendisulphinic Acid.—Dr. Ilse obtained this substance when he made sulphate of chloride of carbon, $C_2Cl_3(S_2O_4)Cl$, and zinc-ethyl act upon each other. The above-named acid has the following formula:—

$$C_2\left\{\begin{matrix}\dot{C}_4H_5\\C_4H_5\end{matrix}\right.\left[\begin{matrix}S_2O_3\\S_2O_3\end{matrix}\right]\begin{matrix}O.H\\O.H.\end{matrix}$$

The baryta salt of this acid is a crystalline solid mass, not readily decomposed spontaneously, of the following composition:—

$$C_{10}H_{10}\left[\begin{matrix}S_2O_3\\S_2O_3\end{matrix}\right]O_3.Ba_3+4H.$$

It is soluble in water, difficultly soluble in alcohol.

Researches on the Influence which the Presence or Absence of Water Exerts in regard to the Vitality of the Yeast, or Ferment Cells.—Dr. J. Wiesner.

Ethylenchloride of Iron and Peruvian Balsam.—M. J. Kachler.—Ethylenchloride of iron, $C_2H_4.Fe_2Cl_3$, is formed when a solution of chloride of iron in ether is submitted to a high temperature in sealed glass tubes; it is a solid crystalline substance. As regards Peruvian balsam, the author states that it yields an excellent source of supply of pure benzilic alcohol. From 100 parts, by weight, of the balsam, he obtained 20 parts of benzilic alcohol, 46 parts of crude cinnamic acid, and 32 parts of resin, which, on being oxidised with potassa, yields benzoic and protocatechucic acids.

System of Elements, according to their Atomic Weights and Chemical Functions.—M. D. Mendeleeff.

NOTES ON LECTURE EXPERIMENTS.

Combustion of Sodium.—The metal sodium is stated not to take fire on cold water, but this is incorrect. A small piece of the metal will not do so, but a piece the size of a nut will frequently ignite; the flame may suddenly "pop" out, and it may as suddenly become ignited again. It is also addicted to the unpleasant habit of suddenly bursting into fragments, and throwing the fragments of metal in all directions. After the combustion of any considerable quantity of the sodium, it is curious to observe how the soda may be seen tinging with a yellow colour the non-luminous portion of any gas jet that may be burning. —G. N. M., Northampton, May 26, 1869.

PATENTS.

Communicated by Mr. VAUGHAN, F.C.S., Patent Agent, 54, Chancery Lane, W.C.

GRANTS OF PROVISIONAL PROTECTION FOR SIX MONTHS.

1277. J. Scharr, Stuttgard, Wurtemburg, "Improvements in the manufacture of liquid soap."—Petition recorded April 24, 1869.

1391. C. D. Abel, Southampton Buildings, Chancery Lane, "Improvements in the treatment of cast-iron for the production of wrought-iron and steel therefrom."—A communication from W. M. Lyon, Pittsburg, Penn., U.S.A.—May 6, 1869.

1409. F. C. Knowles, Lovell Hill, Berks, "A new or improved method of purifying and converting cast-iron into malleable iron or into steel, and for the making and use of materials and appliances for the same."

1413. E. Maybury, G. Matthews, and E. Marston, Pendleton, Lancashire, "Improvements in puddling furnaces."—May 8, 1869.

1414. R. Cadbury and G. Cadbury, Birmingham, and J. M. Rendall, Torquay, Devonshire, "A new or improved description of biscuit manufactured from the cacao bean."—Petition recorded May 8, 1869.

1418. H. R. Lumley, St. John's Wood, "The treatment of molten iron in order to free it from all impurities."

1419. H. A. Dufrené, Rue de la Fidélité, Paris, "Improvements in desiccating and preserving meat and other organic substances."—A communication from C. Tellier, Passy, Paris.

1426. W. E. Newton, Chancery Lane, "An improved process and composition for hardening common or grey cast-iron, and for converting articles of iron into steel, or imparting thereto a steely character."—A communication from B. W. Nichols, Canton, Ohio, U.S.A.

1431. H. Bessemer, Cannon Street, London, "Improvements in the manufacture of malleable iron and steel, and in furnaces and apparatus employed for their fusion and treatment."

1432. H. Bessemer, Cannon Street, London, "Improvements in the construction and mode of working furnaces and apparatus employed in fusing malleable or wrought-iron, and steel and pig, or other carburets of iron, and obtaining cast-steel, or homogeneous malleable iron therefrom."

1433. H. Bessemer, Cannon Street, London, "Improvements in the conversion of fluid crude iron and molten pig, or other carburets of iron, into fluid homogeneous malleable iron and steel, whether such pig, or other crude iron, is used alone, or is mixed with a portion of malleable, or more or less decarburised iron, in a solid or fluid state."

1434. H. Bessemer, Cannon Street, London, "Improvements in the treatment of crude, or pig-iron, and other carburets of iron, and in the apparatus employed for such purposes."—May 10, 1869.

1435. H. Bessemer, Cannon Street, London, "Improvements in the construction and mode of working blast furnaces employed for smelting the ores of iron, and in the mode of employing and utilising the gaseous products of such furnaces, and also in the construction and mode o working blast engines employed to force air into blast and other furnaces."—May 10, 1869.

1440. W. R. Lake, Southampton Buildings, Chancery Lane, "An improved detergent, or saponaceous compound."—A communication from W. H. Newton, New York, U.S.A.—May 11, 1869.

1450. J. Robey, Newcastle-under-Lyme, "Improvements in sugar refining."

1458. P. W. Flower, Neath, Glamorganshire, H. Nash, Water Street, Liverpool, and R. Heathfield, Birmingham, "Improvements in coating sheets of metals with other metals."—May 12, 1869.

1464. E. V. Newton, Oxford Street, Middlesex, and P. M. Crane, Manchester, "A new or improved composition for coating ships, boats, and other surfaces, and for protecting and preventing the fouling thereof."

1469. J. Townsend and P. Forbes, Glasgow, N.B., "Improvements in refining or treating oils and fats, and in apparatus therefor."—May 13, 1869.

1483. G. Felix, H. J. Axel, F. Bang, F. Roch, C. Monestier, and J. P. A. Fignier, Paris, "An improvement in liquids for the lubrication of sheep's, or other wool, or other animal textile fibrous materials."

1486. J. H. Johnson, Lincoln's Inn Fields, Middlesex, "Improvements in the treatment of beet-root and other pulps, and in the machinery or apparatus employed therein."—A communication from H. Champonnois, Paris.—May 14, 1869.

1493. L. A. V. Dubourg, M.D., Leicester Street, Leicester Square, Middlesex, "Improvements in the manufacture of gas for lighting and heating purposes, and in the apparatus employed therein."

1495. W. Wilkinson, Seymour Street, Euston Square, Middlesex, and M. Boss, Cleveland Street, Fitzroy Square, Middlesex, "Improvements in embossing, printing, enamelling, and ornamenting glass, metal, wood, canvas, or other woven prepared fabrics or other substances, and the preparation of the material, or materials and ingredients employed therein, and machinery or apparatus appertaining to a part thereof."—May 15, 1869.

1540. G. Martin, Dursley, Gloucestershire, "Improvements in the means of generating gases and chemical vapours employed in the manufacture of extract wool, and in destroying the vegetable material in mixed fabrics, and in the construction and arrangement of apparatus therefor, which apparatus is also applicable to other purposes."—May 19, 1869.

1562. J. McMillan, Dumbarton, N.B., and J. McGregor, Glasgow, N.B., "Improvements in the preservation of iron and steel, and structures composed thereof."

1568. G. Johnson, San Francisco, California, U.S.A., "Improvements in the distillation of spirituous liquors, and in apparatus to be employed therefor."—May 20, 1869.

NOTICES TO PROCEED.

3959. G. T. Bousfield, Brixton, Surrey, "Improvements in extracting the colouring matter of madder root from the ligneous matter of the plant."—A communication from A. Paraf, New York, U.S.A.—Petition recorded December 29, 1868.

18. H. A. Bonneville, Chaussée d'Antin, Paris, "Certain improvements in the process of refining iron and making steel, and in the apparatus used in carrying out said process."—A communication from C. J. Cainnon, Toulouse, France.—January 4, 1869.

42. K. Walter, Wicklow, "Improvements in the manufacture of sulphuric acid."—January 6, 1869.

62. W. T. Waite, Salisbury Square, London, "Improvements in the treatment of saccharine matters."—January 8, 1869.

98. C. J. Günther, Mark Lane, London, "Improvements in salting and preserving meat."—A communication from Baron J. von Liebig, Munich, Bavaria.—January 13, 1869.

230. A. V. Newton, Chancery Lane, "An improvement in fermenting substances and germinating grain and seeds."—A communication from R. d'Heureuse, San Francisco, California, U.S.A.—January 25, 1869.

1278. T. Forster, Streatham, and P. B. Cow, jun., Streatham Common, "Improvements in compounds containing india-rubber, gutta-percha, or ballata, and in the manufacture of such compounds." April 24, 1869.

NOTES AND QUERIES.

Benzoic and Succinic Acids.—The commercial use of both these acids is very limited. Benzoin *resin* is used in perfumery, varnish making, and dyeing; in this latter operation both benzoic and succinic acids are also used and applied to a limited extent as mordants; beside this, both these acids are used in pharmacy, and, as is well known, applied in analytical chemistry, as ammonia salts chiefly; their high price would prevent their very extended use.

Mineralised Manure.—It appears from a short notice in *Les Mondes*, chiefly intended *pour prendre date*, that there has been found, in the Department of the Haute-Saône, near Lure, a layer of from 40 to 100 metres thickness of a mineral made up of from 3 to 4 per cent of bituminous oil, 2·8 of nitrate of ammonia, 5·8 of nitrate of potassa, 40 of carbonate of lime, 25 of gelatinous silica, 0·5 of oxide of iron, and 0·1 of sulphur. This mineral deposit appears to be the result of the slow decomposition of vegetable and animal matter, especially molluscs, belonging to a former period of animal life on our globe.

Water Saturated with Gypsum.—The result of the analysis, by Dr. F. Goppelsroeder, of a spring water found on the Dürenberg Estate, near Langenbruck in Silesia, gave for the saline matter found in 1000 c.c. of water:—1·636 grms. of anhydrous sulphate of lime, 0·185 of sulphate of magnesia, 0·019 of carbonate of lime, 0·024 of carbonate of magnesia, 0·008 of carbonate of protoxide of iron, 0·005 of silica, 0·06 of chlorine (combined with alkalies); moreover, small quantities of alumina, baryta, strontia, ammonia, phosphoric acid, nitric acid, and organic matter, which were not quantitatively determined. The solid residue of 1 litre of water, dried at 100° C., amounted to 2·503 grms.

Natural Water Containing Excess of Oxygen.—At Neubourg, Departement de l'Eure, France, a spring of mineral water is found, from which a gas is constantly bubbling up and given off in large quantity, which, on analysis, proved to contain 44·6 per cent of oxygen, and 55·4 per cent of nitrogen; the gas causes, just as pure oxygen does, partly extinguished but yet glowing splints of wood to burst into flame. The analysis of the water proved it to contain in 4 litres the following quantities of saline constituents, expressed in gramme weight:—

	grm.
Chloride of potassium	0·0096
Phosphate of lime	0·0128
Alumina and peroxide of iron	0·0200
Silica	0·0140
Sulphate of lime	0·0348
Chloride of magnesium	0·0688
Nitrate of magnesia	0·0878
Carbonate of lime	0·7210
	0·9688
Free carbonic acid	0·3284

—*Annuaire Pharmaceutique for* 1868.

Aniline Black.—The best kind of this dye is called in France, *Noir d'Anilin Lucas*; in England it is known as Petersen's aniline black; it is made, by a process kept secret, by M. F. Petersen, at St. Denis, near Paris. It is met with in commerce as a very deep black-coloured fluid, which, for the purposes of calico-printing and dyeing, has only to be thickened with starch paste, imparted to the tissue, and oxidised, to produce the finest deep black velvety-looking dye ever obtained. Among the very large number of prescriptions for manufacturing aniline black we notice Coupier's method, which is the following:—A mixture is made of 175 parts of nitrobenzin, 175 of aniline, 200 of commercial hydrochloric acid, 16 of iron turnings, and 8 of finely divided copper; this mixture is heated for from 6 to 8 hours at from 160° to 200° C., in an inside-enamelled iron-ware distilling apparatus. The operation is finished when a small portion of the mixture, having been previously removed from the apparatus and cooled, can be drawn into a tough thread-like mass, when rapidly pulled between the fore-finger and thumb. The dye produced in this manner is soluble in acids, alcohol, and wood-spirit. When it is intended to apply this substance as a dye, it is dissolved in sulphuric acid, serving as a dye bath, after which the woven tissue, thread, or yarn, has to be bathed in a solution of either an alkali or hyposulphite of soda, in order to fully develope the black dye; without this precaution a black, verging upon violet or blue, is obtained.

Contraction of Caoutchouc by Heat.—It appears that M. Govi, at Turin, has repeated the well-known experiments of Joule and Thomson about the contraction which caoutchouc, after having been previously stretched out, undergoes when heat is applied. The author has found that this contraction only takes place within certain limits of temperature, and that, if a greater degree of heat be applied, the stretched-out caoutchouc, even though by no means exposed to a degree of heat which softens it to a pasty mass, expands and becomes rapidly longer. This substance, which has, in some aspects, puzzled philosophers, especially as regards some of its physical properties, has been frequently considered to consist of a kind of solid foam, made up of a large number of small vesicles filled with gas. This theory has been proved to be a reality, since Payen and others have seen these vesicles under the microscope, while M. Grovi has succeeded in expelling a portion of the gas from the vesicles by softening the caoutchouc, by means of oil of turpentine, and withdrawing, by means of the vacuum of the air-pump, the ordinary atmospheric pressure. This peculiar kind of constitution of the caoutchouc being admitted, it is easily seen that the vesicles, when that material is stretched, will lengthen in the direction of the stretching force, and contract—become more narrow—in the perpendicular direction to that force. When, under these conditions, the caoutchouc is heated, the gas within the vesicles, while expanding, will have a tendency to return to the spherical shape it possessed before being stretched, and this explains, therefore, the paradox of its becoming shorter while heated; in other words, contracting instead of expanding by heat.—*Les Mondes*.

MEETINGS FOR THE WEEK.

MONDAY, 7th.—Royal Institution, 2. General Monthly Meeting.
TUESDAY, 8th.—Photographic, 8.
WEDNESDAY, 9th.—Microscopical, 8.
—— Geological, 8.
THURSDAY, 10th.—Royal, 8.30.
—— Zoological, 8.
—— Royal Society Club, 6.
FRIDAY, 11th.—Astronomical, 8.
SATURDAY, 12th.—Royal Institution, 3. Mr. Deutsch, "On Semitic Culture."

TO CORRESPONDENTS.

*** We shall feel indebted to correspondents who will forward us Reports of Local Meetings of Societies, Chemical Appointments, and any other subjects interesting to the chemical world. We regret that, owing to the increasing popularity and circulation of the CHEMICAL NEWS, and consequent pressure on our space, we are often obliged to delay the publication of long papers. To those correspondents who wish to favour our readers with Notes of New Discoveries, Descriptions of Apparatus, or Answers to Questions, we would especially recommend our Notes and Queries columns.

E. K.—The lecture will be shortly published in our pages. Our publisher will write to you about the volumes of the CHEMICAL NEWS. The acid liquid is probably deliquesced phosphoric acid. We cannot vouch for the statements made by advertisers unless we have personally inspected the goods.

Tyro.—Add ammonium sulphide to the solution; collect, wash, and dry the precipitate, and fuse with a mixture of nitre and carbonate of soda.

H. Kelsoe.—The Adulteration of Food Bill, passed some years ago, is practically inoperative.

X. Q.—Cadmium amalgam is not at all brittle, but is tough, and highly malleable.

Messrs. J. B. and Co.—A letter is waiting for you at our office.

G. N. M.—There is no good description of the battery published. The manufacturer will give you any information you require.

Communications have been received from A. Voelcker; B. Kernas; C. Higgins, B.A.; P. M. Muir; S. Dunn; J. Davis (with enclosure); J. Pride; R. R. Tatlock; W. A. Todd; E. C. C. Stanford; F. A. Abel, F.R.S. (with enclosure); F. Jennings; R. D. Grindley; Mawson and Swan; A. Baxter; J. Heywood; Longmans and Co.; Dr. Röhrig; J. Spiller; Dr. E. Fleischer (Dresden); J. Hughes; E. H. von Baumhauer; G. Pearson; H. Yeates; C. Tomlinson, F.R.S.; B. Quaritch; Dr. Adriani; The Royal Institution; E. P. H. Vaughan; A. Clarke; and S. W. Rich.

BOOKS RECEIVED.

Spectrum Analysis; Six Lectures delivered in 1868 before the Society of Apothecaries of London. By Henry E. Roscoe, B.A., Ph.D., F.R.S. With appendices, coloured plates, and illustrations. London: Macmillan and Co.

CHEMICAL EXAMINATION OF THE ORIENTAL JARGON.*

By DAVID FORBES, F.R.S., &c.

A SHORT time back, I undertook, at the request of Mr. Sorby, to prepare for him some of the earth or earths which, in combination with silicic acid, formed this gem, and as the means I employed in so doing appeared to throw some little light upon the characters of the earth hiterto regarded as zirconia, I have thought that a notice of the results obtained by me might not be devoid of interest.

The jargon employed was in fragments, being part of an almost colourless crystal, forwarded to me by Mr. Sorby, who had previously found, by optical examination, that it showed with great distinctness the peculiar and characteristic spectrum which he ascribes to the presence of the new element jargonium, and noticed that the bands became much more pronounced after ignition and cooling.

The fragments, which were extremely hard, were broken up in a diamond mortar, previous to being reduced to as impalpably fine a powder as possible in an agate mortar; 16·22 grains of this powder were then thoroughly mixed with 81 grains pure anhydrous carbonate of soda, placed in a platinum crucible, and fused at the highest heat of a large air gas blowpipe jet, after having been previously kept for two hours over a powerful Bunsen's flame, so as to "frit it," or ensure combination previous to fusion. After complete fusion, a small lump of pure hydrate of soda (about 15 grains) was, as recommended by Berzelius, carefully deposited in the centre of the fused mass, and a second similar piece added after the first had been absorbed; the fused substance became much more liquid after this addition; the heat was kept up for another half hour longer, and the whole was allowed to cool.

By the above means the mineral was perfectly decomposed, and the silica so altogether transferred to the soda that it could be completely removed by cold water, leaving no trace behind with the earths. Previous experience with the zircons from various localities, and hyacinths from Ceylon, had proved to me that the perfect decomposition of these minerals is often attended with considerable difficulty.

The fused mass when cold was treated repeatedly with cold water in a silver vessel, decanting off the supernatant solution each time, until the silica was entirely removed, and a white powder, probably a compound of the earth with soda, remained behind.

The solution which contained all the silica was acidified with hydrochloric acid, evaporated to dryness, and the silica determined as usual. The silica obtained weighed 5·45 grains, consequently was equivalent to 33·61 per cent in the mineral.

The white insoluble residue previously mentioned, was found to be perfectly soluble in hydrochloric acid; in order to test if it contained any silica, the solution was evaporated to dryness and re-dissolved in water acidulated by HCl, but left no trace of insoluble matter behind. From the colour of the solution being distinctly yellow, it evidently contained oxide of iron, which I had scarcely expected, since the original mineral was nearly, if not altogether, devoid of colour; the solution, consequently, was a chloride of the earths of the jargon, accompanied by some sesquichloride of iron.

Berzelius many years ago devised a means of separating oxide of iron from zirconia, founded upon the behaviour of their respective chlorides, the sesquichloride of iron being soluble in strong hydrochloric acid, whilst that of zirconia is nearly insoluble; I had tried this process previously with zirconia from Ceylon hyacinths, and had not been satisfied with it, as the iron solution carried along with it a not inconsiderable portion of the earth. It now struck me, however, that possibly the earth so dissolved might differ in character from that contained in the insoluble chloride, and I therefore determined to make the experiment.

The hydrochloric acid solution was consequently again evaporated until it solidified as a yellow saline mass, whereupon it was treated repeatedly with cold strong hydrochloric acid of density 1·138, allowing it to stand some time and decanting the solution as long as the fresh acid acquired the faintest yellow tinge. A yellow solution was obtained, leaving behind a snow white chloride, crystalline in appearance and completely soluble in water, forming a perfectly colourless solution. From this solution ammonia precipitated a flocky, but apparently rather dense, white precipitate, which, after being thoroughly washed, dried, and ignited, was of a pure white colour and possessed a peculiar waxy look and dense appearance; it weighed 7·48 grains, and consequently amounted to 46·12 per cent of the jargon examined.

This earth was examined optically by Mr. Sorby, and, according to his account, did not give a trace of the characteristic jargonium bands in the spectrum, and it was, therefore, concluded to be pure zirconia.

The yellow hydrochloric acid solution was now examined, and found, besides sesquioxide of iron, to contain a considerable amount of an earthy base, like zirconia. I decided to separate the iron by the tartaric acid and sulphide of ammonia process recommended by Berzelius, and, consequently, the solution was first supersaturated by ammonia, which threw down a faint yellowish white somewhat flocculent precipitate. Tartaric acid in excess was then added, which dissolved at once the greater part of the precipitate, but, notwithstanding that a very large excess was added, a portion of the precipitate refused obstinately to re-dissolve, even upon application of heat. In order to examine this, the solution was filtered: a white, flocculent, and somewhat glutinous substance was left upon the filter, which, when well washed with hot water, dried, and ignited, weighed 1·24 grains, equivalent to 7·64 per cent of the original mineral.

This body, after ignition, appeared very different from the previously-obtained zirconia; it was a white powder, but did not aggregate together or form lumps having a waxy lustre on the surfaces of fracture; on the contrary, it was more pulverulent, had a dead white, or mealy, appearance, and did not appear to be of any great density.

From Mr. Sorby I learn that it gave the spectrum of jargonium with intensity, and he concludes that it must probably be its pure oxide or jargonia.

Ammonia was now added in excess to the tartaric acid solution, which remained clear. Upon the further addition of sulphide of ammonium, the solution assumed a dark brown coloration; but no precipitate separated before the lapse of some days, when a black deposit of sulphide of iron formed, which was collected upon a filter, after the greater part of the supernatant liquid had been carefully syphoned off.

This sulphide of iron was converted into sequioxide, and afforded 0·04 grain, equivalent to 0·24 per cent in the mineral.

After separation of the iron, the solution was evaporated to dryness in a platinum capsule, and ignited for some time, to drive off all ammoniacal salts, and oxidise the carbon resulting from the decomposition of the tartaric acid. There then remained behind an earthy body, of a

* Although is commerce this mineral is generally known as the jargon from Ceylon, the name Oriental jargon seems to me to be preferable, since it appears uncertain whether these stones are actually found in the Island of Ceylon, that place being well-known as the principal Eastern mart for precious stones procured on the mainland of India and the adjacent countries.

white colour, having a slight tinge of grey, which weighed 2·03 grains, or 12·52 per cent.

In appearance, this earth was quite different from the zirconia, and more resembled that supposed to be jargonia. Mr. Sorby, upon optical examination, reports that "It seems to contain a good deal of zirconia and a very decided trace of jargonia, but I am very much inclined to suspect that it may contain some other substance. Its behaviour with borax before the blowpipe is very different from that of the zirconia from the jargon, and it turns extremely opaque, and a sort of orange-yellow, by transmitted light." Possibly this substance may contain a third earth analogous to zirconia, such as Svanberg (*Ofversigt. Kongl. Vet. Acad.*, pp. 34, 37, 1845) suggested was present in eudialite and certain zircons.

The result of this examination of the jargon, when summed up, indicates its composition to be as follows:—

	In 16·22 grains.		In percentage.	
Silica	5·45		33·61	
Zirconia α	7·48		46·12	
,, β (jargonia?) ..	1·24	10·75	7·64	66·28
,, γ	2·03		12·52	
Sesquioxide of iron ..	0·04		0·24	
	16·24		100·13	

The formula ZrO_2SiO_2 ascribed to zircon requires—

Silicic acid	33·77
Zirconia	66·23
	100·00

with which the numbers found for jargon are closely approximative.

The results of this chemical examination must be considered as strengthening the evidence, physical and chemical, that the earth usually denominated zirconia is, in reality, a compound of two, if not more, closely-allied oxides. In 1845, Svanberg announced that the zirconia contained in the various zircons from Siberia, Norway, and Ceylon, as, also, in the hyacinths from Expailly and Ceylon, was a compound of two or more earths, one of which he termed noria; and, in a subsequent paper the same year, also found this to be the case with the earth in the Greenland eudialite. His arguments—for he did not succeed in separating the earths—were founded upon his observations that the salts of zirconia did not always contain the same constant proportion of acid to base; that the oxalates, chlorides, and sulphates differed in their behaviour and solubility in certain reagents, and that the specific gravities of the natural silicates (zircon) from various localities differed greatly from one another.

These observations of Svanberg, notwithstanding the promise contained in his short paper on the subject to bring forward fuller evidence, have, as yet, never been followed up by him, and the subsequent researches of other chemists appear to throw doubt as to their correctness in several points, as well as to render the existence of his noria extremely dubious. The researches of Berlin (*Journ. f. Prak. Chemie*, lviii., p. 145, 1853) showed that the results of the fractional precipitation of chloride of zirconia by oxalic acid did not warrant the conclusions of Svanberg, and that the zirconia prepared from zircons from Frederiksvaern, Expailly, Ural, India, and from the Ceylon hyacinths and Norwegian katapleeite, behaved in similar manner with oxalic acid, and that their oxalates were easily and completely soluble in excess of that acid, and that the specific gravity and amount of zirconia obtained from the oxalates from Frederiksvaern zircon and katapleeite which he examined were identical, so that it would seem necessary to seek for some other means of separating the earths than by the employment of oxalic acid. In some experiments I made for the purpose of attempting to isolate noria (in which I used Norwegian zircons from two different localities, and also hyacinth from Ceylon), I failed in so doing, but corroborated the results obtained by Berlin.

In 1864, Nylander, in a paper, "Bidrag til Kännedomen om Zirkonjord" (*Acta Universitatis Lundensis*, 1864), has examined the zirconia from the Norwegian eucolite, and considers that it contains two earths, which differ in their behaviour and solubility of their double potassium sulphate salts, but he also appears to have come to no definite results as to the existence or isolation of the earths themselves.

It is to be hoped, however, that the interest now excited by Mr. Sorby's announcement of the existence of jargonium will induce chemists to work the subject out in more detail.

ON THE

EXAMINATION OF WATER FOR ORGANIC MATTER.*

By R. ANGUS SMITH, Ph.D., F.R.S., &c.

In 1865 I received a request to write on the organic matter of water. I wrote a memoir, which was, without intending to be published, extensively circulated among officers of of health, especially in India.

I there made a division which was entirely new to chemists. The substance styled "organic matter," instead of being given as one to which little or no definite meaning was attached, was considered as existing chemically under at least seven different headings, not forgetting the numerous organised forms which it might assume. These divisions were—

1st. The organic matter decomposed, or putrid.
2nd. Organic matter readily decomposed, and probably ready to become putrid.
3rd. Organic matter slow to decompose.
4th. Recent organic matter.
5th. Old organic matter.
6th. Vegetable organic matter.
7th. Animal organic matter.

The first was known by the gases which instantly decomposed permanganate.

The use of the permanganate of potash, recommended by Forchhammer for ascertaining the organic matter of water, has been tried and admired by some, and found entirely wanting by others.

I endeavoured to show, in the memoir alluded to and in a subsequent paper, how far that salt could be trusted; quite certain of its value for ascertaining bodies of the first and second classes, but having no experience of my own which would guide me to consider it a sufficient test for the total quantity of organic matter.

Bodies of the third class I was therefore inclined to estimate quantitatively by drying and weighing, afterwards ascertaining the condition of the matter as the point of most importance.

Organic matter of the fourth class was estimated by the amount of nitrites in the water, because their existence showed that the matter was oxidising, but had not had time to complete the action.

Bodies of the fifth class were estimated from the nitrates, as in that case the action was finished.

Bodies of the sixth class were reckoned from the absence of bodies of the seventh class, which latter class, again, were considered to exist when they were accompanied by an unusual amount of chlorides, supposing care to be taken to discover that other sources of chlorides did not exist.

It is not to be expected that any of these divisions should be sharply defined; but the one most difficult to decide upon, to all appearance, is really that which I have found, with proper precautions, scarcely ever to fail me, though

* From vol. iv., 3rd series, of the *Memoirs of the Literary and Philosophical Society of Manchester*. (Communicated, with emendations and alterations by the author).

it has been used in hundreds of instances, and for many years—namely, the test for animal matter.

Dr. Woods had written on the use of Forchhammer's chameleon previous to the publication alluded to, and about the same time Prof. W. A. Miller; but I am not aware that any one endeavoured to distinguish the various conditions of the organic matter. I am, and was, desirous of showing that organic matter is not necessarily hurtful; we speak of it in water as an evil, to be measured by the balance, whilst there is as much difference in the qualities of that found in water as there is between good wholesome meat and putrid flesh.

I was desirous also of showing the true value of the permanganate, which is capable of acting on one, but scarcely on the other, and of being used for analysis for sanitary purposes, although not for all the demands of the chemist.

Dr. Frankland next took up the subject, and proceeded to show the amount of organic matter, or of sewage matter, which might flow into a stream; and this he did by estimating the nitrogen gas obtainable from the organic matter of the water. By ascertaining the amounts existing in the water supplied to a town and flowing in the sewage, he found the total thrown out by the inhabitants.

For this he made an organic analysis of the residue of the water, and by a very beautiful arrangement, using Sprengel's pump, he drew out the nitrogen for measurement. I do not doubt that this mode adopted by Dr. Frankland will always be useful, and will remain permanent as a method, but not for constant use, on account of the time required, excepting by those chemists who perform many of such analyses, and have the apparatus in constant readiness. It is, however, always pleasant to find an addition made to our capacity for accuracy, and especially when such beautiful methods are employed.

By this means Dr. Frankland obtains the organic nitrogen, nitrates and ammonia being removable. I have not generally estimated the latter, as being still more unstable than the former, and I have frequently found it to disappear with great rapidity, affording by no remnant any clue to the past. Urea and uric acid must also be excluded from the organic nitrogen before we obtain a clue to the albuminous matter. I think, however, that we require to know, above all, whether this matter is in a state to putrefy, or to produce living forms. If there are organic germs capable of development in a visible form, that condition ought not to be neglected.

Immediately, I believe, after this plan was adopted by Dr. Frankland, Mr. Wanklyn discovered a mode of decomposing albumen by permanganate of potash, obtaining ammonia.

This process was used by Messrs. Chapman and Miles Smith. I shall not attempt here to give the exact amount of honour due to those gentlemen, or to tell precisely the boundaries of their labour.

The result seems to be, that the nitrogen may be obtained without the trouble of the usual organic analysis, although it may be uncertain which process takes the longest time.

Mr. Wanklyn considers that he can, by his method, first remove the ammonia which exists as such, by boiling with carbonate of soda; next, by decomposing the albumen with permanganate of potash and boiling in caustic potash, obtain the ammonia resulting from the decomposition. This is a decided gain to us, and may turn out to be the normal mode of separating the ammonia of the putrescible and unputrescible organic bodies.

We are rather apt, when we find a method of analysis, to look at it as final. I shall endeavour to show how much we obtain by Dr. Frankland's method, and how much by Professor Wanklyn's. I shall perhaps, also, as in such cases, be inclined to show that my own method reveals a greater amount of the peculiarities of water. It makes more divisions, is more complicated therefore in one respect; but every point tells its own tale, and it is the number of tales we have to tell regarding the history of water that measures the fulness of our reports. I shall probably adopt all the methods for a time.

In the paper mentioned, I pointed out the error of supposing that organic matter was all equally unwholesome, or that it was, in all cases, even in the slightest degree so. It was the custom too much to confound the simplest peaty and the most noxious putrescible matter. On this subject I may here quote the paper.

"*Quality of the Organic Matter.*

"Water manifestly containing organised matter is to be avoided; but it may frequently be purified by some mechanical mode of separation, such as simple straining.

"If the water contains organic matter in solution, or a condition approaching in all appearance to solution, it may be wholesome or unwholesome. The mere existence of organic matter is no proof of impurity. We must know if it brings animalculæ or vegetable life or products of putrefaction. We must know the *quality* as well as the quantity. If the matter is peaty, consisting of the ordinary humous class of acids and salts, the colour may be very dark and the water very unpleasant to look at, without being in any way, so far as I have ever heard, injurious to health, although such water cannot be quite so wholesome as pure water, since the oxygen of solution is diminished. The taste and other sensible qualities will be the chief guides.

"If the matter is wholly or nearly colourless, it may still be wholesome or unwholesome. It may, for example, contain the juices of plants of a wholesome character. If these juices are fresh, they may do no injury; but they will not long remain fresh, they will putrefy. Water containing organic matter ready to putrefy ought to be avoided, as we cannot tell when the moment of danger begins; whilst the quality at best is never known to us exactly.

"To ascertain the nature of the organic matter, the water is allowed to stand for a day or two, in which case it may be found that organised bodies show themselves.

"Sometimes plants seem completely to fill the vessel, having come out of a moderately clear solution. When standing, in this case, the water must be prevented from evaporating, and it must be in glass, so as to be exposed to light; a temperature suiting vegetation is also to be given. Animalculæ may appear in great numbers; they are an indication of nitrogenous matter, and one proof of the presence of substances capable of putrefaction. It may be that some form of putrefaction will be the only result; but whether this occurs alone, or along with organised forms, an excess of organic matter is proved.

"Water that will not bear the test of standing will in most cases be rejected at once. If no other can be obtained, it ought to be used before the putrefactive process has begun; but this is very dangerous. The next best method is to wait till after putrefaction has terminated, and the products are separated as much as possible. This is popularly known to be the case when the water has for some time become clear and colourless, and free from smell and taste. There are some difficulties connected with this. Water undergoing putrefaction is manifestly unwholesome. After putrefaction is completed, it may be quite wholesome. Although the process is proved by Pasteur not to begin without the aid of organic germs of some kind, they seem to be of a class constantly existing in the atmosphere, even when it is wholesome, whilst we have reason to believe, from the results, that germs of disease, if there are such, are decomposed, like other albumenoid substances, during the action. It would, therefore, be probably safer to wait till putrefaction was completed, but this is often tedious. At any rate, it was intended to state that, when activity began, it was not safe to use the water. The points of safety and of danger require investigation.

"Water with green organic matter in suspension or semi-solution is generally full of germs of living things, and nauseous to the taste.

"A microscope is very useful in detecting the smaller forms of life, but not always essential. Good water is clear and colourless, or only slightly browned by peat. Clear bright water shows no microscopic objects. It is quite a mistake to suppose that all water contains animalculæ. Those who have sent abroad this saying could not have known what pure water is.

"If the signs of organic matter are clear, it may not be needful to go further, but to reject the water at once. After standing for two or three days, varying with temperature, and showing nothing to the eye except a little film of green on the bottom of the vessel, we may conclude that not much organisable matter is there. We may then proceed to the chemical examination."

Some years ago it was customary, more than now, to examine with the microscope water intended for the use of towns. Attempting at one time to join the chemical and microscopic together, as they were too much in separate hands, I came to certain general conclusions:—That no ordinary pure water produced much vegetable or animal life, and that microscopists were mistaken in allowing people to suppose that every drop of water was inhabited; that nevertheless water, generally considered very pure for drinking, might contain some forms not possessed with distinct locomotion; that whenever distinct locomotion began, especially among soft-bodied forms, the water was more than suspicious; that forms increased with the quantity of organic matter containing nitrogen, until the amount was so great as to cause gases of decomposition which eventually stifled life. How far this stifling of life proceeds I do not attempt to say. I suppose it will not apply to the mucedines, which cause putrefaction to commence.

If the water was impregnated with sewage water (as the Thames at London, for example), bad cases excepted, the amount of vegetation which spread over the sides of a bottle filled with it and set in the sun, was so great as to give the appearance of one solid mass. If the water were taken from the river above Reading, the amount of vegetable matter was seen as a delicate green colouring at the bottom of the vessel; and if it were taken up at the source, no greenness whatever appeared, but, after long standing, minute crystals of limestone. If the water contained sewage, the phosphates and magnesia were generally found collected in some form of the *Navicula*, frequently in large groups of the *Navicula fulva*, and with it also was found phosphoric acid and magnesia. It was sufficient to note the condition of the water with relation to these deposits to ascertain at what part of the Thames the specimen was taken; and without the examination of these deposits, I do not consider that it would have been possible to obtain a distinct idea of the nature of the organic matter present. It is, however, needful that we know the general character of the water; had we a specimen from another situation and found no deposit whatever, it would have been very unfair or very unwise to conclude that it was similar in quality to that from the source of the Thames. It might have been saturated with nitrates, and even a large amount of organic matter not capable of taking the forms alluded to. Perhaps, however, nitrates prevent decay in water as in meat. As the germs of the lower forms of life may pass by us unobserved, it is necessary that we should give them time for development, in order that they may become sufficiently prominent to attract our attention. For this reason I consider it an imperfect examination of water when this is not attended to, in cases at least where we have not the slightest idea of the nature of the water. We find water with less than two grains of organic matter per gallon giving rise to forms by no means agreeable to look at in our food, and water with several grains of organic matter giving rise to no such forms.

It is true that we cannot tell which of these living forms are most dangerous; we cannot tell which of them, if any of them, produce either cholera or any other disease; but we can say that water which contains them may contain the elements of disease, whilst water which does not contain them or matter to make them is innocent. So far as this we are obliged to go at present. It was for these reasons that I have not recommended the method of estimating the total nitrogen in water. I was inclined to believe that the danger arising from water could not be measured by the amount of organic matter, or even by the amount of nitrogen in the organic matter.

Still it is of advantage to estimate the nitrogen of the organic matter, in order to compare the state of one source of water from day to day, as, for example, Dr. Frankland does so frequently in the case of the Thames. It is not, however, the organic matter only that gives out nitrogen; that is given out by ammonia and nitric acid; and these must also be estimated when seeking albumenoids. And this course is adopted by Profs. Frankland and Wanklyn.

We may now inquire how far all these bodies together will give us the amount of the organic matter falling into the water.

When azotised compounds decompose and form ammonia, how long is this ammonia retained in the water? On examining a very putrid stream, I estimated the amount of ammonia at the most putrid portion, where carburetted hydrogen was passing off in great volumes, and where a cubic foot could be obtained in a very few minutes by stirring.

In the sewage stream of which I have spoken, the amount of ammonia was from 0·5 to 0·7 grain per gallon. After going 14 miles, the amount was only 0·07, and, after 20 miles, none at all was found. To say none at all, is to go far, but it was not found by the mode adopted for the others.

The mud of the same stream was in a state of putrefaction, and contained, per cent—

Ammonia	0·797
,, a mile lower	0·420
,, at second mile	0·171

The ammonia rapidly disappeared, and the mud itself dlminished very greatly in amount.

I estimated that one grain of ammonia evaporated, in some seasons, from every square foot per hour.

In taking sewage water to the land, I think it very important that the movement should be as rapid as possible.

The water, in its passage of 20 miles, has lost its valuable ammonia, and that within two or three days. This is a sufficient proof that we must not trust to the ammonia as an indication of the amount of the organic matter which has been present, as it is as rapidly removed as the organic matter is decomposed; that is to say, the length of time necessary for complete putrefaction is, under favourable circumstances, no greater than the time afterwards required for the removal of its products. In enquiries on putrefaction, I have found the temperature 12·2° C. a marked one. Putrefaction may be said to begin actively at that point, and the results here given would, probably, be very different below that. In this water there was no moving life to be observed; but the estimation of the organic matter would have shown no difference, whether vitality had been present, and the substance had been capable of entering into active and unwholesome forms, or had been ready to break up into instantaneous putrefaction, or had been preserved, like a mummy, in carbolic acid for a thousand years.

From this observation regarding the ammonia, we are clearly led to beware, in our schemes of irrigation by sewage water, that the land shall be overflowed before the ammonia is thoroughly formed, or else, if the ammonia is formed, that it shall not be subjected to loss by long exposure to evaporation.

We see, also, that nature provides here for the complete obliteration of organic matter. It ceases altogether to be found in the water. It may be traced, either as such, or as ammonia and carbonic acid, long after the bubbles of carburetted hydrogen have ceased to appear, until, at last, it dwindles down to an amount which is rather difficult to remove from water, and which, so far as we know, may be utterly disregarded.

In the passage of organic matter, we may observe, from figures soon be to quoted, that the volatile and organic matter diminished from 9·33 grains per gallon down to 5·04, even when there was an increase of fixed matter, and that the decomposing matter in solution diminished still more rapidly, in the ratio of 283 to 17. The use of the word decomposing matter is not quite correct; it means the substances in solution, arising from decomposing matter and absorbing oxygen at once. It must be observed that the time required was two to three days; and I may add that I could not have drunk the water at last, but there was great foulness to begin with. Still, it shows great removal of impurity.

The organic matter having left the water, we may next enquire whether any trace of its existence remains behind. That trace we do find in the increased amount of alkalies, sulphates, and chlorides.

The alkalies and alkaline salts, but especially common salt, are prominent. The whole of the common salt which has been used as food, without the slightest loss, is found in water, when vegetation has not removed it. The sulphur has become partly oxidised, leaving sulphates, whilst some may have left in company with hydrogen. Phosphates have been increased for a time; but they rapidly fall, taking lime and some magnesia with them; and, on the whole, the great change to be observed in the water is connected chiefly with the alkaline salts. The most stable and most constant of these, without loss, is common salt.

On this subject, I may quote what has been said elsewhere regarding the chlorides as an indication of the presence of animal matter, proper regard being had to the absence of other sources, which, in this country, are chiefly connected with artificial circumstances. "The absence of the chlorides, especially, may be considered as the certain absence of sewage matter, and their amount to be estimated as an indication of the comparative amount of sewage matter from day to day, in cases where sewage only pollutes the river." I conclude from these data that the organic matter and the nitrogen in it are equally incapable of giving us a sufficient history of the water. We may draw another conclusion, that nature has provided a mode in certain conditions for its perfect removal.

It is worth while to ask whether this purification by putrefaction is not the most complete method; it seems to destroy that which we consider to be germs, which germs may be a beginning of any disease of the most terrible form. Having read most that I can find on this subject, I have been led to think that the water, before and during putrefaction, may contain the diseases that have been washed from cities, but that the air above, containing the gases and vapours, does not contain the germs of these diseases, although, of itself, it is extremely loathsome and decidedly unwholesome. It is rapidly purified by the atmosphere. However, I reason from the facts obtained by others, since disease is not my study. After complete putrefaction and clearing, the water seems to be used with impunity. Our rivers, however, seem too small to purify large quantities in their course, as, even in warm weather, the time must be measured by days if the specimen given is a fair one. I do not pretend to say how much may be allowed to go into a river of a given size without fear, but this may be found, as, after all, every river has some sewage from animals, and, in this country, even from man also.

If the water were allowed to clear itself by standing, producing whatever amount of organic life could be developed from it, the germs might be increased in number, instead of being diminished. It is proper to observe that the liquids must be included. The solids contain little chlorine. The water above might remain very clear, but might be, nevertheless, very dangerous. In such a condition, water seems to be best purified by filtration through the soil, which simply means extremely slow and careful filtration, accompanied with partial oxidation; in that case, the water coming from under the soil would be fit again for use, although it would contain, and does contain, the alkaline salts alluded to.

Waters from rich lands, unless from very deep drains, always contain more organic matter than water from hills, and more albumen, or matter so conditioned that it is capable of assuming a great variety of living forms with and without locomotion. Water from the hills of Scotland and Wales, Cumberland, and many parts of North England, gives rise to no variety of living forms; and, in many of them, there is scarcely anything to be remarked in the deposit, unless opportunity is given for collecting it from a large quantity of water, and concentrating. On studying this subject many years ago, I found that, in some of those cases where the water was peaty, there was also to be found a large amount of ammonia. The words I used were these:—"In a peat bog which is not well drained, and is, therefore, wet and cold, the acids of the peat do not become dissolved so as to form a very deeply coloured solution, but they form a solution of a pale yellow. But in grounds which are warmer, or, what is better, well drained, the amount of soluble matter is very great. The colour of such water is not to be confounded with the water which heavy showers bring down, filled with mud and bits of peat; it is often perfectly clear and bright, but brown like coffee. The acids in solution at such times are kept so by the presence of ammonia. Ammonia dissolves them in large quantities, and along with them also the salts which they form with lime, magnesia, soda, phosphates, &c.

"Plants begin to grow in warm weather; at this time ammonia is formed. It is at this time the organic matter decays, and, in its approach to inorganic matter, passes through this stage of ammonia.

"The peat mould Mulder has shown, but he has not mentioned this excess of ammonia."

I supposed at the time, as it appears, that the ammonia produced by the decomposition of vegetable substances was used for the solution of the ammoniacal humates of Mulder. The paper read was only a short note intended to call attention to an important and curious point—the amount of ammonia on those bare hills. I have had the subject before me frequently since that period, namely, 1847, but have never given it all the time required for its elucidation. Lately, Professor Wanklyn and Messrs. Miles Smith and Chapman have examined the hill-waters, and have rather alarmed the public by informing them that they contain more albumenoid matter than waters coming from rich plains. The process they adopted has, no doubt, shown two conditions of the nitrogen; and it is possible that one may be albumen; but it seems perfectly clear that it is not putrescible albumen. I had long ago found the nitrogen; it still remains to find out all the conditions of its existence, If waters containing nitrogen from the hills are allowed to stand, they neither show their nitrogen by the production of living forms in proportion to the amount of that element, nor by putrefaction; any fear, therefore, of such results may be entirely put out of our minds. The living forms, which are the most dangerous, are fewer than from pretty deeply filtered water of the plains; and putrefation cannot exist when the matter to putrefy is so minute: when the solutions are extremely weak, oxidation overpowers it. Such, at least, is my experience.

A reason for believing that nitrogen exists as albumen is the large amount of fish which the water supports. But protein exists in many conditions. The learned originator of the word had the idea of the prophetical and changeable Proteus in his view, as well as the rank of the substance as first in importance, because it forms man. I think, however, the probability is that the earth acids keep it from change, united to the generally low temperature on the hills. This latter, however, does not seem needful. These soils saturated with peaty water are not to be compared to flat, wet, and ague-bringing grass and other lands. I find the process of Professor Wanklyn still more valuable since I wrote the above, although I adhere

to the reasoning that, although he may be right in believing albumenoids to be present, the water is not, to that extent, hurtful. The same applies to the reasoning, as I understand it, of Dr. Frankland. But we need not quarrel; it is enough if we each try to elucidate the subject.

(To be continued).

ON THE PROXIMATE ANALYSIS OF COALS.*

By Prof. GUSTAVUS HINRICHS,
Chemist of the Geological Survey of Iowa.

DETERMINATION OF THE MOISTURE.

A FLAT-BOTTOMED iron pan, of 20 centimetres in diameter, was filled evenly to the depth of 1½ centimetres with sand, and the latter was covered with a copper plate, on which the watch glass containing the coal was placed. A thermometer (scale to 370° C.) was, by means of a rubber stopper, inserted in an iron arm of the tripod supporting the iron pan, and held with its bulb about half a centimetre above the copper plate. By means of a Bunsen burner it was found very easy to keep the thermometer perfectly constant at 115° C. This apparatus I consider a good substitute for Fresenius's iron plate.

The coal to be dried was finely pulverised, direct experiments having convinced me that the application of fragments was not only very much slower, but also erroneous, on account of the peculiar property of bituminous coal treated of below.

In order to show the accuracy of this method, I transcribe the following examples from my journals:—

No. of Coal.	Weight of Portion.	Time.	Moisture. Per cent.	Deviation from Mean.	Mean.
390 e	0·961	1 hour	4·888	−0·004	4·892
,, f	0·919	1 ,,	4·896	+0·004	,,
,, e	0·961	2½ ,,	4·160	+0·010	4·150
,, f	0·919	2½ ,,	4·140	−0·010	,,
339 e	1·452	1 ,,	8·260	+0·070	8·190
,, f	0·975	1 ,,	8·120	−0·070	,,
,, e	1·452	3 ,,	7·160	+0·170	,,
,, f	0·975	3 ,,	6·830	−0·160	,,
338 e	1·415	1 ,,	3·852	−0·029	3·881
,, f	0·805	1 ,,	3·911	+0·030	,,
,, e	1·415	2½ ,,	3·287	+0·123	3·164
,, f	0·805	2½ ,,	3·042	−0·122	,,
,, e	1·415	5½ ,,	2·722	+0·088	2·634
,, f	0·805	5½ ,,	2·546	−0·088	,,

These results—a few taken from among a great number of determinations—show that the loss (called moisture) decreases regularly after the first hour of drying, that is to say, while the coal loses in weight during the first hour, it steadily gains in weight thereafter. It appears, furthermore, that the accuracy of a determination, expressed in the smallness of the deviations from the mean, is greatest at the end of the first hour of drying, least after about three hours of drying, and thereafter increases again, as expressed in the diminution of the deviations after 5½ hours' drying in coal No. 338.

On account of these peculiar properties of our bituminous coal, I put down as *moisture* the loss in weight of the finely-pulverised coal after one hour's drying at a temperature between 105° and 110° C.

ON THE SLOW OXIDATION OF COAL.

This increase in weight after the first hour's drying I have found in all Iowa investigated as yet. I have also found it to occur in a sample of coal (Steinkohle) from Benthen, Silesia, which showed a loss of 3·62 per cent at the close of 1 hour, and in 4 further hours' drying gained again 0·42 per cent. It was not noticed in brown coal from Bilin, Bohemia, nor in anthracite from Pennsylvania. I am, therefore, inclined to believe this to be a property peculiar to pit-coal (steinkohle).

On page 401 of vol. 1, p. 1, of the "Iowa Geology," Professor Whitney remarks: "A remarkable fact in connection with the determination of the water present in the specimens of coal has been noticed. In numerous instances, after the sample, in the form of a coarse powder, had been dried for several hours in the air bath, at a temperature a little above that of boiling water, during which time it had gradually lost weight until all the water seemed to have been expelled, on continuing the operation for some time longer, a slight increase of weight would become perceptible, and the coal would continue to grow heavier, until a gain of several tenths of a per cent of the original weight had been made. This appears to be owing to the slow oxidation of the sulphur which all these coals contain in a finely divided state, disseminated in invisible particles through the mass, and, perhaps, partly in combination with iron."

It is evident that Professor Whitney failed to discover this property as a general one, because he had the coal in coarse fragments. The want of correspondence in the results of determinations of moisture in the same sample, dried at the same time, but of different weights, made me apply the coal in the form of powder. Thereby the turning point was reduced from "several hours" to less than one hour, the "numerous instances" extended to all samples investigated, the "slight increase of several tenths of 1 per cent" became often 2 and even 4 per cent! Instead of numerous exceptions we now discovered a general law.

We have failed, as yet, to notice any "sulphur" disseminated through the Iowa coal; what popularly is called sulphur is pyrites. Professor Whitney has given no proof of the existence of real "sulphur" in the coal. It is, therefore, unsatisfactory to ascribe this property of the bituminous coals to such "sulphur."

Pyrites might well be the cause of this phenomenon; the red ashes obtained in many cases (in Van Buren county, Iowa, invariably from the upper part of the coal bank) may well be ascribed to pyrites disseminated through the coal in invisible particles. Two FeS_2 will give Fe_2O_3, $+4SO_3$ by exactly doubling their weight.

In order to decide the question, I select the following results from my analyses:—

INFLUENCE OF TIME OF DRYING.

Top coal ..	No. of samples,	4	3	2	
	Time of drying,	2	3	4—5	hours.
	Mean gain, p.c.,	0·45	0·71	0·96	
Bottom coal ..	No. of samples,	3	5	2	
	Time of drying,	2	3	4	hours.
	Gain, per cent,	0·49	0·50	0·96	
Mean of above.	No. of samples,	7	8	4	
	Time of drying,	2	3	4—5	hours.
	Gain, per cent,	0·46	0·63	0·96	
	Gain, per hour,	0·23	0·21	0·24	

or, on the whole, for 19 samples of coal, very nearly proportional to the time, this being not more than four hours. It also appears that no essential difference is apparent in regard to the position of the sample in the coal bank.

By this means we may compare the following determinations, referring to two, three, or four hours drying. We find:—

Coal. Place—No.	Time. hours.	Increase, Total.	Per ct. per hr.	Difference.	Colour of Ashes.
top 390	2	0·75	0·38		pale brown.
				0·22	
bottom 384	2	0·35	0·16		white.
bottom 395	4	0·80	0·20		red and white.
				0·04	
top 375	4	0·64	0·16		white.
top 346	3	0·68	0·23		reddish brown.
				0·08	
bottom 371	3	0·45	0·15		white.

* Communicated by the author. For a previous paper on this subject see, also, vol. xviii., p. 53.

Coal. Place—No.	Time. hours.	Increase, Total.	Per ct. per hr.	Difference.	Colour of Ashes.
top 336	3	0·76	0·25		gray.
				0·06	
bottom 334	3	0·58	0·19		gray.
top 333	3	1·17	0·39		pink.
				0·09	
bottom 340	3	0·91	0·30		light gray.
middle 357	3	0·55	0·18		white.
				0·03	
top 370	3	0·46	0·15		reddish.

Except in the coal from the last mine, we notice that the more ferruginous ash does correspond to a slightly greater increase in weight; but we notice also that this difference is but very small as compared to the total amount of increase, being only 1-5 to 1-3 of the whole. Arranging these coals in the order of this hourly increase, we find the colour of the ashes not at all forming a regular series from white to red, as it ought to be, if this increase was mainly depending upon the oxidation of the pyrites. Besides, the mean of the four white ash coals is 0·16 per cent hourly increase, while the mean of the four coals showing the greatest increase is only 0·33 per cent, or double the former.

Coal.	Increase, per cent.	Ash.
333	0·39	pink.
390	0·38	pale brown.
340	0·30	light gray.
336	0·25	gray.
346	0·23	reddish brown.
395	0·20	red and white.
334	0·19	grey.
357	0·18	white.
375	0·16	white.
384	0·16	white.
371	0·15	white.
370	0·15	reddish.

The greater increase of the pyritiferous coals is accounted for by the oxidation of the pyrites they contain; the comparatively great increase of coals giving a pure white ash seems to force the conclusion upon us that the bitumen of the coal itself oxidises, and that to this oxidation the main increase of all these bituminous coals must be ascribed. Remembering, now, our result regarding the deportment of bituminous coal from Silesia, anthracite from Pennsylvania, brown coal from Bohemia (all of which gave ashes very nearly of same shade, and all of which had been in my air-heated laboratory for two years), it seems not unlikely that this is another characteristic chemical difference between bituminous coals and other fossil coals.

In conclusion, I will give only two additional determinations, showing a very considerable increase in weight, and also that the process of oxidation is completed in about six hours for two-thirds grammes of coal. For No. 329, containing 8·30 per cent of grey ashes, gained in 5½ hours 2·05 per cent of its original weight. Coal No. 348, with 6 per cent red ashes, weighed 0·693.

			Change. Weight.	Per cent.	Total loss Per cent.
After ½	hours,	0·630	loss	0·063—9·091	9·091
,, 2	,,	0·625	,,	0·005—0·722	9·813
,, 5½	,,	0·656	gain	0·031—4·474	5·339
,, 8½	,,	0·656	,,	0·000	5·330

Determination of the Ashes.

The best way to determine the ashes in coal I found to be the coking of the finely pulverised coal in a small platinum dish (weighing about 8 grammes) with subsequent incineration of this coke in the same vessel. The incineration takes place with great ease and rapidity, and the results are perfectly satisfactory. Thus 3·022 grammes of coal No. 333 gave 2·25 per cent, and 5·263 grammes of the same coal gave 2·58 per cent, deviating from the mean 2·46 by + 0·11.

In regard to the ashes of our Iowa coals, I have found that they are very much more uniform in their distribution throughout the coal fields than usually thought possible. In Van Buren county I find the "bottom" coal giving a white or light coloured ash, the "top" coal of the same bank a red-coloured ash, a fact which I intend to make use of in a subsequent paper on the origin of our coal. I also find the amount of ashes to increase quite evenly (in this county) toward the margin of the coal field from about 2 to 7 per 100 combustible.

Determination of Specific Gravity.

Coarse fragments, freed by means of a sieve from all small particles, and averaging 1-10th cubic centimetres in volume, were introduced into a fifty-gramme flask provided with thermometer stopper. The constants for this flask for temperatures varying from 50° to 80° F. had been carefully determined.

The given specific gravity corresponds to the coal perfectly soaked, so that all its pores were filled with water. That required, on the average, 12 hours, permitting two determinations per day, one in the morning, another in the evening.

That this is not at all trifling may be seen from the following example:—2·760 grms. coal (No. 350) gave the specific gravity 1·309 at 64° F., immediately after filling the flask with water; after about 12 hours' soaking, the specific gravity had increased to 1·328, for the same temperature. According to this latter determination, a cubic foot of this coal would weigh 82·76 lbs.; according to the former, only 81·58, or 1·18 lbs. less. This shows a considerable degree of porosity of the coal, and indicates the absurdity of giving the weight in pounds of a cubic foot of coal with four decimals, although no statement in regard to temperature or time of weighing is made! Such accuracy we meet with in some of the official reports!

Calculation of Results.

Referring to my previous paper (CHEMICAL NEWS, vol. xviii., p. 53), it may be sufficient here to state that, besides the percentage composition of the coal, it is proper to reduce the composition to the combustible = 100, in order to obtain a proper comparative estimate of the character of the fuel itself (in regard to the proportion of bitumen and carbon), and of the amount and quality of the impurities (ashes and moisture). It has also been shown in the paper referred to, that, for considerable areas of the coal field, the sum of the constituents on the scale of combustible = 100 is the proper caloric equivalent, and that the percentage of the combustible in the fuel gives a proper estimate of its value.

According to this method, a considerable number of analyses of Iowa coals have already been made, and a greater number are yet to be executed. It is believed that the results will be strictly comparable for the entire coal-field of Iowa, and that the conclusions, both practical and theoretical, will deserve some confidence.

A New Alloy (says *Iron Age*), forming, we are told, a beautiful white metal, very hard and capable of taking a brilliant polish, is obtained by melting together 70 parts of copper, 20 of nickel, 5⅛ of zinc, and 4⅛ of cadmium; it is, therefore, a kind of German silver, in which part of the zinc is replaced by cadmium. It is used largely in Paris for the manufacture of spoons and forks, which resemble articles of silver.

Amalgamation of Zinc for Galvanic Batteries.—In a somewhat lengthy, and not by any means very lucidly written, paper in *Les Mondes*, M. D'Almeida has described a series of experiments made by him with amalgamated zinc and other metals, and, moreover, with polished substances, such as glass, to prove that the cause of the very far less rapid solution and attack of zinc and other metals when placed in contact with acids, which, unless the said metals were amalgamated, would rapidly corrode and dissolve the same, is due, after amalgamation especially, to the physical change of the surface of the metal, and, as a consequence thereof, the adhesion to the metal of a thin layer of very minute bubbles of hydrogen gas retained to that surface by capillary action, and, as a consequence of their presence, the non-immediate and direct contact of the metal with the acid it is immersed in, but action of the latter upon the former through a layer of very minute bubbles of gas, which appears to be one of the causes of the slower corrosion of amalgamated zinc. The author has made a series of experiments, too long to be described in detail, which, certainly as far as the description goes, appear to prove his theory on this subject.

PROCEEDINGS OF SOCIETIES.

CHEMICAL SOCIETY.

June 3rd, 1869.

Dr. W. A. Miller, V.P.R.S., &c., in the Chair.

The minutes of the preceding meeting having been read and confirmed, the following certificates were read:—

For the first time—John Morrison, Analytical Chemist, County Wicklow, Ireland; W. G. Lewis, Fellow of Oriel College, Oxford; Alfred Dudley Keightley, Gatcheck Gunpowder Mills, Old Hall, Milnthorpe, Westmoreland.

For the second time—Temple A. Orme, Teacher of Chemistry and Experimental Physics in University College School; W. Fletcher Barrett, Lecturer on Pysical Science at the London International College.

For the third time—William G. Valentin, Assistant in the Royal College of Chemistry, 126, Lancaster Road, Notting Hill; Thomas Gilham Hewlett, Surgeon, Bombay; Captain A. Noble, Engineer, Elswick Ordnance Works, Newcastle; H. Stillington Grey Stephenson, B.A., Oxford, Sympsham Rectory, Weston-super-Mare. The last-named gentlemen were balloted for and duly elected.

Mr. Gerstl was proposed as an associate of the Society.

The President (Dr. Williamson) then read a lecture on "*The Atomic Theory*," but, as it is difficult for us to give a condensed report which will do justice to so important a subject, and as the author has, with his usual courtesy, kindly promised to send us an abstract, we postpone our report of this paper for a future number.

The Chairman proposed a vote of thanks to Dr. Williamson, and said that it would be better to defer the discussion until the next meeting. He would, however, remark that those who opposed the atomic theory must explain how, according to the notion of the infinite divisibility of matter, they had combination in definite proportion at all. It seemed to him utterly impossible to explain combination in definite proportion by the theory of infinite divisibility.

The President announced that, as the next meeting would be taken up by M. Dumas's lecture at the Royal Institution, another meeting would be held for the ordinary business of the Society; the date was not, however, announced.

The meeting then adjourned till the 17th inst., at the Royal Institution.

NOTICES OF BOOKS.

Spectrum Analysis: six lectures delivered, in 1868, before the Society of Apothecaries of London. By H. E. Roscoe, B.A., F.R.S. Macmillan and Co., 1869.

Lessons in Elementary Chemistry; Inorganic and Organic. By H. E. Roscoe. New Edition. Macmillan and Co., 1869.

Few men are so competent as Professor Roscoe to discuss the various processes and results of spectrum analysis. He has worked much on the subject of light, sometimes alone, sometimes with the men who founded the mode of analysis under discussion: it will also be remembered that he was the first to introduce the subject in a practical form to the attention of scientific men in this country; and he has translated many important memoirs relating thereto into English during the last few years.

The work before us appears at a peculiarly opportune time, since the recent spectroscopic observations of the eclipse of 1868, and the brilliant results in stellar chemistry obtained yet more recently, have made this branch of science perhaps more prominent than any other, whether we look to the novelty and magnitude of its deductions, or to the fact that it enables us to exercise, not alone a cosmic analysis, but a system of analysis embracing the universe.

Starting with Newton's discovery of the composition of white light, Professor Roscoe passes to the consideration of the properties of sunlight, and of the various coloured rays composing white light. The key-note of the whole subject was struck by Newton, in 1675, in the demonstration that "lights which differ in colour, differ also in refrangibility;" he proved, at the same time, that light which has once passed through a prism cannot be further decomposed, and that the various coloured rays constituting white light, when brought together again after decomposition, form white light. The author next considers the various conditions of different portions of the spectrum, and gives illustrations of the fact that the calorific intensity of the spectrum attains a maximum near the red end of the spectrum, while the chemical intensity culminates near the violet end of the spectrum. An account of Fraunhofer's lines concludes the first lecture.

A noticeable feature of the work is the addition of an appendix to each lecture (often exceeding in length the lecture itself), in which extracts from the more important of the memoirs quoted are given, and the most recent discoveries—too late for insertion in the text of the lectures—are described. In the appendix to the first lecture, a lengthy extract is given from Newton's "Optics," regarding the *modus* of the original experiment on the decomposition of light. There are, also, some remarks on the application of magnesium wire as a source of light for photographic purposes, in the course of which it is stated that "a burning magnesium wire, of the thickness of 0·297 millimetre, evolves . . . as much light as seventy-four stearine candles of which five go to the pound."

The second lecture treats of the spectrum of incandescent solids and gases, and the method of producing and examining their spectra. In speaking of the delicacy of the method of spectrum analysis, it is stated that 180,000,000th part of a grain of sodium can be readily detected; 6,000,000th of lithium, and 1,000,000th of strontium. Among the more important results produced by this branch of the subject, is the discovery that lithium, previously known to exist in but four minerals, is now found to be one of the most widely-distributed metals. An interesting account is appended to this lecture of Bunsen and Kirchhoff's mode of working with the spectroscope.

The third lecture contains an historical sketch of the rise and progress of spectrum analysis, and an account of the various new elements discovered by its means. We learn from this that, so far back as 1822, the spectra of many-coloured flames were examined by Sir J. Herschel. On page 96, elaborate analyses are given of the mineral waters in which cæsium and rubidium were first discovered. The lecture concludes with an account of, perhaps, the greatest application of spectrum analysis to the purposes of the manufactures which has yet been made, viz., its application to the process of making steel by the Bessemer process. In this operation, it is of the utmost importance that the operation of blowing air through the molten metal should be stopped the instant that the proper amount of carbon has been removed from the metal. "If the blast be continued for ten seconds after the proper point has been attained, or if it be discontinued ten seconds before that point is reached, the charge becomes either so viscid that it cannot be poured from the converter into the ladle from which it has to be transferred to the moulds, or it contains so much carbon as to crumble up, like cast-iron, under the hammer." The precise moment to stop is judged of by examining the flame as it issues from the mouth of the converter, by means of a spectroscope, and the moment that the carbon lines disappear from the field of view, the blast is shut off.

In the fourth lecture, Professor Roscoe discusses the spectra of metals volatilised in the electric arc, a subject which received much attention from Angström in 1853,

he having mapped no less than 32 spectra, while Mr. Huggins has mapped 24. Thalén has recently investigated and mapped the lines of some of the rarer metals; among them, glucinum, thorinum, and zirconium. At page 156 will be found two very admirable maps of metallic lines, from the drawings of Mr. Huggins, and these are followed by extracts from the memoirs in which he describes them.

In the fifth lecture is commenced the important subject of solar and stellar chemistry, an account is given of the discovery of the coincidence of the dark solar lines with bright metallic lines, of Kirchhoff's explanation of the cause of the coincidences and the deduction therefrom of the well-known theory of the constitution of the sun. We find here two very beautiful reductions of Kirchhoff's maps of the solar spectrum, together with the map of Angström and Thalén, of the spectrum from G to H_2 drawn to the same scale. An experiment is described on page 191 in which "a constantly burning black soda flame" is produced by viewing a soda flame through a surrounding shell of soda flame; this is an admirable experiment for a large audience, provided they are not seated on gradually ascending seats, when of course many look down upon the inner soda flame without looking through the surrounding flame. The appendix to this lecture contains a detailed account of the spectroscopic observations of the solar eclipse of 1868.

The last lecture is devoted to the subject of stellar chemistry, and is accompanied by a beautifully coloured map of the spectra of various stars and nebulæ, among them Sirius, and the blue and orange stars of β Cygni. The spectra of Aldebaran and α Orionis drawn to scale are given on page 235; in these stars no less than seventy lines have been observed, and Dr. Miller and Mr. Huggins have detected nine elements in Aldebaran, which, strange to say, include bismuth (not found in the sun), tellurium, antimony, and mercury. Finally, the spectra of comets and nebulæ are discussed, and it is stated that Brorsen's small comet, which is now visible, has been found by Mr. Huggins to give lines dissimilar to those yielded by any substance known on earth. The final appendices contain very lengthy abstracts from the memoirs of Huggins and Miller on stellar spectra, Kirchhoff's elaborate tables of the coincidences of the bright lines in the spectra of the metals with the dark solar lines, and the work is terminated by a list of the principal memoirs on spectrum analysis, divided into three parts. (1) "Lectures or Memoirs Relating to the subject of Spectrum Analysis generally," eighteen in number; (2) Memoirs relating to the Application of Spectrum Analysis to Terrestial Chemistry," ninety-four in number; (3) "Memoirs relating to the Application of Spectrum Analysis to Celestial Chemistry," seventy-five in number.

The great extent of the literature of the subject well indicates the rapid growth (mainly since 1861) of the science of spectrum analysis, and we have in the work before us a condensed account of everything of importance which has been done in connection with it from the pen of a man who who has himself contributed no insignificant labours in this direction. As to the book itself, it is clearly and concisely written, and is in no place unnecessarily complex. The numerous illustrations, together with the maps and coloured plates, tend greatly to simplify the more abstruse matters, and we heartily recommend the book to the general as well as to the scientific reader.

We are glad to notice the issue of a new edition of Professor Roscoe's useful "Lessons in Elementary Chemistry," a work now generally used by the junior classes in those schools (happily on the increase) in which natural science is taught. The present edition contains no less than fifty-six pages more than the edition of 1866, together with a few additional woodcuts; the index is very complete and comprehensive, and the examination questions have proved of service to science masters: we feel assured that this work will continue to occupy the position which it has gained among our school books.

Observations on some of the Fundamental Principles and Existing Defects of National Education. By NEIL ARNOTT, M.D., F.R.S., &c. Longmans, 1869.

IN about 32 duodecimo pages, Dr. Arnott very clearly sketches the outline for a good and useful system of education. The little book opens with what is very aptly called a general map or table of human knowledge, showing the natural divisions. The first embraces the three Kingdoms of Nature; the second the four orders of changes or phenomena among things, the knowledge of which is called Science. The third division is divided into two sections; (*a*) the two arts by which man acquires and stores knowledge; (*b*) industrial arts, fruits of human invention.

This is a comprehensive scheme, but it certainly appears to be the right way. The subjects just enumerated are briefly but lucidly explained and discussed in the subsequent pages of the book, which is a very valuable shilling's worth.

LABORATORY NOTES.

PHOSPHORUS HOLDER.

A FEW inches of lead tube, ¼ in. bore, is contracted to an open cone, at one end. As much phosphorus as one may choose is put into the cone of the tube; the phosphorus is made to project slightly from the cone; the upper part of the tube is filled with water, and corked. Thus is had a phosphorus "crayon" perfectly safe in the hand for luminous writings, &c.

To put in the phosphorus, as much as may be required is melted in a conical glass, or test tube, the cone of which is larger than that of the lead tube.

This is put standing in the melted phosphorus, which fills the cone and tube to its own outside level. When cold, there is a nice projecting crayon, from the form of the glass. Any phosphorus outside the lead tube may be melted off.

To renew the writing point, a test-tube, conical below, is fitted to the cone of the lead; the whole held in warm water for a minute, as much phosphorus flows out as forms a new point.

E. KERNAN.

PHOSPHURETTED HYDROGEN.

THE solution of caustic potash and phosphorus are put into anything like an evaporating basin. On the application of heat, the gas comes off, taking fire at various points of the liquid surface. The cup may be very small, even a watch glass will do.

The basin with its contents may be put aside until required to act again. Even when quite cold, odd bubbles of gas come off.

An objection to this method is that the "rings" do not show; the gas bubbles are too small, and burst before they can unite to form one large one strong enough to overcome the air currents. Could this be effected, the open basin would be a considerable improvement on the retort production of phosphuretted hydrogen.

E. KERNAN.

MISCELLANEOUS.

New Work by Dr. Odling.—Shortly will be published, in 1 vol., "Outlines of Chemistry; or Brief Notes of Chemical Facts," by William Odling, M.B., F.R.S., &c., Fellow of the College of Physicians, and Fullerian Professor of Chemistry at the Royal Institution. This volume will consist of the notes from which the author has lectured for the last six years at St. Bartholomew's Hospital, revised and somewhat extended, so as to furnish the student with a connected outline of the leading facts of chemistry in their relations to each other. It will be essentially descriptive in its character, and aim at calling to mind,

in as few words as possible, the ascertained origins, properties, and metamorphoses of chemical substances. It will include a systematic account of the monad, diad, and triad non-metallic elements, and their principal combinations with each other; of silicon and carbon with its series of methylic, formic, and cyanic compounds; and of the various metals, arranged, as far as practicable, in natural groups, with their respective series of halides, oxides, and oxisalts, &c.

Extraordinary Phenomenon.—The Caspian Sea or Lake is dotted with numerous islands which produce yearly a large quantity of naphtha, and it is no uncommon occurrence for fires to break out in the works, and burn for many days before they can be extinguished. Early last month, owing to some subterraneous disturbances, enormous quantities of naphtha were projected from the wells and spread over the entire surface of the water, and, becoming ignited, notwithstanding every precaution, converted the sea into the semblance of a gigantic flaming punch-bowl, many thousands of square miles in extent. The fire burnt itself out in about forty-eight hours, leaving the surface of the water strewed with the dead bodies of innumerable fishes. Herodotus mentions a tradition that the same phenomenon was once before observed by the tribes inhabiting the shores of the Caspian Sea, which exceeds in area that of England and Scotland together.

Essential Oil of Cochlearia officinalis.—It appears that this essential oil has been frequently confused with the essential oil of mustard, from which the author (Dr. A. W. Hofmann), on experiment, found it essentially different. The boiling point of the oil of *Cochlearia* is at about 160° C., that of the genuine oil of mustard at 147° C. On being treated with ammonia, the essential oil of *Cochlearia* yields a beautifully-crystallising substance (the thiosinnamin of the essential oil of *Cochlearia*), which fuses at 135° C. Analyses of the oil and the ammonia compound just alluded to, prove the oil to be the mustard oil (*Senföl*), of the butyl series—

$$C_4H_9NS = \left.\begin{matrix} C_4H_9 \\ CS \end{matrix}\right\} N.$$

When butylamine (prepared from butyl alcohol by fermentation) is treated with sulphide of carbon and chloride of mercury, a mustard oil is obtained of the same composition and about the same boiling point, but the odour indicated that only an isomeric substance had been obtained, and further research proved that the ammonia compound of the oil, thus artificially produced, had its melting point at 90° C. The author intends to proceed with researches on this subject.—*Berichte der Deutschen Chemischen Gesellschaft zu Berlin.*

CHEMICAL NOTICES FROM FOREIGN SOURCES.

In accordance with the generally expressed wishes of our friends and readers, we are endeavouring to effect arrangements to enable us to give, under the above heading, notices of EVERY CHEMICAL PAPER IN THE WORLD, *as soon as possible after publication. Whenever possible, these notices will appear in the form of carefully prepared, although necessarily brief, abstracts; as respects papers either too long or too abstruse to render condensation possible, their titles will be chronicled; and in all cases accurate reference will be made to the original publication. The two half-yearly volumes of the* CHEMICAL NEWS, *with their copious indices, will therefore be equivalent to an English edition of the "Jahresberichte," with the additional advantage of keeping the readers week by week on a level with the latest advances of science.*

Moniteur Scientifique, No. 299, June 1, 1869.

This periodical contains the following original papers:—

Molecular State of Bodies.—M. Persoz.—This paper is a continuation of a series already published on this subject in the above-named periodical, but far too lengthy and abstruse for abstraction.

History of Urea.—M. Bouchardat.—This is a very valuable essay, but too lengthy and too much condensed already to be fit for this portion of our paper. We may, perhaps, afterwards return to this subject.

M. Margueritte's Process of Sugar Extraction from Molasses.—The leading portion of this lengthy paper is known to our readers; it was published some time since.

Chemisches Centralblatt, No. 19, May 12, 1869.

This periodical contains an original paper—

On the Sulpho-Acids of the Isomeric Hydrocarbons, C_9H_{12}.—M. O. Jacobsen.—Cumolsulphuric acid, $C_6H_3(C_3H_7)SO_3$. The cumol was obtained from cuminic acid, by distillation with five parts of quick-lime. (Boiling point of cumol, 149°—151° C.) It was dissolved in a mixture of equal parts of fuming and ordinary sulphuric acid, next treated with water and carbonate of baryta, and the cumol-sulphate of baryta purified by crystallisation. Free cumol-sulphuric acid is a solid substance, very soluble in water and alcohol, and is decomposed by heat without previously fusing. The author studied the potassa, ammonia, lime, strontia, baryta, zinc, copper, and other salts of this acid. The baryta salt belongs to the more stable of these substances.—Isocumol-sulphuric acid, $C_6H_3(CH_3)_3SO_3$. This acid, in a free state, is likewise a solid substance, deliquescent, and readily soluble in water and alcohol; it fuses, but becomes at the same time decomposed. It forms crystallisable salts with bases.—Mesitylen-sulphuric acid, $C_6H_3(CH_3)_3SO_3$, is also a solid substance, crystallising in six-sided prisms, not deliquescent, readily soluble in alcohol and water, fuses at 100° C., and forms salts with bases, most of which may be obtained in regular crystalline form.—Ethyltoluol-sulphuric acid, $C_6H_4(CH_3)(C_2H_5)SO_3$. Only the baryta and potassa salt of this acid were obtained.—The sulpho-acid of phoron-cumol is a solid substance, readily soluble in water and alcohol; the baryta salt is sparingly soluble in water, and less soluble even in alcohol.

On Ethyldimethylcarbinol.—M. A. Popoff.—This substance—

$$C\left\{\begin{matrix} (CH_3)_2 \\ C_2H_5 \\ H \end{matrix}\right\}O,$$

is a fluid boiling between 98·5° and 102° C., and does not freeze at −17° C. Its percentage composition is—C, 68·18; H, 13·62. On being oxidised with chromic acid, it yields acetic acid only.

Bayerisches Industrie und Gewerbeblatt, No. 2, 1869.

This periodical contains chiefly original papers and communications relating to machinery and mechanical engineering; the only original chemical paper is—

Colouring Matter of Wafers.—Dr. Furtenbach.—Although wafers are at the present day far less commonly used for sealing letters than was the case before the introduction of the machine-made gummed envelopes, the researches on this subject are not without interest. The manufacture of wafers is largely carried on at Nurenberg and Munich, and other towns of Germany, and the samples submitted to research were made in the two places just named. Small bright-red coloured wafers left, on incineration, an ash, consisting of oxide of lead, sulphate of baryta, and some sulphate of lead; another sample of wafers, of very bright red colour, was found to be free from sulphate of baryta, and the lead, having been quantitatively estimated, was found to amount to 46·9 per cent of red lead. White wafers were coloured with sulphate of baryta—no white-lead was found; blue wafers are coloured, partly with ultramarine, and partly with Prussian blue, but contained, in all instances, besides these substances, sulphate of baryta, and, in some cases, some white-lead; pink-coloured wafers contain carmine lake, alumina being found in the ash; brown coloured wafers are tinged with iron ochre; violet wafers were found to be coloured with some violet lac-dye, containing alumina; black wafers are coloured partly with lamp-black, and also with harmalin-black, which, on incineration, left oxide of iron; green coloured wafers are coloured with so-called green cinnabar (chromate of lead and Berlin blue, mixed), also with poisonous copper and arsenical compounds; buff-coloured wafers are coloured with a mixture of oxide of lead, sulphate of baryta, and some oxide of iron.

Journal de Pharmacie et de Chimie, No. 5, May, 1869.

This paper contains the following original essays and papers:—

Formation and Decomposition of Disulphide of Carbon.—M. Berthelot.—Too long and too abstruse for abstraction.

Action of Ammonia upon Phosphorus.—M. Commaille.—The contents of this paper have been already given in an abridged form.

Influence of Pressure upon Chemical Phenomena.—M. Caillet.—Too long for condensation.

Mineral Chalybeate Water from the Département de Maine et Loire.—M. Andouard.—Of local interest only.

The remainder of this number of this periodical is filled with abstracts from the *Comptes Rendus* and other papers already noticed by us.

Journal fur Praktische Chemie, No. 5, 1869.

This periodical contains, in the first place, three papers, by the late Professor Schönbein, on the following subjects:—

1. **Peroxide of Hydrogen as a Medium for Recognising the Ferment-like Properties of Organic Matter.**

2. **Peculiar Activity of One-Half of the Oxygen Contained in Oxide of Copper, and the Dependence thereupon of a Highly-Delicate Reagent for Hydrocyanic Acid and Cyanides.**

3. **Existence of Peroxide of Hydrogen in the Atmosphere.**

We regret that the above essays, though highly interesting, are too long for abstraction; perhaps we may, at a future day, give abbreviated translations of some of them.

On Hydrocarbons.—M. Fritzsche.

On Benzol.—M. Rochleder.

On Catechin and Catechutannin.—M. Rochleder.

Behaviour of Narcein towards Iodine.—M. Stein.—The author has found that narcein is coloured blue by iodine, but only when the alkaloid is in a solid state; for as soon as the crystals of narcein become dissolved, the colouration disappears. None of the other alkaloids of opium behave in the same manner with iodine.

Analysis of an Alloy found at Pompeii.—M. Milan Nevole.—Specific gravity of alloy, at 13° C., 6·66. It contained, in 100 parts:—

Silica, 0·08; lead, 1·12; copper, 55·04; iron, 29·56; antimony, 3·53; zinc, 10·67.

Decomposition of Disulphide of Carbon by Heat.—M. W. Stein.—The author states that the vapour of perfectly pure disulphide of carbon, prepared on purpose for this experiment, was not decomposed when passed through a porcelain tube kept red-hot by a Bunsen gas burner; but, on repeating the experiment, and increasing the heat, by the application of a strong coke and charcoal fire, the inner space of the tube having been filled with broken porcelain, it was found to be lined with a deposit of carbon, owing to the decomposition of the sulphide, while sulphur was collected in a receiver.

Isocitric Acid.—M. Rochleder.—This acid is formed when citric acid in aqueous solution is treated with sodium amalgam, care being taken to keep up an acid reaction of the liquid by the addition of dilute sulphuric acid. The isocitric acid may be obtained pure by a rather circuitous process, and then exhibits a crystalline mass, which has not yet been further investigated; neither have any of the salts it forms been studied.

Polytechnisches Journal von Dingler, second April number, 1869.

This periodical, though chiefly bearing upon mechanical science occasionally contains original communications which are interesting to our readers; from the present number we only abstract :—

Very Durable Cement for Iron and Stone.—M. Pollack, of Bautzen, Saxony, states that, for a period of several years, he has used, as a cement to fasten stone to stone and iron to iron, a paste made of pure oxide of lead, litharge, and glycerine in concentrated state. This mixture hardens rapidly, is insoluble in acids (unless quite concentrated), and is not affected by heat. M. Pollack has used it to fasten the different portions of a fly-wheel with great success; while, when placed between stones, and once hardened, it is easier to break the stone than the joint.

First May number, 1869.

The greater number of the papers of the present number relate to mechanical science; we notice briefly :—

Diaphonometer to Determine the Transparency of Different Kinds of Glass.—M. Jicinsky.—Without the engravings, it is impossible to make this instrument understood, but, from what is said about it, it is no doubt a useful instrument, especially as the author has proved that the diaphanicity of divers kinds of glass is not dependent so much on its chemical composition, as on certain physical properties due to the heat applied in making it.

Improvement of Acid Waters often Pumped up from Coal-Pits and Mines.—Dr. Willigk.—The author had an opportunity to analyse a water pumped up from a coal-pit in Bohemia. This water, it appears, was very acid, from acid sulphates and some free sulphuric acid present therein, consequently attacking and corroding the pumping gear and machinery, and seriously affecting the steam boiler wherein it had to be used. No other feed-water being on the spot, the author advised, and with good success, that the water should, previous to use, be filtered over witherite, carbonate of baryta, which happened to be abundantly present in that locality.

Analysis of a Cement Marl.—Dr. Lindenmeyer.—In 100 parts:—Lime, 36·84; carbonic acid, 28·50; silica, 23·24; alumina, 4·30; peroxide of iron, 1·14; magnesia, 0·96; potassa, 1·48; water, 2·45. Of this quantity, 29·16 per cent was insoluble in hydrochloric acid.

Volumetrical Estimation of Sulphuric Acid.—Dr. A. Clemm.—After reviewing the methods of R. Wildenstein and Carl Mohr, applied for this purpose, the author describes his mode of operating at length. Briefly stated, his method is the following :—The solution to be experimented upon is coloured with litmus, and very carefully neutralised; a solution of chloride of barium of known strength is added in excess, and all the sulphuric acid thereby precipitated. Next, a titrated solution of carbonate of soda is added, in order to precipitate the excess of baryta; and next, again, the excess of soda solution used is estimated, volumetrically, by means of a titrated dilute sulphuric acid. During these operations, no salt is formed which can injure the colour of the litmus. In case salts might be present in the original solution, the bases of which could be precipitated by carbonate of soda, that precipitation is performed previous to the addition of soda. The filtrate, which contains the sulphuric acid combined with soda, is neutralised, and again volumetrically titrated. The solutions required for this experiment are :—A solution of chloride of barium, containing 52 grms. to the litre of water; a solution of carbonate of soda, containing 26·5 grms. of this salt to the litre of water; a solution of sulphuric acid, containing 20 grms. of strong sulphuric acid to the litre of water. These solutions agree among each other, drop for drop. The advantage claimed for this method is the non-necessity of having to wash out the sulphate and carbonate of baryta, and also the advantage that titration does not take place in a fluid rendered turbid by therein-suspended sulphate of baryta, which always tends to render the observation of colouration of litmus more difficult.

Experiments on the Direct Decomposition of Sulphide of Calcium as met with in Soda Waste by means of Chloride of Manganese.—Dr. Richter.—The author has instituted experiments with the view to obtain, directly, the sulphur in such a state as to render its extraction, by means of sulphide of carbon, an easy matter. Although he has not succeeded quite so well as he desired, he says he hopes his experiments will be repeated by others on a larger scale.

Cryolite Glass, or so-called Hot-Cast Porcelain.—M. Benrath.—The specific gravity of a sample obtained by the author, director of the Imperial Russian Plate-Glass Works at Dorpat, from the American Hot-Cast Porcelain Company, was found to be 2·471. Composition, in 100 parts :—Silica, 67·07; alumina, 10·99; peroxide of iron, 1·02; protoxide of manganese, 1·09; lime, traces; soda, 19·38.

Annalen der Physik und Chemie, von J. C. Poggendorff, No. 3, May 15, 1869.

This periodical contains the following original essays, chiefly relating to mathematico-physical subjects, and hence too abstruse for abstraction :—

Construction of Galvanometers to be Applied when Electric Discharges take place, and on the Way Followed by Electric Co-Currents (Nebenstrome).—M. E. Edlund.

Compounds of Tantalum and Niobium.—M. Rammelsberg.—This is the concluding portion of a lengthy essay on this subject.

Reproduction of Siemens's Unit of Resistance.—M. von Dehms.

Mineralogical Miscellany.—M. von Rath.—*Angles of the Vivianite System.—Chemical Formula of Silicate of Bismuth.* Eulytin contains, in 100 parts :—Oxide of bismuth, 69·38; Silica, 22·23; phosphoric acid, 3·31; peroxide of iron, 2·40; oxide of manganese, 0·30; hydrofluoric acid and water, 1·01; total, 98·63. The specific gravity of this mineral, at 17° C., is 6·106; formula, according to this author—

$$6BiO_2Si_2O_3 + \left\{\begin{matrix}BiO_3\\Fe_2O_3\end{matrix}\right\} PO_4 + BiFl.$$

Crystalline Form of Atelestite.—Labradorite from Närödal, near Gudvangen.—Boulangerite from the Argentiferous Sand near Mayen. This mineral is made up according to the formula $3PbS,Sb_2S_3$, and contains, in 100 parts :—Sulphur, 18·21; antimony, 22·83; lead, 58·96. *—New Crystalline Alloy of Zinc and Calcium.* This alloy contains, in 100 parts :—Zinc, 95·13; calcium, 4·87. Formula, $Zn_{12}Ca$; crystalline form, quadratoctahedron; specific gravity, 6·3726; when in contact with water, hydrogen is at once disengaged by this alloy.

Collections of Meteorites.—M. Buchner.

New Sulpho-Salts.—M. R. Schneider.—Sulphide of potassium and iron, $K_2Fe_2S_4$, in 100 parts :—Potassium, 24·59; iron, 35·19; sulphur, 40·22. Sulphide of potassium and bismuth, $K_2Bi_2S_4$, in 100 parts :—Potassium, 12·57; bismuth, 66·85; sulphur, 20·58.

Galvanic Relations of Palladium.—M. Poggendorff.

Simple Expression for the General Fundamental Principles of Electric Action.—M. Weber.—A mathematical essay.

Galvanic Resistance of Liquids.—M. Paalzow.

Minerals met with in the Baryta-Bearing Gangue of Wittich, in the Duchy of Baden.—M. Petersen.—Analysis of *Wittichenite.* Specific gravity, 4·45. It contains, in 100 parts :—Sulphur, 20·30; arsenic, 0·79; antimony, 0·41; bismuth, 41·13; iron, 0·35; copper, 36·76; silver, 0·15; zinc, 0·13.—*Epigenite.* In 100 parts :—Sulphur, 31·57; arsenic, 12·09; bismuth, 2·12; iron, 13·43; copper, 40·32; traces only of silver and zinc.—*Magnetic Pyrites*, in hornblende. In 100 parts :—Sulphur, 39·93; arsenic, 0·15; lead, 0·10; copper, 0·36; iron, 58·31; nickel and cobalt, 0·63; with traces of titanium, manganese, bismuth, and minute traces of silver.

Specific Gravity of Basaltic Lava.—Dr. A. von Lasaulx.—It appears that this material varies in specific gravity from 1·93 to 2·79. Eight different samples were operated upon, all of which had been previously reduced to a finely-divided powder.

Pharmaceutische Zeitschrift fur Russland, March and April, 1869.

We take these two numbers together, since the leading original paper contained therein is carried through both these numbers. The paper is an essay, bearing the title—

Glycerine: its History, Manufacture, Occurrence, Estimation of Purity, and Various Applications.—J. W. Klever.—Glycerine is met with in some natural oils and fats, also in the products of the vinous fermentation of sugar; hence it is found in wine in small quantity. It does not occur in fats as such by itself; these substances are to be considered rather as ethers. 100 parts of glycerine dissolve of—Arsenious acid, 20 parts; benzoic acid, 20 parts; oxalic acid, 15 parts; bicyanide of mercury, 27 parts; corrosive sublimate, 7·50 parts; alum, 40 parts; arseniate of potassa, 50 parts; sulphur, 0·10 parts; strychnia, 0·25 parts; morphia, 0·45 parts; acetate of morphia, 20·0 parts. The following substances are insoluble in glycerine :—Ether, benzol, camphor, sulphide of carbon, chloroform, the bromide and iodide of mercury, calomel, fatty acids, fatty and ethereal oils. Glycerine is decomposed by chromic acid, bichromate of potassa, and permanganate of potassa.

On the Microscope, and the Discoveries made by it.—M. O. Löwenthal.—This paper contains a short history of the discoveries made by this useful optical instrument, from Antony van Leeuwenhoek's time down to the present age.

Testing Chloroform for the Presence of Alcohol and Ether.—The chloroform should be first treated with fused chloride of calcium, to eliminate any water, next some iodine should be added. If the chloroform is free from either alcohol or ether, the colour produced by the solution of the iodine is bright red; but when either alcohol or ether are present, the colour of the solution is brown. In order to distinguish between alcohol and ether, a small piece of a crystal of fuchsin is added to the chloroform in question; when the slightest trace of

alcohol is present, a deep red solution will ensue. Perfectly pure chloroform yields, with fuchsin, a solution which is only slightly pinkish tinged.

Salt Deposit near Berlin.—M. Jahn.—It appears that there has been discovered near Berlin, at Sperenberg, a rock-salt deposit, which in some localities has a thickness of 669 feet. The locality where this important discovery has been made is within eight miles from the capital city of Prussia, and, from borings instituted, it appears, in every aspect, a highly valuable mineral deposit.

Non-Identity of Caffeine and Theine.—M. Hager observes that, although elementary chemical analysis of these substances yields results which would conclusively prove the identity of these two substances, yet the author found that the physiological effect, after partaking of a dose of 0·25 grm. of both substances, in chemically pure state, and prepared by himself, is by no means the same. The human organism is imbued with testing powers, compared with which chemical reagents are of little delicacy.

On the Ground Nut, Arachis Hypogœa.—M. F. A. Flückiger.—This is a monograph on the subject, and includes the origin, discovery, occurrence, and commercial history of the fruit of a plant belonging to the natural order of the *Leguminosæ*. The fruit is known, in English language, as ground-nut, earth-nut, pea-nut, and manilla-nut; in French as *arachide*, or *pistache de terre*. The plant which yields this fruit is a native of tropical and sub-tropical regions, and belongs especially to Africa. The average weight of the seeds contained in the fruit and bearers of the oil is 0·5 grm.; they yield from 38 to 50 per cent of oil, which consists of a mixture of glycerine compounds and three different fatty acids—arachinic acid, $C_{40}H_{40}O_4$, fusing at 75° C.; hypogœic acid, $C_{32}H_{30}O_4$, fusing at 35° C.; and palmitinic acid, $C_{32}H_{32}O_4$, fusing at 62° C. The seeds contain 28·85 per cent of protein compounds, 13·87 per cent of woody fibre, and 7·16 per cent of gum and sugar.

Sensitiveness of Divers Methods for the Detection of Arsenic.—M. Frank.—Marsh's apparatus admits of detecting 0·0003 milligramme AsO_3, dissolved in 150,000,000 of its weight of liquid; the method of Von Babo and Fresenius admits of detecting 0·002 milligramme AsO_3; Reinsch's method, by means of copper, detects 0·001 milligramme AsO_3, in 5,000,000 as much liquid; Rieckher's method, by means of ammoniacal nitrate of silver solution, detects 0·002 milligrammme in 3,000,000 parts of liquid.

NOTES AND QUERIES.

Rendering Walls Impervious to Damp.—I am at present erecting a new laboratory, and am anxious to get the walls, &c., as impervious as possible to damp. Can any of the readers of the CHEMICAL NEWS tell me what agent is the best to use for this purpose on brick, plaster, and cement? A wash of silicate of soda has been recommended, but I fear the effects of efflorescence afterwards. Would a mixture of silicate of soda with some other agent obviate this? I see several makers of soluble glass advertise in your columns, perhaps they might be induced to answer this question.—BUILDER.

Recovered Grease.—Could any of your readers tell me how to detect recovered grease in tallow.—C. W.

Picrates.—Can any of your correspondents tell me the simplest and cheapest way of making picrate of ammonia and other picrates.—T. E. D.

Scale of Temperatures.—Will any of your numerous correspondents kindly direct me to any good and dependable scale of temperatures at which glasses and metals fuse, comprising all usual silicates of potassa and soda, and such compound metals as have been noted, the object being to obtain a pyrometric guage for temperatures between 900° and 2000° F.—ALFRED PAYNE.

Colour of Vermillion.—It is a fact well known to artists, that the splendidly bright colour of vermillion (cinnabar, sulphide of mercury) has a tendency, especially if it has been mixed with white-lead, to become blackish brown and very dark coloured in a comparatively short time. This tendeney of the vermillion is altogether obviated if, previous to being mixed with oil, it is thoroughly and intimately mingled with about $\frac{1}{4}$th of its weight of flowers of sulphur.

Action of Different Bodies on Sulphuretted Hydrogen.—M. Bœttger remarks that oxide of thallium inflames this gas when coming into contact with it; so do pure peroxide of manganese, peroxide of lead, and peroxide of silver obtained galvanically. With binoxide of barium, chlorate of lead, and chlorate of silver, the gas becomes vigorously inflamed; fulminate of silver also inflames the gas, and the salt explodes. Iodide of nitrogen explodes in contact with this gas, which, under certain conditions, is inflamed by gun-cotton.

MEETINGS FOR THE WEEK.

WEDNESDAY, 16th.—Meteorological, 7. Anniversary Meeting.

THURSDAY, 17th.—Royal, 8.30.

—— Chemical, 8. Inaugural Faraday Lecture by Professor Dumas, in the Theatre of the Royal Institution.

FRIDAY, 18th.—Chemical Society Dinner at Willis's Rooms, at 6.30.

TO CORRESPONDENTS.

*** We shall feel indebted to correspondents who will forward us Reports of Local Meetings of Societies, Chemical Appointments, and any other subjects interesting to the chemical world. We regret that, owing to the increasing popularity and circulation of the CHEMICAL NEWS, and consequent pressure on our space, we are often obliged to delay the publication of long papers. To those correspondents who wish to favour our readers with Notes of New Discoveries, Descriptions of Apparatus, or Answers to Questions, we would especially recommend our Notes and Queries columns.

Professor Attfield's letter shall appear next week.

E. K.—The book is excellent; the price a guinea. Thanks for the notes.

Sulphate of Manganese.—(No. 494, p. 252). A letter is waiting for our querist on this subject.

E. H.—Good medicinal carbolic acid will answer the purpose; add it to the water in which the linen is washed, in the proportion of a teaspoonful of the acid to half a gallon of water.

Messrs. Macniven and Cameron, 23, Blair Street, Edinburgh.—We have received the pens, and like them much. The "Waverley" is as pleasant to use as a quill, while the "Owl" answers well for small, fine writing. The "Pickwick" is also good.

B. B.—We did not speak of the original articles contained in the periodical quoted by you, but only to articles abstracted and translated from other periodicals. We find, on page 308, a paper originally published in June last; several other abstracts are from papers as old as those published in October last year. We will assume your correction of 1868 for 1858 to be correct; but it must be remembered that we do not, unless in special cases, abstract or mention the abstracts from other foreign sources met with in the periodicals we quote. At page 323 is a paper published a year ago at the time the periodical you allude to was issued.

Communications have been received from E. H. von Baumhauer; Macniven and Cameron; Sir William Thompson, F.R.S.; T. Bloxam; E. Kernan; Johnson and Sons; E. Hayes; C. Collins; C. Tomlinson, F.R.S.; C. Williams; A. Payne; R. W. Roberts; H. Fletcher; J. Wallace; E. C. C. Stanford (with enclosure); Mawson and Swan; E. Weston; D. Swan, jun. (with enclosure); H. H. Watson; E. Jones; Dr. R. Angus Smith, F.R.S.; Young and Co.; J. Davis; J. J. Lundy; J. Gregory; J. Riley; W. A. Todd; J. Muspratt and Sons; Kingsbury and Co.; R. D. Grindley; A. Gow (with enclosure); H. Nicol; W. Smith; Evans, Lescher, and Evans; G. G. Walmsley; C. S. Romains; and G. W. Bucklyn.

KERL'S METALLURGY, BY CROOKES AND RÖHRIG.

Vol II., now ready, in 8vo., with 273 woodcuts, price 36s.

Practical Treatise on Metallurgy, adapted from the last German edition of Professor Kerl's "Metallurgy," by WILLIAM CROOKES, F.R.S., &c., and ERNST ROHRIG, Ph.D., M.E. Vol. II. comprising Copper and Iron.

Vol. I., comprising Lead, Silver, Zinc, Cadmium, Tin, Mercury, Bismuth, Antimony, Nickel, Arsenic, Gold, Platinum, and Sulphur, with 207 Woodcuts, price 31s. 6d.

"This seems, in all respects, an admirable work, and will, without doubt, take a high place in technological literature."—AMERICAN CHEMICAL NEWS.

Vol. III., completing the work, is in the press.

London: Longmans, Green, and Co., Paternoster Row.

Chemical Technology, or Chemistry in its Applications to the Arts and Manufactures. By THOMAS RICHARDSON and HENRY WATTS. Second Edition, illustrated with numerous Wood Engravings.

Vol. I., Parts 1 and 2, price 36s., with more than 400 Illustrations.

Nature and Properties of Fuel: Secondary Products obtained from Fuel: Production of Light: Secondary Products of the Gas Manufacture.

Vol. I., Part 3, price 33s., with more than 300 Illustrations.

Sulphur and its Compounds: Acidimetry: Chlorine and its Bleaching Compounds: Soda, Potash: Alkalimetry: Grease.

Vol. I., Part 4, price 21s., 300 Illustrations.

Aluminium and Sodium; Stannates, Fungates, Chromates, and Silicates of Potash and Soda: Phosphorus, Borax: Nitre: Gun-Powder: Gun Cotton.

Vol. I., Part 5, price 36s.

Prussiate of Potash: Oxalic, Tartaric, and Citric Acids, and Appendices containing the latest information and specifications relating to the materials described in Parts 3 and 4.

Vol. II., price 21s.

Glass, Clay, and Limes.

Vol. III., on Food, Sugar, &c., is at present out of print.

H. BAILLIERE, 219, Regent Street, London.

THE CHEMICAL NEWS.

VOL. XIX. No. 498.

RESEARCHES ON GASEOUS SPECTRA

IN RELATION TO THE PHYSICAL CONSTITUTION OF THE SUN, STARS, AND NEBULÆ.*

By E. FRANKLAND, F.R.S., and J. N. LOCKYER.

I. THE Fraunhofer line in the solar spectrum, named *h* by Angström, which is due to the absorption of hydrogen, is not visible in the tubes we employ with low battery and Leyden-jar power; it may be looked upon, therefore, as an indication of relatively high temperature. As the line in question has been reversed by one of us in the spectrum of the chromosphere, it follows that the chromosphere, when cool enough to absorb, is still of a relatively high temperature.

II. Under certain conditions of temperature and pressure, the spectrum of hydrogen is reduced in our instrument to one line in the green, corresponding to F in the solar spectrum.

III. The spectrum of nitrogen is similarly reducible to one bright line in the green, with traces of other more refrangible faint lines.

IV. From a mixture of the two gases we have obtained a combination of the spectra in question, the relative brilliancy of the two bright green lines varying with the amount of each gas present in the mixture.

V. By removing the experimental tube a little further away from the split of the spectroscope, the combined spectrum was reduced to the two bright lines.

VI. By reducing the temperature, all spectroscopic evidence of the nitrogen vanished; and, by increasing it, many new nitrogen lines make their appearance, the hydrogen line always remaining visible.

The bearing of these latter observations on those made on the nebulæ by Mr. Huggins, Father Secchi, and Lord Rosse is at once obvious. The visibility of a single line of nitrogen has been taken by Mr. Huggins to indicate possibly, first, "a form of matter more elementary than nitrogen," and which our analysis has not yet enabled us to detect†; and then, secondly, "a power of extinction existing in cosmical space."‡

Our experiments on the gases themselves show not only that such assumptions are unnecessary, but that spectrum analysis here presents us with a means of largely increasing our knowledge of the physical constitution of these heavenly bodies.

Already we can gather that the temperature of the nebulæ is lower than that of our sun, and that their tenuity is excessive; it is also a question whether the continuous spectrum observed in some cases may not be due to gaseous condensation.

ON THE ELECTROLYSIS OF NITRATES.

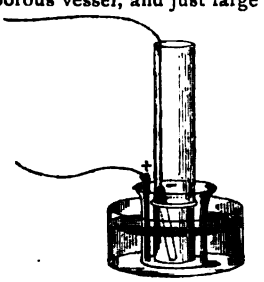
By THOMAS BLOXAM,
Lecturer on Chemistry, Cheltenham College.

THE conversion of nitric acid into ammonia by the well-known method of boiling with zinc, iron, and potash, practised by Mr. Harcourt, suggested the idea of such conversion being possible with the hydrogen furnished by means of electrolysis. An experiment of the following nature proved the possibility in a qualitative sense:—Into a small porous earthern cylinder, 1 inch in diameter and 1½ inches high, was placed a little dilute nitric acid the negative pole of a three-cell arrangement of Bunsen's battery was introduced, and the vessel placed in a small beaker, containing dilute nitric acid and the positive pole of the battery.

The liquid was withdrawn from the cylinder in about half-an-hour, and the usual test of boiling with excess of potash was tried, when the ammonia was easily detected by the odour and its action upon test-paper.

Nitrate of potassium was substituted for the dilute nitric acid in the porous vessel: ammonia was easily detected in this case also. Nitrate of potassium solution was acidulated with hydrochloric acid, and submitted to voltaic action for an hour. The solution was mixed with bichloride of platinum, and evaporated to dryness, when a fair amount of the double chloride of platinum and ammonium was obtained. This precipitate was examined, and found to be entirely pure.

The question then suggested was, whether any quantitative result could be obtained. For this purpose, the porous cylinder used in the previous experiments was cemented to a glass tube, of the same diameter and 6 inches long, in order that any splashings caused by the escaping bubbles of gas should not cause an error. The compound tube was placed in a beaker, high enough to take the porous vessel, and just large enough to admit the positive pole. The tube and beaker were placed in a moderately large vessel of cold water, to keep down the temperature, which, in a previous experiment, had softened the cementing material joining the tube and porous vessel. The arrangement is represented in the figure. A weighed amount of pure nitrate of sodium was placed in the porous vessel, and submitted to electrolysis, the ammonia being estimated as the double chloride of platinum and ammonium.



From a considerable series of experiments, the amount of double chloride yielded was found to be below the calculated result. Several modifications were then tried; such as dropping the solution of the nitrate very slowly upon the negative pole, elevation of the temperature both of the solution and of the battery; reduction of the resistance offered to the voltaic battery. It is to be regretted, however, that, in spite of a fairly extensive series of experiments with these various modifications, I have only succeeded in converting half the nitrate into ammonia. It has been also proved that no loss of liquid takes place through the porous vessel.

I have been induced to make known these results with the hope of obtaining some suggestion which may solve the difficulty of the non-conversion of the other half of the nitrate.

ON THE

ACTION OF HYDROCHLORIC ACID ON MORPHIA.*

By AUGUSTUS MATTHIESSEN, F.R.S.,
Lecturer on Chemistry in St. Bartholomew's Hospital,
and C. R. A. WRIGHT, B.Sc.

WHEN morphia is sealed up with a large excess of hydrochloric acid, and heated to 140°—150° for two or three hours, on opening the tubes after cooling no gas is found to have been formed, nor is there any formation of chloride of methyl. The residue in the tube contains the hydrochlorate of a new base, differing considerably in its properties from morphia. It may be obtained in a state of purity by dissolving the contents of the tube in water,

* Abstract of a paper read before the Royal Society, June 10th, 1869.

adding excess of bicarbonate of sodium, and extracting the precipitate with ether or chloroform, in both of which the new base is readily soluble, whilst morphia is almost insoluble in both menstrua. On shaking up the ethereal or chloroform solution with a very small quantity of strong hydrochloric acid, the sides of the vessel become covered with crystals of the hydrochlorate of the new base. These may be drained from the mother liquors, washed with a little cold water, in which the salt is sparingly soluble, and re-crystallised from hot water and dried on bibulous paper or over sulphuric acid.

This hydrochlorate contains no water of crystallisation. After drying in the water-bath, it yielded results on combustion with chromate of lead and oxygen agreeing with the formula $C_{17}H_{17}NO_2HCl$.

From a solution of the hydrochlorate in water, bicarbonate of sodium precipitates a snow-white non-crystalline mass, which speedily turns green on the surface by exposure to air, and is therefore difficult to obtain dry in a state of purity. This precipitate is the base itself.

It hence appears that the new base is simply formed from morphia by the abstraction of the elements of water.

Morphia. New base.

$$C_{17}H_{19}NO_3 = H_2O + C_{17}H_{17}NO_2,$$

We propose to call the new base apomorphia, for reasons given subsequently.

When the hydrochlorate of apomorphia in a moist state is exposed to the air for some time, or if the dry salt is heated, it turns green, probably from oxidation, as the change of colour is accompanied by an increase of weight. The base itself, newly precipitated, is white, but it speedily turns green on exposure to air. The green mass is partly soluble in water, communicating to it a fine emerald colour—in alcohol yielding also a green tint, in ether giving a magnificent rose-purple, and in chloroform with a fine violet tint.

The physiological effects of apomorphia are very different from those of morphia; a very small dose produces speedy vomiting and considerable depression, but this soon passes off, leaving no after ill effects,—facts of which we have repeatedly had disagreeable proof while working with it.

Dr. Gee is now studying these effects, and has found that 1-10th of a grain of the hydrochlorate subcutaneously injected, or ½ grain taken by the mouth, produces vomiting in from four to ten minutes. Our friend Mr. Prus allowed himself to be injected with 1-10th grain, which produced vomiting in less than ten minutes. From Dr. Gee's experiments on himself and others, he concludes that the hydrochlorate is a non-irritant emetic and powerful antistimulant. As from these properties it appears probable that it may come into use in medicine, we have called it apomorphia, rather than morphinine, to avoid any possible mistakes in writing prescriptions.

CONTRIBUTIONS TO ANALYTICAL CHEMISTRY.*

By DR. E. FLEISCHER, of Dresden.

Estimation of Baryta, Strontia, and Lime.

The estimation of these three alkaline earths is generally effected after they are separated from each other. These separations can be dispensed with if the indirect method be employed, thereby avoiding the loss attendant upon different separations, and materially hastening and simplifying the whole estimation. The following indirect method, which has proved to be the most preferable for the estimation of these three bases, may also be employed in the presence of magnesia. In the first place, the lime, strontia, and baryta, must be precipitated as carbonates, by means of carbonate of, and caustic, ammonia. The following is worthy of remark:—It is well known that, in a liquid containing much sal-ammoniac or nitrate of ammonia, neither lime, strontia, nor baryta will be completely precipitated by carbonate of ammonia; so that, after filtering, it is possible, by means of sulphuric acid or oxalate of ammonia, to recognise a more or less considerable quantity. The cause of this phenomenon is, that ammoniacal salts of strong acids have a solvent action upon carbonate of lime, which effect is still stronger upon carbonates of strontia and baryta. Should, on the other hand, acetate or carbonate of ammonia be used, instead of sal-ammoniac or nitrate of ammonia in solution, the precipitation of the three bases by carbonate of ammonia will be so complete that it will be impossible to discover in the filtrate, by means of the before-mentioned reagents, any traces of lime, strontia, or baryta.

In order to have in solution no other ammoniacal salts than acetate and carbonate of ammonia, it will suffice to add to the tolerably neutral solution as much acetate of soda as there is supposed to be sal-ammoniac or nitrate of ammonia held in solution, and then to supersaturate with ammonia and carbonate of ammonia, and, after a short digestion, to cool the solution: the carbonated alkaline earths which have in this manner been completely precipitated are now filtered off.

Digestion is not absolutely necessary here; it only serves to render deposits granular, which would otherwise be voluminous. On the other hand, in order to obtain complete precipitation, it will be necessary to reduce the whole to the ordinary temperature before filtering, because hot acetate of ammonia has a solvent action upon carbonated alkaline earths, although in a far less degree than sal-ammoniac.

A certain degree of dilution of the ammoniacal salt is to be recommended; in any case, the solution must not be more concentrated than in the proportion of one salt to twenty water. According to rule, I manage so as to dilute the digested mass with its own volume of distilled water, allowing it to cool still further before filtration.

The carbonate of soda may be substituted for the acetate, in order to decompose the sal-ammoniac; but if, at the same time, magnesia be held in solution, the presence of much salts of ammonia, with stronger acids than carbonates, will be necessary, in order that it may not be deposited with the alkaline earths. For this purpose, the addition of acetate of soda is eminently suitable; because the acetate of ammonia thus formed (as with oxygenated salts of ammonia generally) prevents the precipitation of the magnesia much more than sal-ammoniac does, without, as before remarked, dissolving baryta, strontia, or lime.

In the presence of magnesia, a too great excess of carbonate of ammonia must be avoided as a reagent, in order to hinder the formation of ammoniacal carbonate of magnesia, which is difficult to dissolve. After these precautionary measures, the baryta, strontia, and lime having been separated (also from magnesia, if such be present), the deposit is washed, filtered, dried, heated, and weighed; it is then dissolved in a measured quantity of normal muriatic acid and estimated. This is done, after removing the carbonic acid by digestion, from the diluted solution (which is coloured with litmus), by estimating with one-half normal ammonia the amount of muriatic acid which had been required to transform the three carbonated salts into chlorides. The solution is now mixed with bichromate of potash and caustic ammonia in excess, to precipitate all baryta, so that no trace of it may be detected in the acidulated filtrate, by fluo-silicate of potash and spirit of wine.* The chromate of baryta is filtered off, and washed until sugar of lead ceases to give a yellow precipitate in the solution which runs through; to this chromic acid is now added, according to the known pro-

* Communicated by the Author.

* Pure chloride of barium solution, also, produces no turbidity when, after the precipitation of baryta by chromate of potash and ammonia, the filtrate is mixed with sulphuric acid. It is, of course, understood that the reagents employed in precipitation are quite free from sulphuric acid.

cess, together with a measured quantity of a standard solution of green vitriol; and the amount of baryta is then obtained, according to the formula—

$$CrO_3 \times 1{,}527 = BaO,$$
$$\text{or } CrO_3 \times 1{,}964 = BaOCO_2.$$

If, on the one hand, the amount of carbonate of baryta thus obtained be deducted from the weight of the three carbonates, and, on the other, the amount of muriatic acid answering to the baryta be calculated, the difference between this amount of HCl and the amount found will be the quantity of muriatic acid which corresponds to the united weight of CaO,CO_2 and SrO,CO_2, which has just been calculated. The amount of carbonate of lime and carbonate of strontia is obtained as follows:—

Calculate the amount of carbonate of lime which is equivalent to the known quantity of HCl contained in the excess of $CaOCO_2$, and $SrOCO_2$; deduct this from the weight of the two carbonated salts, and multiply the remainder by the constant factor $3_{11}^{1}{}_{8}$ and the product will then be the required quantity of $SrOCO_2$; this, when again subtracted from the united weight of both salts, yields, as its remainder, the quantity of carbonate of lime. The constant factor, $3_{11}^{1}{}_{8}$, may be obtained by the following calculation:—

	$CaOCO_2 =$	50
	$SrOCO_2 =$	74
	$CaOCO_2 + SrOCO_2 =$	124
hence	$2CaOCO_2 =$	100

and the remainder, 24, in the equivalent of $SrOCO_2$, equal to 74, yields, when divided, $S = \frac{74}{24} = 3_{11}^{1}{}_{8}$.

This method of estimating these three alkaline earths always yielded very satisfactory results. One advantage is that it is quickly carried out and also very exact, because the precipitations will be all perfect, and the two volumetric estimations involved in the method admit of great exactitude. Moreover, the troublesome and somewhat uncertain separation of the strontia and lime with a concentrated solution of sulphate of ammonia is avoided, and which is very inconvenient in estimating the lime. In the absence of strontia, I either precipitate the lime and baryta as carbonates,* estimating the precipitate alkalimetrically; or I precipitate the baryta as sulphate, the lime as carbonate, by digesting the solutions of both with a mixture of three parts of sulphate of potash and one part of carbonate of potash; weigh the dried and ignited precipitate, and estimate the carbonate of lime alkalimetrically.

A CHEMIST'S VIEW OF THE SEWAGE QUESTION.†

By EDWARD C. C. STANFORD, F.C.S.

(Continued from p. 270.)

No. II.

ABOUT twelve months ago, I read a paper on this subject before the Sewage Association of Glasgow; since then, the members of that association, with all their varieties of opinion, have passed one unanimous resolution—that, whatever system be adopted, the excreta must be kept out of the public sewers, the expression of a conviction which will be that of any patient enquirer into this difficult question.

In the paper referred to, I endeavoured to show that, whatever may be the best, the present water-closet system, with all its boasted advantages, is the worst that can be generally adopted; briefly, because it is a most extravagant method of converting a mole-hill into a mountain. It merely removes the bulk of our excreta from our cities, to choke our rivers with foul deposit, and rot at our neighbours' doors. It increases the death-rate, as well as all other rates, and introduces into our houses a most deadly enemy, in the shape of the sewer gases.

Since then, the report of Messrs. Bateman and Bazalgette has appeared, and it proposes (what every one knowing the views of the authors would at once have predicted) to put down miles of costly sewers to carry the excreta to the Ayrshire coast, where, perhaps, the inhabitants may oblige us to take it back again; in other words, to commit the error of London, and wake up in a few years to the same bitter repentance.

We cannot be surprised at this; we cannot expect homœopathic treatment from an allopathic physician, especially if, as in this case, "bleeding" is to be again the universal cure. The engineer's treatment of town excreta always reminds me of the country doctor in America, who put all his feverish patients through a course of convulsions, because, though he didn't understand *fevers*, he *could* cure *fits*. In our numerous discussions, I have always maintained that chemists have been most unfairly treated in this matter. The public like to see what they pay for; they can see bricks and mortar, and therefore have allowed engineers to give them an intimate pocket-purse knowledge of this expensive commodity, for which they have paid in more than one sense—through the nose. Engineers have too fondly believed that water is the great purifier, and so they dilute the excreta with 365 times its bulk of water, and reduce its value to 1d. per ton, and then turn round on the chemist and expect him to reverse the process, pick out the penny, and repay the expenditure. Now, if it were a simple mixture—if it were only to separate the grain of wheat from the sack of chaff—the problem would be difficult enough; but we know the case to be far worse than this—it is the handful of yeast in the sack of flour that we are called upon to extract, and the fermentation of which we are expected to prevent, *after* it has occurred. A small portion of dilute sewage, mixed with a large excess of water, soon renders it all equally offensive, and the problem of extracting its value is one which no chemist need ever attempt to solve.

The water-closet, with many apparent advantages, and with all our prejudices in its favour, carries an attendant train of evils, which I am fully persuaded will ultimately doom it to oblivion.

As, therefore, engineers have not put the subject fairly before chemists, I propose to take a noble revenge, and put the subject fairly before engineers. I ask them why they consider water to be the only vehicle for removing excreta?—why not earth?—why not air? Have they ever fairly investigated or thoroughly experimented on the other methods? Have they not rather confined their studies to *fits*, and forgotten *fevers*?

So many attempts have been made by chemists to pick up the halfpence that engineers have so plentifully flung into the mud, that I cannot even notice them, except to remark that, in the opinion of all the scientific chemists who have specially investigated these attempts, they have all signally failed.

I must allude, however, to the process of Mr. Chapman, as one of the latest methods of dealing with town sewage; this is a process of distillation, after treatment with lime and thorough putrefaction. He, however, confesses his difficulty, by wishing to reduce the sewage of this city from 31,000,000 gallons to 1,000,000 gallons daily. This, of course, requires a complete alteration in the existing system, and it still dilutes the excreta with more than ten times its bulk of water. The lime process, and the putrefaction required to decompose the urea, would be extremely offensive, and require vast storing tanks. In working 1,000,000 gallons daily (it would more probably amount to 2,000,000 gallons); he would have to treat 4464 tons daily, the total chemical (not the extractible) value of which is 2s. 6d. per ton; and he expects to do this with 20 tons of coal. He proposes to adopt an ingenious arrangement of eight boilers, steaming exhaus-

* Especially when mangnesia is present.

† Read before the Chemical Section of the Glasgow Philosophical Society, April 19th, 1869.

tively, to distil off the ammonia, heating up the feed sewage, after precipitation by lime, by the hot water discharged from the boilers by a kind of brew-house refrigerator with its object reversed. He expects to distil off 1-12th; but I think it must be at least 1-10th, or 100,000 gallons, evaporated by 20 tons of coal = 5,000 gallons to 1 ton. The report of Professors Lyon Playfair and Johnstone puts the average evaporation for Scotch coal at 7·7 tons, or 1712 gallons per ton, and at this rate 58 tons would be required for the mere evaporation. Then, for raising the heat, the same report says that 1 ton of Scotch coal raises 56 tons of water from 32° to 212° F., or, say, 50 tons of water from 52° to 212° F., requiring, therefore, 96 tons for heating up, making a total of 148 tons a day. Mr. Chapman, therefore, expects to save, by heating feed water, and by exhaustive steaming, a total of 128 tons of coal daily, or 600 per cent. Can this be done? If it can, then whatever may be the result of his process, as applied to sewage, it will make him the greatest and most daring authority on that equally important subject, the economy of fuel. He puts down no loss for radiation. This should, I think, be at least 10 per cent, which would require nearly as much as his total calculated expenditure for fuel. In using eight boilers, of 4,000 gallons each, he expects to get off all the ammonia in half an hour's steaming. Now, we all know that the estimation of free ammonia in the laboratory is one of the most tedious processes, requiring a long-continued ebullition, and the experience of distillers, on the large scale, amply corroborates this, and proves that it does not pay to distil liquors containing under 1 per cent of ammonia (some manufacturers double this estimate). The total amount in the sewage to be distilled would be under 0·2 per cent; I think, therefore, that the process of Mr. Glassford, of evaporation with sulphuric acid (for which I must refer you to his pamphlet on London sewage), is better than this; fuel is the great question in both, but in his the results are certain, in Mr. Chapman's they are problematical.

Both are, however, connected with the water system, which I believe to be a mistake, and I think we must ultimately come, either to a system like Capt. Liernur's, by what may be called pneumatic despatch, or to the dry-closet system. Of the former I have fully treated in a former paper, and wish now to speak more particularly of the latter. During the past year, Moule's dry-closet has been largely introduced; all who have used it speak in the highest terms of its efficiency, and there are already strong indications of its becoming the system of the future. It is the only system that has succeeded during the hot fortnight at the Wimbledon meeting; and it is particularly adapted to hot climates, where the evils of the water-closet are most conspicuous. The objections urged against the system, when earth is used, are—1st, the large quantity of earth required—three and a half times the weight of the excreta; and, 2nd, the difficulty of obtaining the quantity required, and of drying it. Now, both these difficulties are disposed of by using charcoal. I employ, by preference, sea-weed charcoal, because it is the most porous, the best absorbent, and the cheapest. It only requires one-fourth of the weight, compared to earth; and when the mixture is removed and placed under cover, it soon dries. This mixture can be stored for any length of time, and used again several times. When convenient, it is re-burned, like the char in sugar refineries, except that this process is carried out in apparatus which admits of collecting the ammonia and other products condensed. The whole of the ammonia is thus collected; whilst the phosphoric acid, potash, and mineral matters accumulate in the charcoal, together with the carbon from the organic constituents of the excreta. The weight of the charcoal is increased to the extent of about 5 per cent with each using, and, if dried and re-used five times, about 25 per cent with each re-burning. With this constant addition, the char does not require replacing with fresh material, so that its cost is only a primary outlay—the ultimate result being that the excreta is deodorised by a charcoal derived from itself, and a company working this process would, in addition to securing the whole of the ammonia, become sellers of a charcoal second only in value to that from bones to the extent of, in Glasgow, if the process were general, 19 tons a day, or 6,935 tons a year; the total quantity of excreta which Glasgow has to remove being 385 tons a day, and its value, at 29s. 6d. per ton, = £569.* The ultimate result being the same, any charcoal may be used at first. The process is carried out without odour, from the closets to the finished products. Of course the process may be modified; for instance, suppose the char to be used five times, and only dried, the addition to its value would be as follows (I take equal parts, as this charcoal will absorb at least an equal weight of even urine):—

1 ton seaweed char, at £2 } = 30 cwts. manure at £9 7s. 6d.
5 tons excreta, at 29s. 6d. } = £6 5s. per ton.

Or, if re-burnt, it would yield 25 cwts. of charcoal, and the whole of the nitrogen would pass over in the distillation, as ammonia. Dr. Wallace estimates the cost of re-burning char in sugar refineries at 3s. 6d. per ton for labour and fuel, containing 31 per cent moisture, which would be much over that referred to. Here, then, we have a simple process for recovering the whole of the value from excreta, of general application, and the results of which can be predicted by chemists with absolute certainty, as far as those products to which we at present attach value are concerned; but the uncertain portion is, as usual, the most interesting, for in the destructive distillation of excreta we are exploring a new field, which promises great interest.

I regret that I am obliged to bring this paper forward before the new products have been studied. The distillation generally is remarkably similar in its products to that of bones, and also to that, which most resembles it, of sea-weed. Besides ammonia, acetic acid, with a little butyric acid, acetone, and pyrrol are the most marked bodies. I cannot speak more definitely of these products in this paper, as they are still under investigation. The following analysis of urine is taken from Miller, representing the average composition in 1,000 grs., sp. gr. 1·020. The calculated percentage of nitrogen is appended:—

			Nitrogen.	In 100 parts of solid matter.	Nitrogen.
Solid Matter, 43·20.		Water	956·80		
	Organic, 29·97.	Urea	14·23	6·64	33·00	15·40
		Uric acid	0·37	0·12	0·86	0·27
				6·76		15·67 = 9 NH_3, 19. Sulphate of ammonia, 75·72.

		Soda	0·05		0·12	
			999·94		100·00	

= 1·36 NH_3, 8·2. Sulphate of ammonia, 31·86, or 3·18 per cent.

The average portion voided by each individual may be taken at 40 ozs., and of fæces, 4 ozs., total 44 oz. daily; or, 1·7 ozs., solid, from urine, and 1 oz., solid, from fæces = total of 2·7 ozs. solid excreta daily. The following analysis of the fæces is from Berzelius:—

Water		75·3	
Bile	0·9	5·7	Solid matter, 24·7.
Albumen	0·9		
Extractive matter	2·7		
Salts	1·2		
Insoluble residues of digested food		7·0	
Insoluble matters added in intestinal canal—mucus, biliary resin, and peculiar animal fat		12·0	
		100·00	

Containing, according to Playfair—
15 p.c. nitrogen, and 45 p.c. carbon, and about 25 p.c. ash.
= nitrogen 3·75 p.c.
= 4·55 NH_3.
= 17·65 p.c. sulphate of ammonia.
= 70·71 in dry solid matter.

* Value given in my former paper.

The ash contains, according to Porter:—

	Ash of Fæces.	Ash of Urine (calculated).
Chloride of sodium	1·33	54·15
Phosphoric acid	36·03	15·89
Sulphuric acid	3·13	12·73
Lime	26·46	1·57
Magnesia	10·54	0·89
Potash	6·10	14·45
Soda	5·07	0·38
Peroxide of iron	2·50	—
Carbonic acid	5·07	—

Assuming, then, the proportions voided to be in the proportion of 17 dry, from urine, to 10 dry, from fæces, the resulting chars may be expected to have the following composition:—

	Urine.	Fæces.	Mixed Excreta.
Percentage of char in dry solid matter	50	70	57
Ammonia = sulphate	73·72	70·71	72·60

COMPOSITION OF CHARS.

	Per cent.	Per cent.	Per cent.
Carbon	33·33	45·00	37·65
Chloride of sodium	36·10	0·33	9·51
Phosphoric acid	10·60	9·01	10·01
Sulphuric acid	8·49	0·78	5·63
Lime	1·05	6·61	3·11
Magnesia	0·60	2·63	1·35
Potash	9·64	1·52	6·63
Soda	0·26	1·26	0·63
Peroxide of iron	—	0·62	0·23
Carbonic acid	—	1·26	0·46

The nitrogen in the mixed excreta, in the proportions voided, is equal to 4·49 per cent of sulphate of ammonia.

In the char from urine, the phosphoric acid is principally combined with potash, and therefore soluble. This char alone would be a valuable manure as containing a large proportion of soluble phosphates; but the result of commencing with seaweed charcoal, which is rich in carbonate of lime, will be to form phosphate of lime at the expense of the carbonate—in other words, to form, by treatment with urine, re-burning, and washing, the animal charcoal required by the sugar refiner. This expected result is verified in the following tables of analyses. I regard the phosphate of lime thus gradually formed, from its minute state of division, to be quite equal, in agricultural value, to ordinary soluble phosphate. The washed residual char from fæces is at once available for the refiner, as it contains about 26 per cent of phosphates of lime and magnesia, with but a small proportion of carbonate. I know no reason why the product of disintegrated bone and muscle should not be used for this purpose as well as the bones themselves.

In distilling 100 tons of the dry product from mixed excreta, therefore, we should obtain 72 tons of sulphate of ammonia, and 57 tons of a charcoal containing 10 per cent of phosphoric acid in its most available form for manure, and 6 per cent of potash. It will be seen, from Berzelius's analysis, that nearly 50 per cent of the fæces consist of fatty matter—how will this appear in the distillation? In a population of 500,000, this item amounts to nearly 7 tons a day!

I expected a loss of ammonia in drying, but it is very small, and appears to arise from the free lime in the char, as it will be seen further on that the loss decreases in using the char with urine. In a small experiment with urine, I found the total loss, in drying by artificial heat with new char, to be 2·06 per cent of the ammonia, or 0·105 per cent of the urine employed.

I append analysis of 1 lb. of char which was re-burnt fifteen times with an equal weight of urine; a portion of the char was lost, which prevents my giving the increase in weight; I believe, however, the addition of carbon would be too slight to effect an increase in the total, with so many re-burnings. The percentage is decreased:—

	Char used.	After re-burning.	Increase per cent.
Water	10·0	2·80	—
Soluble salts	0·6	11·15	10·55
Insoluble	89·4	86·05	—
Soluble.			
*Chloride of sodium	—	8·75	8·75
Sulphuric acid	0·3	0·34	0·04
Phosphoric acid	—	2·00	2·00
Potash	0·3	2·40	2·10
Insoluble.			
Carbon	54·4	29·40	—
Silica, &c.	9·1	13·10	4·00
Phosphate of lime	4·8	20·05	15·25
Carbonate of lime	17·4	19·75	2·35
Carbonate of magnesia	3·4	3·40	—

The urine used appears to have been deficient in sulphates and high in phosphates, these two ingredients being subject to considerable relative variation. The distillates gave 192 ozs. liquid, containing free ammonia equal to 3,047 grs. sulphate, or 2·9 per cent of the urine, showing a slight loss, inseparable from destructive distillations on the small scale. The charcoal should be used at least five times before re-burning, and for urine alone it may be employed ten times. I append a table, showing the analytical results of this process with urine:—

* In this and the following analyses, the whole of the chlorine has been calculated, for convenience, as chloride of sodium, which, in some cases, is therefore too high.

	Increase, per cent.				Increase, per 1,000 grs. of Urine.			
	1.	2.	3.	4.	1.	2.	3.	4.

* Decrease.

No. 1 is from charcoal dried up with ten times its weight of urine before re-burning; No. 2 has been treated with twenty times its weight, No. 3 with fifty times its weight, and No. 4 with 100 times its weight of urine before re-burning. It will be seen, that in No. 4 more than the theoretical amount of ammonia is obtained; that from Nos. 1, 2, and 3 are obtained by simple destructive distillation. No. 4 only yields ammonia equal to 50·48 per cent of sulphate when heated in this way, the quantity given, 105·64 per cent, being that obtained with soda-lime; the residual nitrogen is not left in the char, but goes off in the distillation in some other form than ammonia. I shall recur to this subject in a subsequent paper. The retention of nitrogen after drying is, however, extraordinary, when the product yields ammonia equal to 105 per cent of sulphate. No Peruvian guano can be compared to this in fertilising value.

The washed chars acquire the composition which fit them eminently for the sugar refiner.

The experiments with closet excreta are unfinished, and it is difficult, in working on small quantities, to obtain uniform results. We find one of Smith's dry-closets use ½ lb. of seaweed char per charge, the charge of dry earth being 2 lbs. Moule's closet uses rather less. There were seven uses in our first experiment, the contents of the pail being re-burnt at once, without drying.

Weight before distillation .. .. 130 ozs.
Residual char weighed .. .. .. 48 ,,
Weight of excreta 82 ozs.=11·7 ,, per use.

The distillation gave 66 ozs. of gas liquor containing free ammonia=2·8 ozs. sulphate=3·4 per cent of mixed excreta; this represents only the free ammonia, or that existing as carbonate, a portion is combined with acetic acid, which was not estimated.

The same method is equally well adapted for treating pot ale from distilleries, and blood and offal from slaughter-houses. The former is an important subject in Glasgow, and I can, in this paper, only shortly allude to it. According to Dr. Wallace, one of the distilleries in Glasgow sends into the sewers 83,000 gallons of this pot ale, containing nitrogen equal to 118 grs. of ammonia per gallon; so that the daily discharge of this one distillery is equal to the total excreta of 48,970 persons, or one-tenth the population of Glasgow.

The process can be adapted with ease to urinals as well as closets. I am enabled to exhibit some mixtures of charcoal and night soil made twelve months ago. I was curious to know if these mixtures had gone further in the oxidation of the ammonia, and formed some nitrates, but not a trace can be detected.

I submit that the dry-closet system, with this process, has the following great avdantages:—

1. Total freedom from all odour. All must have noticed sometimes the sickly odour of a water-closet, arising, not from the excreta, but from the gas from the sewers.

2. Certain prevention of all contamination and spread of infectious diseases arising from sewer leakage into our wells or sewer gas into our houses.

3. Saving of water, equal, in Glasgow, to £40,000 a year, if the water-closet system were general.

4. Saving of expense in repairs and removal. 1 cwt. of charcoal per month is sufficient for each closet when used by six persons daily, and the whole may be allowed to fall at once from the closet, through a 12-inch pipe, to a cesspit below the house. A cess*pool* is a serious evil, but I know of no evil to a cess*pit*.

5. By this process alone can the whole of the valuable material be recovered for our lands.

Dr. Fergus has shown some remarkable examples in which gastric fever has been traced to the escape of sewer gas through small openings eaten through the top of the soil-pipe. This appears to be a wide-spread evil. I have examined some of these specimens, and find the substance to be a sort of lead plaster, containing, also, lime and some fatty acid, which requires further examination. I have shown that only remedial measures can be adopted, where the water-closet system has been carried out, by placing boxes of charcoal in the closets, and filtering the sewage through charcoal before allowing it to enter rivers.

Our authorities want, of course, some grand scheme; but they forget that the question is one of minute details. We are assailed by a large army of small nuisances—one, at least, to every house, and we must attack them one at a time. Attacked in their united strength, they will assuredly overcome us. Ought we not rather to strike at the root of the evil? Ought we not to stop the mischief at its numerous sources, and before these can combine into a mighty force, which carries everything before it?

Let the subject be calmly and carefully discussed; let us not be carried away by great schemes and useless expenditure; let us not leave to posterity heavy taxes, with barren wastes and desolate cities, but let us rather pay our own way, and leave our country fertile and our towns pure, and I shall never regret that, however imperfectly this subject has been brought before you, my earnest wish has been to strike "one more blow for life."

A lively discussion followed the reading of the paper, the general opinion of the members of the section being highly favourable to the process, which was considered the most novel and practical which has yet been introduced.

NOTICES OF BOOKS.

Proceedings of the American Association for the Advancement of Science; Sixteenth meeting, held at Burlington, Vermont. Cambridge, U.S.: J. Lovering. 1868.

IT will be new to some of our readers to hear that there exists an American Association for the Advancement of Science, corresponding to our British Association, and that the meeting which is chronicled in the work we are about to discuss is the sixteenth meeting of that association. The institution and support of such an association indicates a zeal for science among our American brethren which is surely a good omen, and a healthy sign of the times. Nothing more conduces to the spread of a love for science, and to the diffusion of scientific knowledge, a tutored scientific taste, and a *modus* of scientific thought, and nothing more encourages original research, than the banding together of scientific men for the one purpose of furthering each his individual study and pursuit. And what greater proof of this can be needed than that which Europe furnished in the seventeenth century? The downfall of Aristotelianism, and the consequent spreading love for the "new philosophy," did not culminate in, but almost started with, the rise of numerous scientific societies—the Accademia del Cimento, the Royal Society, the Collegium

Curiosum, and the Académie des Sciences, all appeared in less than half a century after the death of Bacon and Galileo. A period of great intellectual activity exists not without the blossoming and blooming of such institutions, and they react upon the period, and induce in it a greater charge of intellectual vigour. In a country like America, mighty in great works, the effect of such an association, if well supported, ought to be immense. We say "mighty in great works," because the opening of the Pacific Railway is yet in our minds, and, if there had not been some hundreds of eighth wonders of the world since the hanging gardens of Babylon were, with her "Babylon magna, mater fornicationum et abominationum terræ," razed to the ground, and since the Rhodian Colossus was broken up and sold as old brass, we think the Pacific Railway would be that eighth wonder. Perhaps the only work to be compared with it for extent and magnitude is that other among the ancient (and modern) wonders of the world, the Great Wall of China; let us, however, remember that the Suez Canal and the Mont Cenis Tunnel are approaching completion, and will soon have to be placed in the same category with the Pacific Railway. But we are plunging into a theme which, if extended, will bear us far from our present subject.

The subjects which engage the attention of the American Association for the Advancement of Science are thus divided:—A. (1) Mathematics and Astronomy; (2) Acoustics; (3) Physics and Chemistry; (4) Physics of the Globe (or, as we usually say in this country, Meteorology). B. (1) Geology and Mineralogy; (2) Palæontology; (3) Zoology.

The Association possesses a President, Vice-Presidents, Standing Committees, and Local Committees; and it appoints special committees for the discussion of special subjects. Among the latter we notice "a Committee to report in relation to uniform standards in weights, measures, and coinage." The address of the President (Professor J. S. Newberry), although short, gives a fair *resumé* of the dominant subjects of the day, in regard to both the philosophy of matter and the philosophy of mind.

The first paper which calls for our notice is by C. S. Lyman, of New Haven (Conn.), "*On a New Form of Wave Apparatus.*" It is designed to illustrate waves whose "type is the ordinary ocean wave in deep water. The apparatus exhibits not only the wave profile, with its progressive motions, but also the motions taking place below the surface in the whole mass of liquid effected;" and it illustrates the wave theory established by Gerstner, Scott Russell, Rankine, and others. The apparatus could scarcely be described without the aid of a woodcut, but it somewhat resembles the wave apparatus invented some years ago, by Wheatstone (?) We frequently wish that some apparatus of this description appeared upon the lecture table, specially in lectures on light and sound. The subject of plane polarised light is difficult enough, in all conscience; what, then, shall we say to circular and elliptic polarisation? Surely, some means of visualising these actions might, with advantage, replace the black-board, and the old story of the wire grating and the card, and the ray of light with its *two sides*, an expression nearly as appropriate, we always think, as that about the two sides of a round plum-pudding.

In a paper entitled "*Tellurium a Metal*," Mr. L. Bradley adduces experiments and facts which compel him to regard tellurium as a metal. "It is true," he says, in conclusion, "that tellurium is not malleable, nor ductile, as are many of the metals; neither is bismuth nor antimony. Like the non-metallic substances, it unites with oxygen to form acid; so do antimony, arsenicum, gold, chromium, manganese, and many other metals. With hydrogen it unites to form a hydruret; so do potassium, arsenicum, and antimony. In short, it possesses the universally-admitted distinguishing characteristics of metals, and nothing either in physical character or chemical behaviour which it does not hold in common with some other metals. I must, therefore, call it a metal."

We come now to a paper entitled "*Chemical Diagrams and Derivative Symbols, Illustrating the Prominent Characteristics of Chemical Elements.*" Here we are introduced to a species of diagram appertaining more to heraldry than to chemistry, albeit, there is a touch of alchemical mysticism introduced. They are, for the most part, a sort of half-bred between John Rudolf Glauber's three enigmatical designs and the illustrations to the article "Heraldry" in Chambers's old "Encyclopædia." What have we here? A black triangle; along the sides of which the words carbon, boron, and silicon appear, the whole surrounded by a shield. Here, again, is a shield, "simple," bearing a triangle, "proper," on a field, "argent." In the next diagram, the triangle has burst out eruptively, and is vomiting forth small jets of bromine, sulphur, tellurium, &c. The mysticism is obviously on the increase; is this a treatise *De Secretis* of the Middle Ages? At least, we recommend the author to peruse the "Pretiosa Margarita Novella." But what is this shield with a bar sinister? Have we illegitimate compounds in chemistry? If so, we rather imagine that pseudomorphs ought to be ranged under this head. A greater wonder yet remains: the author proposes to designate lithium, sodium, potassium, rubidium, and cæsium by a star with five points. He is, perhaps, unaware that the precise star which he has drawn is used in heraldry to designate a third son. Now, to say that a third son in heraldry, and five alkaline elements in chemistry, are symbolically the same, is palpably absurd. *Q. E. D.* And we are bound to confess that we must apply the same mode of argument to the whole of the paper. We would beg to suggest to the author the term "Heraldic Chemistry."

This paper is followed by another by the same author, on "*A New Chemical Nomenclature*;" and here his mystical longings crop up again with renewed vigour. The terms of the nomenclature are mystical, heathenish, barbarous—shall we add insensate? Without a doubt, they are closely related to the words wherewith, in former ages, many have tried and some have hoped to raise the devil. What shall we say to *kalamalt*, *nobamet*, *tanamet?* The "acid chromate of sesquioxide of chromium" rejoices in the name of *chreamyut*. The bromide of ammonium is *olanab*; sulphate of soda *natemasot* [happily, poor Glauber is dead], while chloride of sodium becomes *sodamad* (and we do not wonder at it, after such treatment). One more example, and we have done. "Bihydrochlorate of bibromoterchloronaphthaline" is to be called *curulebod*, a term which must originally have been suggested by a Regius Professor of the language of the Feejee Islanders. The cardinal question yet remains. Whence comes this jargon? and what does it mean? We cannot tell, unless it is the production of that wonderful book-composing machine used by the Laputan philosophers, which took in letters and turned out completed books, in any language and on any subject; and we would venture to remind our author that hard by, was a philosopher, who proposed to build houses from the roof downwards, beginning with the chimney-pots. In all seriousness, we say to the author of this paper, seek rather to discover new chemical facts than to generalise upon those already discovered; avoid mysticism, give up heraldry and bars sinister, and, above all, remember a very pertinent passage in the "De Augmentis Scientiarum" (and does not the title-page say "The American Association for the *Advancement of Science?*"), in which Bacon says with great felicity, "*Quocirca non certæ magis experientiæ quam rectæ etiam rationi consonum videtur, utres ponatur doctrinarum intemperies. Prima est doctrina phantastica, secunda doctrina litigiosa, tertia doctrina fucata et mollis: vel sic; vanæ imaginationes, vanæ altercationes, vanæ affectationes.*"

It only remains for us to say that the work we have considered contains several admirable papers, and that we wish all success to the "American Association for the Advancement of Science."

LABORATORY NOTES.

LABORATORY PUMP.

I FORWARD a description of a slight addition which I have devised to the valuable filter pump of Professor Bunsen, whereby the filtrate, if required, may be retained for further research.

Take an ordinary bell-glass receiver used in collecting gases, open and ground at the bottom, and closed at the neck with a stopper. Remove the stopper, and replace it by a cork, through which passes the funnel and exhausting tube, as shown in the flask in Professor Bunsen's arrangement. The receiver can then be placed on a glass plate, a beaker introduced within it, and the joint between the receiver and the plate made good with a little tallow. The funnel should be lengthened by fusing a piece of glass tube to it, so that it may reach half way down the beaker, as the liquid dropping from the funnel in the rarefied medium is very apt to splash upwards.

JOHN DODS.

L. and N.-W. Railway Co.

CORRESPONDENCE.

MAWSON AND SWAN'S LABELS.

To the Editor of the Chemical News.

SIR,—A thorough revision of the new Book of Chemical Labels, published by Messrs. Mawson and Swan, of Newcastle, has led to the dicovery of three obvious errors of the press, which, I trust, you will permit me to point out. In the labels for Barium and Calcium Chlorides, the modern formulæ are printed as $BaNO_3$ and $CaNO_3$ respectively, instead of $Ba(NO_3)_2$ and $Ca(NO_3)_2$, and in the table of combining weights, the old number for Silicon is erroneously given as 14 instead of 28. By a singular mischance, one of the incorrect labels has been taken as a specimen for the publishers' advertisements. The indicated errors, which may be easily corrected by the pen, do not appear in the copies of the work which are now being issued. The fact that only three mistakes are discoverable in a long series of formulæ may, perhaps, be deemed satisfactory evidence of careful compilation by those who have published chemical works, but after the precautions taken to insure correctness and consistency, even these few errors suffice to disturb the equanimity of

THE EDITOR OF THE BOOK OF LABELS.

London, June 16th, 1869.

QUANTIVALENCE.

To the Editor of the Chemical News.

SIR,—The only apparent objection to the word quantivalence as a substitute for the expression atomicity is that mentioned by "C.H.," namely, that Naquet uses the latter term to indicate the maximum, and the former the varying saturating power of an element. Such limitations, however, are entirely unnecessary, and have not received general acceptance. Surely we may attack or defend the notion of constant against varying atomicity, otherwise synonymously termed quantivalence, without inventing special words or engaging in the vain endeavour to give to existing words fresh meanings in violation of etymology. Besides, if the question is to turn on priority, quantivalence was, I believe, originally offered by Hofmann as the pure equivalent of atomicity.

So much for the name; now for the subject. As a teacher of chemistry to large classes of students, I have found the doctrine of quantivalence of immense value to learners. At first, following good leaders, I treated radicals as if possessing, but not always exerting, constant quantivalence; latterly the one or two prevailing values of the (chemical) atom of the common elementary or compound radicals have been pointed out, the hypothesis of the self-contained or "latent" affinities of an atom being suppressed. This is the position I intend occupying until more evidence is forthcoming.

Reverting to the word. We recently heard one learned lecturer utter the barbarism monovalent, giving the accent to the last syllable but one; another speak of the barbarism pentavalent, also accenting the penultimate. I believe we simply follow rule in emphasising the third syllable from the end in the case of each of the words u-niv'-a-lent, biv'-a-lent, triv'-a-lent, quad-riv'-a-lent, quin-quiv'-a-lent, sex-iv'-a-lent. This matter is worthy of reference, inasmuch as, amongst other reasons, euphonious words are the most acceptable—quan-tiv'-a-lence has a better chance of employment than quan-ti-va'-lence. Taking for guidance the pronunciation accorded to the old word e-quiv'-a-lent, there need be no difficulty in this matter.—I am, &c.,

JOHN ATTFIELD, Ph.D.,
Professor of Practical Chemistry to the Pharmaceutical Society.

MISCELLANEOUS.

Memorial to Faraday.—A public meeting, at which H.R.H. the Prince of Wales will take the chair, will be held at the Royal Institution on Monday next, June 21st., at half-past 3, to consider the measures to be taken for the promotion of a memorial to Faraday.

Proposed New Physical Society.—It has been proposed to establish a Physical Society in London, and already many promises of support and proposals for membership have been received. We shall be glad to receive the views and opinions of our readers on this subject.

The British Association.—At a meeting of the council, on Saturday last, Sir Roderick Murchison in the chair, it was reported by the General Secretary that the following Presidents of sections had consented to preside at the Exeter meeting. The following Vice-Presidents were nominated:—Section A (Mathematical and Physical Science).—President, Professor Sylvester, F.R.S.; Vice-Presidents, Professor Adams, F.R.S., and Mr. W. R. Grove, Q.C., F.R.S. Section B (Chemical Science).—President, Dr. Debus, F.R.S.; Vice-Presidents, Professor Odling, F.R.S., and Professor Williamson, F.R.S. Section C (Geology).—President, Professor Harkness, F.R.S.; Vice-Presidents, Mr. R. Godwin-Austen, F.R.S., and Mr. W. Pengelly, F.R.S. Section D (Biology).—President, Professor Rolleston, F.R.S.; Vice-Presidents, Mr. C. Spence Bate and Mr. E. B. Tylor. Section E (Geography).—President, Sir Bartle Frere; Vice-Presidents, Sir George Grey, K.C.B., and Mr. A. G. Findlay, F.R.G.S. Section F (Economic Science and Statistics).—President, the Right Hon. Sir Stafford H. Northcote, M.P.; Vice-Presidents, Mr. T. D. Acland, M.P., and Colonel Sykes, M.P., F.R.S. Section G (Mechanical Science).—President, Mr. C. W. Siemens, F.R.S.; Vice-Presidents, Mr. G. P. Bidder, F.R.G.S., and Mr. C. Vignoles, F.R.S. The Mayor of Exeter, Sir Stafford Northcote, and Sir John Bowring were present, and supported the application of the working men for a special lecture during the meeting, which was unanimously agreed to, and subsequently Professor W. A. Miller, Vice-President and Treasurer of the Royal Society, was invited to undertake the duty.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

In accordance with the generally expressed wishes of our friends and readers, we are endeavouring to effect arrangements to enable us to give, under the above heading, notices of EVERY CHEMICAL PAPER IN THE WORLD, *as soon as possible after publication. Whenever possible, these notices will appear in the form of carefully prepared, although necessarily brief, abstracts; as respects papers either too long or too abstruse to render condensation possible, their titles will be chronicled; and in all cases accurate reference will be made to the original publication. The two half-yearly volumes of the* CHEMICAL NEWS, *with their copious indices, will therefore be equivalent to an English edition of the "Jahresberichte," with the additional advantage of keeping the readers week by week on a level with the latest advances of science.*

Berichte der Deutschen Chemischen Gesellschaft zu Berlin, No. 8, May 8, 1869.

We notice, in the brief report of the general meeting of the 26th of April last, under the presidency of Professor A. W. Hofmann, that the Committee of this Society had arranged and approved of the proposal of M. Scheibler, that a photographic album be made to contain the photographic portraits of the members of the *Gesellschaft*, taken in the well-known card size, and each photograph to bear, moreover, the autograph of the member it represents. At the ordinary meeting of the Society, held on the same day, the following papers were read:—

Simple Method for Determining the Percentage of Water contained in Various Kinds of Starch.—M. C. Scheibler.—The author states that he had been requested by a number of starch and glucose manufacturers to try to find a readily-executable, yet reliable method of determining the quantity of water contained in starch, especially in its green, or raw state. M. Scheibler further says, that it occurred to him that, since starch is insoluble in alcohol, and only contains very slight traces of fatty matter, the object to be obtained might be readily attained by determining the change of the specific gravity alcohol suffers after having been for a length of time in contact with wet starch. In order to test this point practically, some preliminary experiments were first made with starch and alcohol of 90° Tralles (equal to 0·8339 specific gravity at 12 4-9ths degrees R.), and afterwards the following mode of testing was devised:—100 c.c. of the alcohol, weighing 83·4 grms., were placed in a glass-stoppered bottle, and thereto was added 41·7 grms. of divers samples of starch, in separate samples, of which the quantity of water therein contained had been previously ascertained with great accuracy. These samples were left in contact with the alcohol for one hour, care being taken frequently to shake the bottle. After that lapse of time, the alcohol was separated from the starch by filtration, and its specific gravity accurately determined. While experimenting, the author observed that, when the starch contains less than 11·4 per cent of water, instead of yielding up water to alcohol of the above-named strength, it withdrew water from that alcohol. The lengthy paper contains several tabulated forms, and is, on the whole, intended especially to aid starch and glucose makers in their business, and the experiments refer to so-called green starch.

Essay on the Affinity in Solutions of Perchloride of Iron, without Change of the State of Aggregation.—M. A. Müller.—The author says, in the introduction to his paper:—Only when the intensity of a coloured solution decreases, by dilution, in the inverse ratio of the increase of bulk, are we entitled to assume that the molecules of the colouring material are simply mechanically put asunder, and not also chemically modified; when, however, the intensity of colour is affected, in a more or less degree, in a different manner, by becoming more dilute, we are almost forced to assume a chemical change. The author next states that, from experiments made by him, and with solutions of chloride of iron and other coloured metallic chlorides, platinum chloride being preferred, he has found that the intensity of the colour of the solution really depends—1st, on the nature of the diluent; 2nd, on the temperature of the solution; and, 3rd, on the age of the solution—*i.e.*, whether recently prepared or not. As diluents, have been applied—water, hydrochloric acid, solution of chloride of ammonium, and solution of chloride of sodium. The experiments made are described at great length. It appears that the addition of hydrochloric acid, chloride of ammonium, and chloride of sodium have the effect of increasing the intensity of colour of a solution of chloride of iron, even after it has been largely diluted with water; increase of temperature has the same effect.

Varying Behaviour of Iodine towards Sulphuretted Hydrogen under Different Conditions, and the Causes thereof.—M. Naumann.—When iodine is dissolved in perfectly anhydrous sulphide of carbon, and dry sulphuretted hydrogen is passed into that solution, no action whatever takes place. Water, as well as an increase of temperature, are required for the formation of hydriodic acid and the separation of sulphur. The author has gone at great length in studying both the thermic and hydric conditions, which are called into play when the two substances alluded to react upon each other; and, in the second part of his paper, discusses—

The Preparation of an Aqueous Solution of Hydriodic Acid.—Several experiments have been made on this subject, and, as result thereof, the author recommends that, first, a concentrated solution of iodine in pure sulphide of carbon be made; this solution to be next diluted with more of the latter fluid, and then only water to be added, previous to the passing of sulphuretted hydrogen gas into the solution.

Essential Oil of Balsam of Peru.—M. Kraut.—The author found that this oil may be separated, by distillation under reduced pressure, and in an atmosphere of carbonic acid gas, into three different oils:—*a*. Boils at 200° C.; contains 76·20 per cent C, and 6·68 per cent H; and is converted, by chromic acid, into benzoic acid, no carbonic acid becoming disengaged. *b*. Boils at 300°; contains 79·09 per cent C, and 6·00 H; an alcoholic solution of potassa converts this oil into benzoic acid and benzylic alcohol. *c*. Boils at about the boiling point of mercury; contains 81·21 per cent C, and 6·12 H; treated with alcoholic solution of potassa, it is converted into cinnamic acid and benzylic alcohol.

On Cumonitrilamine.—M. E. Czumpelik.—The author describes at great length a series of experiments made by him to prepare this base; the description being too complicated for abstraction, we content ourselves with giving the ultimate result of his labours. Cumonitrilamine is a solid substance, readily crystallising, difficultly soluble in water, but readily so in alcohol and ether; fuses at 45° C.; and boils at 305° C. With acids, salts are formed, and with chloride of platinum a beautifully-crystalline double salt is obtained. The elementary organic analysis of this salt gave, in 100 parts, the following result:—C, 32·74; H, 3·54; N, 7·68; Pt, 26·97; Cl_6, 29·07. These numbers lead to the following formula:—

$$C_{20}H_{26}N_4PtCl_6 = 2[C_{10}H_{12}N_2HCl],PtCl_4.$$

The equivalent of this platinum compound is 733.

Base of the Cumin Series, which agrees with Benzylamine.—M. E. Czumpelik.—In this paper, the author tells us how he effected the hydrogenisation of the cumonitrile. While obtaining various intermediate products, he at last got thioamide, an oily liquid, yielding, with hydrochloric acid, a readily crystallisable salt, which combines with chloride of platinum, yielding a crystalline compound, insoluble in water, and soluble in alcohol and ether. This, on being submitted to elementary organic analysis, gave the following results for 100 parts:—C, 33·78; H, 4·15; N, 3·94; Pt, 27·18; Cl_6, 29·95. Formula—

$$C_{20}H_{28}N_2PtCl_6 = 2[C_{10}H_{14}N,HCl]PtCl_4.$$

The equivalent of this platinum compound is 711.

On Trimethylglycerammonium.—M. V. Mayer.—By a complicated set of reactions between substances, the very length of the names of which would occupy too much space. The author succeeded in obtaining a double gold salt of the base named at the head; this salt—

$$AuCl_3N(CH_3)3C_3H_5(OH)2Cl,$$

that is to say, the trimethylglycerammonium chloride of chloride of gold exhibits orange-coloured, very lustrous crystals, soluble in water, as well as in absolute alcohol, and fuses at 190° C. The trimethylglycerammonium chloride is a solid substance, crystalline, soluble in water, and decomposed, by boiling with baryta water, into trimethylamine. The author states that his researches on the trimethylglycerammonium, in free state, are not yet quite complete.

On the Means of Entirely Preventing Bumping of Fluids while Boiling.—M. E. Winkelhofer.—The author reviews what has been done by others, and especially by Dr. Pellogio, and next describes, at length, some experiments of his invention, embracing the following fluids:—Methyl-alcohol, sulphuric acid, alcoholic solution of sulphate of protoxide of iron, alcoholic potassa solution, hydrochloric acid, and dilute sulphuric acid, containing some sulphate of lead. His plan, to prevent bumping, is simply an electric current, led into the fluids by means of suitable conducting wires; his contrivances are very ingenious, but certainly too complicated for general use.

Hypotheses respecting the Constitution of Benzol.—This paper cannot be well understood without the diagrams annexed thereto, upon the value of which the reasonings contained in the paper are based.

This number of the *Berichte* concludes with a brief notice, by M. Rammelsberg, correcting some of Mr. Maskelyne's statements in respect of a meteorite and minerals found therein, and the specific gravity of these minerals. Maskelyne observed in a meteorite from Breitenbach in Bohemia, occupying a middle place between iron and stone meteorites, a mineral embedded in the iron, of 3·3 sp. gr., and having the composition of enstatite. He found another mineral, which yielded, on analysis, from 97 to 99 per cent of silica, and only having the low sp. gr. of 2·1 to 2·2, and is therefore not quartz; Maskelyne says it is optically doubly axial, and takes it as identical with tridymite, which, however, has a sp. gr. of 2·3, and is optically uni-axial.

Der Papier Fabrikant, No. 5, May, 1869.

This periodical, published in Southern Germany, is not a mere trade circular, but a very well got up paper; and, in the present number, an interesting paper is met with on a subject not quite familiar to scientific, and less so to many practical readers, in this country. We abstract some of the leading features of a valuable paper—

On Ultramarine.—M. Zuber.—The beautiful blue pigment now known as ultramarine, and manufactured in France and Germany on a large scale, has become common by the results of scientific and analytical chemistry. The native ultramarine, also called lazulite, lapis lazuli, and zeolite blue, is a rather rare mineral, of which, in pure state, according to Patrin, Central Asia is the native place. This native mineral consists, in 100 parts, according to Varrentrapp's analysis, of:—Silica, 45·40; alumina, 31·67; soda, 9·09; lime, 3·52; sulphuric acid, 5·89; sulphur, 0·95; iron, 0·52; chlorine, 0·42; water, 0·12. According to Field, the formula for this mineral is—

$$6[3SiO_2.NaO.Al_2O_3],FNaS.$$

The finest specimens of native ultramarine are used as precious stones; and some of it is still used by artists, it being prepared for that purpose, in a peculiar manner, chiefly at Rome and Florence. Artificial ultramarine was first made by a process discovered by M. Guimet, in France, in 1826, but kept secret, and remaining so up to the present day. Although the pigment obtained by artificial means is one of great beauty and permanency, under ordinary conditions it is never made equal to the pigment derived from the native *lapis lazuli*. Notwithstanding a large number of scientific and practical men have studied this subject, the precise answer to the question, whence the blue colour of this substance is derived from, is a perfect mystery; the only fact certainly known is, that a portion of the sodium is combined with the sulphur, to form a certain sulphuret, and that that alkaline sulphuret is chemically combined with a double silicate of alumina and soda. Iron and calcium have been proved to have nothing to do with the cause of the blue colour, and to be simply accidental. In the original paper, from which we condense the results, no less than 10 analyses of samples of artificial ultramarine, made by different analysts, and from different makers, are given. Varrentrapp's results are, for 100 parts, as follows:—Silica, 46·60; alumina, 23·30; soda, 21·46; sulphur, 1·68; potassa, 1·75; iron, 1·06; lime, 0·02; sulphuric acid, 3·08; with traces of chlorine, oxide of iron, oxygen, and an accidental trace of clay. The ingredients required for the manufacture of artificial ultramarine are—sulphur, wood charcoal, sulphate of soda, carbonate of soda, and kaolin; curiously enough, the latter substance is preferred from Cornwall, and fetched thence to be transported abroad, while the manufacture of ultramarine in this country is of little or no importance. The product of ultramarine met with in commerce is rarely, if ever, adulterated, unless it be with the pure sulphates of lime and baryta, to reduce the original deep blue colour to a less dark shade. In order to test the colouring value of a sample of ultramarine, it is usual to weigh off 0·1 grm., and to mix it, in a dry state, with 1 grm. of powdered French chalk, and to compare the tinge obtained with other mixtures of the kind and a standard sample of ultramarine. Besides being largely used in oil painting, ultramarine yields blue printing ink, blue for calico, silk, and woollen tissues; for colouring paper, sugar (it is largely used in sugar refineries to brighten the loaf sugar), fresco and stucco painting, and other purposes. All acids, especially the more concentrated ones, destroy the colour, which, however, stands fire, as well as many other agents. The native ultramarine is not affected by acids unless heat is at the same time applied.

Monatsberichte der Königlich Preussischen Akademie der Wissenschaften zu Berlin, February, 1869.

None of the papers contained in this periodical bear upon chemical science, or subjects more immediately connected therewith.

Annalen der Chemie und Pharmacie, May, 1869.

This periodical contains the following original essays and papers:—

On Indium.—M. R. E. Meyer.—The author opens this lengthy essay with a review of the labours of others on this subject. He then states that the source whence he extracted indium is the zinc from Freiberg, in Saxony. The preparation of the metal, and its purification, are described at great length, but, since no new method was applied, we need not enter into details on this subject. The various combinations of this metal with iodine, bromine, chlorine, cyanogen, sulphuretted hydrogen, and, next, salts of the oxide, are described. The iodide of indium, InI_3, equivalent 329·6, contains, in 100 parts:—Indium, 22·94; iodine, 77·06. The chloride of indium, $InCl_3$, equivalent 146·6, contains, in 100 parts:—Indium, 51·57; chlorine, 48·43. A large number of double salts and compounds of the halogens of indium, with similar compounds of other metals forming double halogen compounds, are described in detail; in fact, the essay is an exhaustive monograph on this subject.

On Lactic Acid and β Iodpropionic Acid.—M. Socoloff.—This essay is a review, rather of what has been done on this subject by other experimenters, than an account of the author's own labours. He states that the β iodpropionic acid was prepared by him in the same manner as was done by MM. Beilstein and Moldenhauer. Several salts of this acid were prepared by M. Socoloff, and submitted to organic elementary analysis. The calcium salt yielded, in 100 parts:—Carbon, 33·08; hydrogen, 4·62; calcium, 18·34; the remainder being oxygen. In a tabulated form, the author records the physical properties of the calcium, barium, zinc, and lead salts of the acid submitted to research by him, and of ordinary lactic acid, paralactic acid, and methylglycolic acid. The lengthy essay winds up with a theoretical discussion on mono-acid, bin-acid, and even hepta-acid alcohols.

Researches on the Derivatives of Salicine.—M. Hugo Schiff.—This paper is the first of a series to be continued by the author on this subject, and this portion is headed—1. *Amide of Salicyl Aldehyde*. The author begins by stating that the formula for the aldehyde of salicyl should be written—

$$C_6H_4\begin{cases}OH\\CHO'.\end{cases}$$

Next, the preparation of this aldehyde is described as follows:—Take, from 300 to 400 grms. of salicine, and the Ettling oxidation mixture (nothing is said as to what this mixture consists of); during the time the distillation is going on, water is allowed to drop continuously into the retort, in order thereby to keep up the original degree of concentration of its contents, and to prevent the formation of resin as much as possible. The aldehyde, after having been separated from the water, is saturated with common salt, and mixed with ether; in this manner, about one-third of the weight of the salicine originally taken is obtained as aldehyde. The author next treats of the products of the action of aniline upon salicyl-aldehyde, and then describes, at great length, several complicated combinations, as, for instance, salhydrethylanilide, formula—

$$C_6H_4\begin{cases}OH\\CH.\end{cases}\begin{cases}NC_2H_5.C_6H_5\\NC_2H_5.C_6H_5\end{cases}-C_{32}H_{36}N_2O;$$

ethylsalhydranilide—

$$C_{15}H_{15}NO;$$

and ethylsalhydrethylanilide—

$$C_{32}H_{30}N_2O.$$

Several metallo-compounds are next described—Copper salhydranilide—

$$C_{26}H_{20}CuN_2O_2,$$

containing, in 100 parts:—Carbon, 68·2; hydrogen, 4·6; copper, 13·7.

Derivatives of Propane.—M. Carl Schorlemmer.—Propane, a hydrocarbon, C_3H_8, is described, first, as regards its preparation from isopropyliodide and zinc turnings; next, a chloride of propane is prepared, which, on being analysed, yielded results leading to the formula C_3H_7Cl. The author describes several experiments, made with the view to obtain chemically pure products, and ends his paper by promising more accurate and full details on this subject.

On Hydroxylurea.—Drs. Dresler and Stein.—When hydroxylamine and cyanic acid act upon each other, a substance is obtained, the composition of which may be expressed by the formula $N_2CH_4O_2$. The authors state how they proceeded to obtain this substance, in a pure state, by a rather complicated and lengthy process. The hydroxylurea is a solid substance, very soluble in water, sparingly in alcohol, crystallising in needle-shaped crystals; it fuses at 130° C., and is decomposed when that temperature is continued, yielding carbonic acid and ammonia. The substance is readily acted upon by caustic potassa and nitric acid; its solutions, in neutral fluids, reduce solutions of salts of silver to the metallic state.

Comptes Rendus des Séances de l'Académie des Sciences, Monday, May 31, 1869 (No. 22).

We notice, in the first place, an abstract of a memoir—

Decomposition of Chloride of Sodium and Chloride of Potassium by Metallic Iron under the Influence of Moist Air.—M. E. Chevreul.—After having entered upon some historical details, and gone back as far as the year 1779, when Scheele experimented on this subject, he proves, by a simple experiment made before the meeting, that, when chloride of sodium, iron, water, and air are in actual contact, decomposition of the alkaline chloride takes place; further, that this decomposition is not, as has often been stated, an effect of efflorescence, but a double decomposition, according to the well-known law of Berthollet, which, however, was rather too vaguely formulated by its original author.

New Spectrum Observations of the Sun's Atmosphere and Protuberances.—Rev. Father Secchi, S.J.—In the shape of a letter, addressed from Rome, and dated May 21st, the eminent *savant* states:—The spectrum observations of the solar protuberances made by M. Rayet, during the eclipse of the sun, in the month of August last year, have revealed a considerable number of luminous rays, seven of which were especially prominent; only four of this number have afterwards, when no eclipse takes place, been found to exist with certainty—viz., the three principal rays of hydrogen, and the yellow ray in the neighbourhood of sodium. It was highly interesting to try whether, under favourable conditions, these three other rays could be again found. I am happy to be able to state that, during my observations yesterday (May 20th), I have succeeded in seeing these rays with perfectly absolute certainty. The author proceeds to describe the exact locality where he discovered these rays, and gives a diagram to illustrate this portion of his letter; and next describes the nature of these rays at length, illustrated by a diagram. It appears, from this description, that the rays exhibit great brilliancy, and are more remarkable, even than could be expected at first from M. Rayet's former observation. The rays are those of magnesium, hydrogen, and a non-gaseous (as yet undetermined) substance.

Scientific Aerostation.—M. Tissandier states that a balloon, of 10,000 cubic metres (about 354,000 English cubic feet) capacity, and of 2500 square metres surface, has been placed, by M. le Ministre de la Guerre, at the disposal of several scientific men, and that it is intended to have (on June 27th and July 11th ensuing, from the Champs de Mars, Paris) ascents with this balloon, the car of which is capable of carrying with comfort ten people, and, in addition, 1500 kilos. weight; members of the Academy desirous of being of the party are requested to state so. This balloon is formed of four layers of tissue, glued together by means of india-rubber, and is to be filled with hydrogen; and experiments already made have proved that it preserves that gas unaltered for a long time.

On a New Thermo-Electric Battery made with Galena.—MM. Mure and Clamond.—This battery is composed of sixty elements, made up of small bars of galena, 40 m.m. in length by 8 m.m. thick, and bars of thin sheet iron, 55 m.m. in length by 8 m.m. in width, and 0·6 m.m. thickness. These materials have been arranged so as to form a hollow cylinder, which, when it is intended to be used, is to be heated by a peculiarly constructed gas burner. The specimen of this battery exhibited at the meeting had an electro-motive force of 1½ Bunsen element. M. Becquerel read a lengthy paper on the subject of this battery, the result of which is, that thermo-electric batteries, constructed either of metallic alloys, or as in this case, of a metallic sulphide and a metal, are not economical in use, and are too liable to changes brought on by the effects of the heat.

The Law of Mariotte, and on the Liquefaction of Gases in Relation to the State of Dryness of these Gases.—M. Dubrunfaut.—Curiously enough, in spite of, and against all evidence to the contrary, the author insists that perfectly pure and dry gases cannot be liquefied by any pressure or any lowering of temperature, however great. He says, the intervention of water is an absolute condition of the condensation of gases to fluids; no wonder that M. Dumas should vehemently protest against a heresy so flagrantly in opposition with experience.

Chemical Constitution of Amylaceous Matter.—M. Musculus.—The author has made a series of experiments, in order to prove that the formation of dextrine from starch is only the first step in the process of splitting up which starch undergoes when it is placed in contact with water and diastase at a temperature of from 60° to 75° C., and that the quantity of sugar obtained by this process represents at least two equivalents. The lengthy paper contains the results of a series of experiments, too long and too many to be further quoted here, but the author has to confess that his main object has not been attained.

Researches on the Ethers of Phenol.—M. E. Lippmann.—The author has studied—*Ethylen-diphenol*—

$$\left.\begin{matrix}(C_6H_5)\\C_2H_4\end{matrix}\right\}O_2.$$

Ethylen-diphenolsulphuric Acid.—The lead-salt of this acid crystallises, and is soluble in hot water, but insoluble in cold water. The analysis of the salt, dried at 120° C., gave, in 100 parts—C, 29·49; H, 2·0; Pb, 35·7. Formula—

$$\left.\begin{matrix}C_6H_4SO_2Pb''\\C_6H_4SO_2\\C_2H_4\end{matrix}\right\}O_2.$$

Ethylen-diphenosulphate of barium. A crystalline powder, not very soluble in boiling water. Its elementary organic analysis gave, for 100 parts:—C, 33·0; H, 2·3; Ba, 26·9. Tetrabromide of ethylen-diphenol is composed, in 100 parts, of:—C, 31·6; H, 2·0; Br, 60·3. Formula—

$$\left.\begin{matrix}C_6H_2Br_2\\C_6H_2Br_2\\C_2H_4\end{matrix}\right\}O_2.$$

The author states that the preliminary note from M. Burr on this subject, published in the *Zeitschrift fur Chemie*, No. 6 (see CHEMICAL NEWS, vol. xix., p. 251), had not come into his possession when he made his experiments.

New and General Method for the Preparation of Nitriles.—M. L. Henry.—The author has succeeded in transforming amides into nitriles, by means of pentasulphide of phosphorus, and has especially operated upon acetamide and benzamide, making use of 1 equivalent of the pentasulphide of phosphorus upon 5 equivalents of the amide. The result of the action of the pentasulphide of phosphorus upon acetamide is aceto nitrile, $(C_2H_3)N$; while the result of the action of this material upon benzamide, is cyaphenine, a polymere of benzonitrile, $(C'''_7H_5)N$.

Physiological Effects of Stanethyl and Stanmethyl.—MM. Jolyet and André Cahours.—The authors describe the preparation of these chemical compounds, which may be obtained by means of the perchloride of tin, Sn_2Cl_4, at great length, and then describe the physiological effects, which are those of stupor, inducing narcotism in the very highest degree.

No. 23, June 7, 1869.

We notice, from this periodical, the following memoirs, papers, and communications, omitting those relating to physiology, medicine, mathematics, and mechanical science:—

Synthesis of the so-called Aromatic Acids.—M. Wurtz.—The author describes, in the following terms, a new method for the synthesis of the above acids:—When an organic chloride, or bromide, is treated with chloroxycarbonic ether and sodium amalgam, the haloid element is eliminated by the sodium, and replaced by the group $CO_2(C_2H_5)$; if it is, therefore, required to convert a carbide of hydrogen into a higher monocarbon acid of the series, the monochloride or monobromide of that carbide of hydrogen is first prepared, and then heated with chloroxycarbonic ether and sodium amalgam. The author next proceeds to describe some experiments made by him, and the results obtained, at length; starting with bromide of phenyl, C_6H_5Br, and mixing this chloroxycarbonic ether and sodium amalgam, the following formula represents the reaction, resulting in the formation of benzoic ether:—

$$C_6H_5Br+CO\left\{\begin{matrix}O.C_2H_5\\Cl\end{matrix}\right.+Na_2=NaCl+NaBr+C_6H_5.CO_2(C_2H_5).$$

Use of the Spectroscope to Distinguish a Feeble Light, Present with a Stronger Light.—M. Seguin.—The author describes a series of experiments with electric light, and observations thereon with Duboscq's vertical spectroscope. The result and conclusion arrived at is, that the spectroscope serves eminently the purpose of detecting (proved, also, by the observations made with it of the sun's light and protuberances) a more feeble light present along with a much stronger, and the former of which would be invisible to the naked eye, or by means of other optical instruments.

On Acetochlorhydrine and Octylglycol.—M. de Clermont.—Into 50 grms. of anhydrous acetic acid, strongly cooled, anhydrous hypochlorous acid is passed, until the acetic acid has absorbed 10 grms. of the latter; no stronger solution should be made, as there is danger of explosion. To the mixture of acetate of chlorine and anhydrous acetic acid is added a quantity of 14 grms. of pure octylen, previously mixed with anhydrous acetic acid; acetochlorhydrine is thus formed, which, being held in solution by the acetic acid, is separated therefrom by addition of water. The acetochlorhydrine of octylen is a highly mobile liquid, devoid of colour, of agreeable and aromatic odour, soluble in alcohol, ether, and acetic acid, insoluble in water, burns when ignited, with a sooty greenish-bordered flame, and boils, without decomposition, at 225° C. The specific gravity of this liquid is, at 0° C., 1·026, and it consists, in 100 parts, of:—C, 58·11; H, 9·20; Cl, 17·19. Density of vapour, 7·12.

Acetic Derivatives of Mannite.—M. E. Grange.—When crystallised mannite is heated, in an open vessel, with strong acetic acid, and boiled, there is left, on cooling, a crystalline mass embedded in a syrupy liquid; the latter is separated by filtration over asbestos, and the dry solid residue washed with strong absolute alcohol, to eliminate the acetic acid. The material, thus purified, is hardly soluble in boiling alcohol, not at all in ether, and very soluble in water and acetic acid. Submitted to analysis, it yields, in 100 parts:—C, 45·42; H, 7·027; O, 47·553; corresponding to the formula $C_{14}H_{24}O_{11}$, equal to $C_{12}H_{22}(C_2H_3O)O_{10}$. The author describes a series of results of experiments of various reactions of divers substances with this compound, but our space does not permit us to enter into details.

We only notice the titles of the two next papers, which are not suitable for abstraction:—

Observations on the Phenomena of Supersaturation.—M. Margueritte.

Second Notice on the Theory of Supersaturation and Solution.—M. Lecocq de Boisbaudran.

Salts of Phenetolsulphuric Acid.—MM. Opt and Lippmann.—Phenetol—

$$\left.\begin{matrix}C_6H_5\\C_2H_5\end{matrix}\right\}O,$$

is a liquid, boiling at 168° C. When sulphuric acid is added to it, a pink colour ensues, and, after the mixture has been heated upon a water-bath for about an hour and a half, a crystalline mass is formed; this is dissolved in much water, treated with baryta water, and the excess thereof eliminated with carbonic acid. In this manner, a beautifully crystallising baryta salt of the phenetolsulphuric acid is obtained; the composition of this salt, in 100 parts, is:—C, 35·62; H, 3·03; Ba, 25·04; H_2O, 11·78. The formula is—

$$(C_6H_4SO_2C_2H_5O)_2Ba''+4H_2O.$$

The authors briefly describe the lead and potassium salts of this acid.

Elimination of the Nitrogen contained in Beet-Roots during the Process of Manufacturing Sugar therefrom.—M. A. Renard. This paper is chiefly of importance to beet-root sugar makers.

On the Meteoric Stone Fallen from the Sky, on the 22nd of May, 1869, at Cléguérec, Département du Morbihan, France.—M. Limur states that, on the evening of the 22nd of May last, at 9·45 p.m. local time, there was heard at Vannes, the capital town of the department, a heavy report, like that due to the firing of large ordnance, while the sky was at the same time illuminated by a bluish white light, accompanied by sparks somewhat like those of fireworks. The next day the author learned that, at Cléguerec, a meteoric stone had fallen, which had been broken into pieces by the peasantry, and fragments of which, weighing 22 and 16 kilos. had been secured by some parties, who, knowing the value scientific men attach to these extra-terrestrial visitors, will shortly send them to Paris for investigation.

Palladium and Hydrogen.—M. Favre states that, according to his experiments, the hydrogen in palladium saturated therewith is present as a chemical compound, and not simply in the state of condensed gas. The author also states that the vapour of boiling mercury is as little a conductor of electricity as hydrogen is, and that, therefore, the non-conductibility of hydrogen for electricity cannot be regarded as an objection to its being a metal.

Cosmos, No. 23, June 5, 1869.

The only communication contained in this number suitable for translation to our pages is—

New Marking Ink for Linen.—M. Kuhr recommends the following preparation:—One part of hypophosphite of soda, and two parts of gum arabic are dissolved in sixteen parts of distilled water. The tissue, linen, or cotton to be marked is thoroughly moistened with this liquid, and then left to dry. After having become well dried, the following liquid, composed of one part of nitrate of silver, and six parts of gum dissolved in six parts of distilled water, is used as marking ink, with a quill pen. The mixtures here described are stated to yield an indelible, and very deep black-coloured ink.

Bleaching Soap.—This is a soda soap prepared according to the excellent prescription of the Prussian Pharmacopœia, which prescription has been copied in almost all other works of the kind; the soap is separated by common salt, and after this one-fourth of its weight of sulphite of soda is added, which has been previously made into a homogeneous paste by means of a little water; the soap is next dried in the usual manner. In order to apply this soap, chiefly intended for the bleaching of straw hats, but perfectly fit for application to silk and wool, it is dissolved in its own weight of cold water, and to every 2 lbs. of soap, ½ oz. of liquid ammonia is added. As soon as the mass has assumed a gelatinous aspect, 1 part thereof is dissolved in 8 parts of warm water. The materials which it is desired to bleach are washed and scrubbed by means of a brush in this soap-sud; while yet moist, the materials are placed in acidulated water (25 parts of water and 1¼ of hydrochloric acid), left in this liquid for 2 hours, and then well washed, and rinsed with pure cold water, and dried. This soap is very largely and successfully used in Russia, and was first prepared in that country by Dr. Werner.—*Pharm. Zeitschr. f. Russl.*

PATENTS.

Communicated by Mr. VAUGHAN, F.C.S., Patent Agent, 54, Chancery Lane, W.C.

GRANTS OF PROVISIONAL PROTECTION FOR SIX MONTHS.

1243. A. Borgnet, Swansea, Glamorganshire, "An improved composition to be employed as a paint."—Petition recorded April 22, 1869.

1539. W. R. Lake, Southampton Buildings, Chancery Lane, "An improved process for obtaining gelatine and other products from animal substances."—A communication from D. K. Tuttle, O. Lugo, W. J. Hooper, and T. Hooper, Baltimore, Ma., U.S.A.—May 19, 1869.

1575. C. W. Siemens, Great George Street, Westminster, Middlesex, "Improvements in calcining and smelting ores, and in furnaces and apparatus employed in connection therewith, which furnaces are also applicable to other purposes."—May 21, 1869.

1582. H. R. Lumley, St. John's Wood, London, "Improvements in treating and purifying crude iron, and in making steel, and in an apparatus for such purpose."—May 22, 1869.

NOTICES TO PROCEED.

106. C. P. Coles, Mountfield, Bonchurch, Isle of Wight, "Improved means of protecting the bottoms of ships, or other submerged structures, from fouling."—Petition recorded January 13, 1869.

130. P. Spence, Newton Heath, Manchester, "Improvements in the production of sulphate of potash for the manufacture of alum."—January 15, 1869.

148. F. Braby, Camberwell, Surrey, "Improvements in the commercial manufacture of sulphate of ammonia."—January 16, 1869.

186. H. A. Bonneville, Paris, "Improvements in the manufacture of illuminating gas, and of sponge, by the action of hydrocarbon liquids, or fluids, on metallic ores, and in the furnaces for melting said sponge and other metals."—A communication from C. J. Caumon, Toulouse, France.—Petition recorded January 20, 1869.

223. W. M. Welling, New York, U.S.A., "Improvements in compositions resembling ivory."—January 25, 1869.

246. C. Gil, Boulevard des Capucines, Paris, "Improvements in the manufacture of sugar."—January 26, 1869.

252. T. Vaughan, Middlesborough-on-Tees, Yorkshire, and J. W. Smith, Manchester, "Improvements in treating smoke and soot for the preparation of an article of commerce therefrom."—January 27, 1869.

262. A. C. Pass, Bedminster, Bristol, "Improvements in the method of, and apparatus for, condensing and purifying metallic and other fumes, vapours, gases, and smoke, and in obtaining oxide of zinc."—January 27, 1869.

287. F. Jay, South Lambeth Road, London, "Improvement in the manufacture of oil paint."—January 29, 1869.

1260. J. Major and W. Wright, Swallow Street, Middlesex, and G. H. Jones, Alpha Road, Middlesex, "A new or improved manufacture of white lead, and apparatus employed therein."—April 24, 1869.

1409. F. C. Knowles, Lovell Hill, Berks, "A new or improved method of purifying and converting cast-iron into malleable iron, or into steel, and for the making and use of materials and appliances for the same."—May 8, 1869.

1426. W. E. Newton, Chancery Lane, "An improved process and composition for hardening common or grey cast-iron, and for converting articles of iron into steel, or imparting thereto a steely character."—A communication from B. W. Nichols, Canton, Ohio, U.S.A.—May 10, 1869.

1431. H. Bessemer, Cannon Street, London, "Improvements in the manufacture of malleable iron and steel, and in furnaces and apparatus employed for their fusion and treatment."

1432. H. Bessemer, Cannon Street, London, "Improvements in the construction and mode of working furnaces and apparatus employed in fusing malleable or wrought-iron and steel, and pig or other carburets of iron, and obtaining cast-steel, or homogeneous malleable iron therefrom."

1433. H. Bessemer, Cannon Street, London, "Improvements in the conversion of fluid crude iron, and molten pig or other carburets of iron, into fluid homogeneous malleable iron and steel, whether such pig or other crude iron is used alone, or is mixed with a portion of malleable, or more or less decarburised iron, in a solid or fluid state."

1434. H. Bessemer, Cannon Street, London, "Improvements in the treatment of crude, or pig-iron, and other carburets of iron, and in the apparatus employed for such purposes."

1435. H. Bessemer, Cannon Street, London, "Improvements in the construction and mode of working blast furnaces employed for smelting the ores of iron, and in the mode of employing and utilising the gaseous products of such furnaces, and also in the construction and mode of working blast engines employed to force air into blast and other furnaces."—May 10, 1869.

1582. H. R. Lumley, St. John's Wood, London, "Improvements in heating and purifying crude iron, and in making steel, and in an apparatus for such purpose."—May 22, 1869.

NOTES AND QUERIES.

Picrates.—"T. E. D." is referred to either Watts's "Dictionary of Chemistry, the *Handwörterbuch der Reinen und Angewandten Chemie*, vol. vi., or any treatise on chemistry, wherein he will find the required information, too long for the space at our disposal in Notes and Queries.

Recovered Grease.—We do not quite understand the meaning; for, as long as grease is not saponified, or otherwise altered, or purposely adulterated, so as to become thereby unfit for use, it remains grease to all intents and purposes, and its physical and chemical properties remain then, of course, unaltered.

Scale of Temperatures.—The latest edition of Gehler's extensive *Physikalisches Lexicon*; also the works of Karmarsch, and Prechtl's *Technologische Encyclopedie*, contain what is desired by our correspondent, who will find these works either in the library of the British Museum, or that of the Commissioners of Patents.

Ineradicable Writing.—A French technical paper, specially devoted to the art and science of paper manufacture, states that any alterations or falsifications of writings in ordinary ink may be rendered impossible by passing the paper upon which it is intended to write through a solution of 1 milligram (0·01543 English grain) of gallic acid in as much pure distilled water as will fill to a moderate depth an ordinary soup-plate. After the paper thus prepared has become thoroughly dry, it may be used as ordinary paper for writing, but any attempt made to alter, falsify, or change anything written thereon, will be left perfectly visible, and may thus be readily detected.

New Sulpho-Salts.—Can any one explain the notation and formulæ of Schneider's new sulpho-salts? If the new notation be intended, the nearest approach would be, in old terms,—

			Schneider.
$KS+Fe_2S_3 =$	K	19·6	24·59
	Fe	37·6	35·19
	S	42·8	40·22
		100·0	100·00

But the bismuth salt is much more discrepant.—CHEMICUS.

["Chemicus" is reminded that all formulæ and all cyphers are correctly reproduced from the original papers they are taken from; and that the authors, and not we, are responsible for the formulæ, &c., which we have no right to alter or change.—*Ed.* C. N.]

"On Employment of Constant Factors in Calculation of Indirect Analysis."—The following appears to me to be a more simple and more easily recollected method for determinations by indirect analysis:—Presuming the salt is ascertained to be a mixture of the chlorides of potassium and sodium, and the amount of chlorine has been determined, calculate the weight of NaCl corresponding to the weight of chlorine found; then, since for every molecule of NaCl that is replaced by KCl there will be an increase of weight equal to 15 (*i.e.*, the difference between K and Na), the *difference* between the calculated weight of NaCl and the weight of the salt, being due to the extra weight of K over Na, will, if divided by 15, give the number of atoms of Na which are replaced by ⅋ in the mixture; and the number of atoms, multiplied by the atomic weight 39, will give the weight of potassium, which, together with the weight of chlorine, being deducted from weight of salt, will give the weight of sodium. A general formula may also readily be used for determination of any substance formed by three elements—

Let (*a*) be the combining equivalent of the heavier element;
Let (*b*) be the combining equivalent of the lighter element;
Let (*c*) be the combining equivalent for the determined element.

$$(a^m + b^n + c^m + n)$$

will then be the formula for any such compound; let it be equal to (*x*), calculate—

$$(b^m + n + c^m + n);$$

let it equal (*y*); then—

$$\frac{x-y}{a-b} \times a$$

will give the weight of (*a*) contained in the substance.—M. P.

MEETINGS FOR THE WEEK.

THE CHEMICAL NEWS.

VOL. XIX. No. 499.

THE FARADAY MEMORIAL.

THE Faraday Lectureship has been worthily inaugurated. M. Dumas, representing not alone the chemists of France but the chemists of Europe, has given us a lucid and comprehensive discourse, in which he has surveyed, from our present stand-point, the position of chemistry and its relations with past science, and has, moreover, pronounced an admirable *éloge* of him whom the discourse commemorates. No one could be more eminently fitted than M. Dumas to undertake this duty: he was the intimate friend of Faraday, and with him he somewhat connects the chemistry of the past with the chemistry of our day; he stands pre-eminent among the chemists of his country, and has had much influence upon the entire *cultus* of France during the last quarter of a century. And what are his relations with the past? He was born a few years after the death of Lavoisier; at the time when he entered the chemical world the system of Lavoisier was firmly established, was universally accepted. He may have seen as a boy the death of Phlogiston—that slow, long-drawn-out death, not with gasping and a discoloured visage, not with a strong clinging to life and mortal strugglings; it was rather the death of the aged and worn-out, almost a euthanasia. Phlogiston died as an old king, once infinitely dominant, somewhat tyrannical, not always just; now deposed, decrepit, utterly senile, forsaken by all, and ever harping upon his former glories. It was Lavoisier who founded the new dynasty, of which ours is as much a continuation as was the dynasty of Elizabeth of that of Henry VII. The times have changed, the *modus* of thought has changed, characteristic developments have assumed new features, and appeared with altered and contingent phases; but the basis is the same—it is firm and immutable as to its facts; and all philosophy, of what kind soever it be, all science, all social actions, are alone stable when they are founded upon the immutability of fact. We were glad to notice that M. Dumas made much mention of Lavoisier in his discourse; but not glad to observe that, while the names of Davy and Dalton were received with applause, that of Lavoisier was passed in silence. This is ungenerous and illiberal. We need not go quite so far as M. Wurtz, in his recent "History of Chemical Theory," but let us at least acknowledge to the full that which Lavoisier has done for chemistry. In neglecting him, we not only act unjustly, but we injure ourselves; for, did not Lavoisier confess himself the pupil of Black? And, as to the arrogance attributed to him in regard to the name of his chemistry, it seems to be forgotten that Fourcroy introduced the term *La Chimie Française;* it was a just term, and, till lately, no one has complained of it. Does not Davy speak of the "new French chemistry?" Let us forget these petty jealousies. The very institution of the Faraday lectures will, by establishing cordial unions between scientific men of foreign countries and those of our own, help to dissipate these feelings, and to produce a more complete *entente cordiale*. Meanwhile, let us express for Lavoisier, in the words of M. Dumas (in his admirable "Leçons sur la Philosophie Chimique"), "notre profonde admiration pour son génie, et notre douleur éternelle pour sa mort prématurée." And let us express, for M. Dumas himself, the first of these sentiments, and thank him for having come among us; this man, who was a great chemist before many of us were born; who, more than forty years ago, wrote a many-volumed work on chemistry, which has been the text-book of a generation or so of young chemists; and who has ever furthered and adorned our science.

A word or two, about the medal which accompanies the Faraday lectureship. Of the design, and the legend which accompanies it, we fear we cannot speak in great praise, and therefore shall not speak at all; but some may be interested in knowing that the medal is to be struck in palladium, and that a quantity of this rare metal, sufficient for the medals of at least ten years to come, has just been presented to the Chemical Society by an eminent metallurgical firm. And, *apropos* of this, we may mention that M. Dumas carries back to France with him, in addition to the Faraday medal, a medal of the alloy of palladium and hydrogenium to commemorate the discovery of the latter by the Master of the Mint.

It is a matter of much satisfaction to know that at length steps have been taken to provide a memorial to Faraday in another form. While the lectureship and medal are the special memorial of the Chemical Society, this is to be the memorial of the country at large, and it is proposed that it should take the form of a statue. That the Government have held aloof from taking any part in this memorial is much to be regretted, but the Chancellor of the Exchequer has stated that he is only following precedent in not allowing public monies to be expended on a memorial to a "private citizen." But was Faraday a *private citizen?* In one very limited sense, indeed, he was, but, in point of fact, he was a cosmopolitan. "Faraday," said M. Dumas, "n'appartient pas seul à l'Angleterre,

il appartient à tout le monde." A private citizen! Who has worked more for the public good? Who has more promoted works for the weal of his country, for the welfare of his race? We hope that not only the scientific men of this country will promote the Faraday memorial, but that the whole country will subscribe to it, and that we may have not alone a statue to this great man, not alone the lectureship and medal, but some greater work, and we would suggest, as we have before done, that it should take the form of a Public Laboratory, which would afford to those who have longings for science, but who lack opportunity, a means of satisfying the yearnings of their genius. To those who "fall gloriously fighting" in the service of their country,—to those who in the Senate have promoted large interests, successful negotiations, an honourable peace, or a triumphant war,—the country and the Government never fail to raise memorials, and to give honour: let them honour him who, working quietly, and steadily, and firmly, has added so much to the internal wealth of this country, so much to the scientific literature of the world. Faraday ever held in his hand "Lampas investigationis, non torris contradictionis," and the bright steadfast light illumines all that he did, and enveloped him as he passed untimely from our sight.

ON THE

ATOMIC WEIGHTS OF GOLD, PLATINUM, IRIDIUM, OSMIUM, RHODIUM, AND PALLADIUM.

By W. M. WATTS, D.Sc., F.C.S.

THE atomic weight of gold was determined by Berzelius from the analysis of its double chloride with potassium. He obtained, as mean result, the number 196·67, which was calculated from the weight of potassium chloride left, assuming its atomic weight = 74·57. My pupil, Mr. R. A. Jones, has pointed out that, since Berzelius determined in each case not only the potassium chloride left, but also the metallic gold set free, we have data for calculating both the atomic weight of gold and also that of potassium; so that, by comparing the atomic weight of potassium calculated from Berzelius's numbers with that given by the marvellously accurate researches of Stas, we are able to estimate the degree of accuracy of Berzelius's results. Berzelius obtained (*Lehrbuch der Chemie*, iii., 1212), in four experiments, the following results:—

	$AuKCl_4$. Grs.		KCl. Grs.		Au. Grs.
(1).	4·14450	gave	0·81850	and	2·15900
(2).	2·24950	,,	0·44425	,,	1·17200
(3).	3·41300	,,	0·67400	,,	1·77725
(4).	4·19975	,,	0·82950	,,	2·18800

Calculating from Stas's number for chlorine, viz., 35·457, we obtain the following atomic weights for potassium and gold:—

No. of Experiment.	Atomic weight of Potassium.	Atomic Weight of Gold.
1	39·149	196·79
2	39·166	196·87
3	39·088	196·57
4	39·176	196·86

If we select experiments 3 and 4 as the best, and take the mean, we have K = 39·132, and Au = 196·71.

The extremely close agreement of the numbers for potassium with that given by Stas, viz., 39·133, can be considered as little less than marvellous, and may, I think, be regarded as investing the atomic weight of gold with authority scarcely less than could be obtained by a repetition of the determinations, with all the minute precautions which Stas employed in his experiments.

It must not be forgotten, however, that in this way we check only the accuracy of manipulation, but obtain no evidence of any error arising from impurity of the metal employed.

I have applied the same criticism to the results obtained in precisely the same way for platinum, iridium, osmium, rhodium, and palladium, none of which, however, exhibit the accuracy of the gold determinations; and the best result is probably obtained by calculating from the atomic weight of potassium chloride instead of from chlorine alone.

The results are subjoined—

	Calculated from Cl = 35·457.		Calculated from KCl = 74·59.	Authority.
Platinum	K = 39·35	Pt. = 197·75	Pt. = 197·18	Berzelius
Iridium	K = 39·39	Ir. = 197·54	Ir. = 196·87	,,
,,	K = 39·87	Ir. = 198·56	—	Claus
,,	K = 39·93	Ir. = 196·62	—	,,
Osmium	K = 39·28	Os. = 199·42	Os. = 199·03	Berzelius
Rhodium	K = 39·12	Rh. = 104·21	—	,,
,,	K = 39·89	Rh. = 104·76	—	,,
Palladium	K = 39·62	Pd. = 107·19	Pd. = 106·57	,,

ON THE

ACTION OF HYDROCHLORIC ACID ON CODEIA.*

By AUGUSTUS MATTHIESSEN, F.R.S.,
Lecturer on Chemistry in St. Bartholomew's Hospital,
and C. R. A. WRIGHT, B.Sc.

CODEIA was sealed up with from twelve to twenty times its weight of strong hydrochloric acid, and heated to about 140° for two or three hours. After cooling, a layer of colourless liquid was observed floating on the top of the brown tarry contents. It immediately became gaseous on opening the tubes, and was presumedly chloride of methyl, as the issuing gases were found to be free from carbonic acid. The residue in the tubes, when dissolved in water and precipitated by carbonate of sodium, yielded, on extraction with ether and agitation with hydrochloric acid, a crystalline chloride, having when purified by recrystallisation, all the properties of the chloride of apomorphia derived from morphia. It gave the same qualitative reactions, produced the same remarkable physiological effects, and yielded numbers on combustion with chromate of lead and oxygen agreeing with the formula $C_{17}H_{17}NO_2HCl$. Hence the reaction which takes place is in accordance with the formula—

Codeia. Apomorphia.

$$C_{17}H_{17}CH_3HNO_3 + HCl = CH_3Cl + H_2O + C_{17}H_{17}NO_2.$$

Manufacture of Sugar.—The *Journal des Fabricants de Sucre* states that experiments are now in progress in some French colonies, to try, on the large scale, Messrs. Rousseau and Bonnaterre's plan of converting the saccharine juice of cane or beet-root into a peculiar saccharate of lime, and to transport that salt, instead of raw sugar, for the purpose of refining. It is said that this compound is as hard as sand, and can be transported without the risk of damage and injury sugar is subject to, and be kept for any length of time.

* Abstract of a paper read before the Royal Society, June 10th, 1869.

CONTRIBUTIONS TO ANALYTICAL CHEMISTRY.*

By DR. E. FLEISCHER, of Dresden.

NORMAL LIQUIDS FOR VOLUMETRIC ANALYSIS.

IN the greater number of analytical examinations of free acids and alkalies, the rule is to employ a normal acid, and a normal solution of caustic potash, and also a ten-fold dilution of them (1-10th of the normal liquids). In choosing the most appropriate acid for this purpose, it must be taken into consideration that it should form with alkalies or alkaline earths only soluble salts, in order that certainty in discerning the change of colour in the liquid under examination—which is coloured with litmus—may not be injured by precipitates, and also that the carbonates of the alkaline earths may be perfectly transformed by the normal acid. On this account, nitric acid is much more useful as a normal liquid than sulphuric or oxalic acid; but hydrochloric acid is quite as appropriate as a standard solution as nitric acid, and more so, inasmuch as it is more easily obtained pure, and is more constant to one standard, while nitric acid is generally more or less contaminated by nitrous acid. Another advantage possessed by hydrochloric acid is, that the acid contained in it may be not only estimated alkalimetrically, but also quickly and exactly by a standard silver solution, a trial which is impossible in the case of nitric acid.

With regard to volatility, it is to be mentioned that hydrochloric acid, diluted to one-fifth of the normal strength, when heated for ten minutes, whilst replacing the evaporating water, will not impart the slightest tinge of red to a blue litmus paper held in the vapours evolved, and, as in alkalimetric investigations the dilution is much greater, there need not be any fear of ever driving off the free acids by digestion. Moreover, since the constancy of normal hydrochloric acid is so great that, after keeping for months, the slightest change can scarcely be perceived, provided it has been preserved in bottles well closed with glass stoppers, no impediment exists in this respect to its employment as a standard liquid.

It is well known that many chemists besides myself have performed these experiments successfully with normal hydrochloric acid, and that, in all alkalimetrical determinations, they already use it instead of normal sulphuric or oxalic acid; it is hoped, therefore, that these remarks will suffice to demonstrate the utility of this testing liquid.

The second important normal solution for analysis by saturation is normal caustic potash or soda. These caustic liquids should be completely and absolutely free from carbonic acid, and, in order to prevent them from absorbing this gas from the air, a mixture of Glauber's salt and caustic lime is employed. This is contained in a tube fastened into the stopper of the bottle which contains the alkali; but this precaution does not always suffice to retain the solution of caustic alkali perfectly free from carbonic acid, for it almost always happens that an addition of a solution of chloride of barium to it produces a precipitation of carbonate of baryta in greater or smaller proportion. The preservation of caustic alkali by this means is also inconvenient, as, on account of the syphon in the bottle, it requires to be placed over the working bench, and can, therefore, only be protected from the dust by a special cover. To these drawbacks may, perhaps, be ascribed, in technical laboratories, the frequent substitution of the more easily preserved, though less appropriate, solutions of carbonate of potash or soda for the caustic alkaline solution as a normal standard liquid.

All these inconveniencies, which exert more or less influence upon the exactitude of estimation, may, however be remedied by employing, instead of the normal potash or soda solution, caustic ammonia of half the normal strength. Of all caustic solutions, caustic ammonia displays the most complete indifference to carbonic acid; so complete, in fact, that a flask half filled with half-normal ammonia, well closed with a glass stopper, and which was frequently opened for estimations to be made, gave such slight indications of carbonic acid after three months' preservation, that, upon half filling a large test-glass with it, and adding some drops of concentrated acetate of lime, no perceptible turbidity ensued, even on heating; whereas two bubbles of carbonic acid gas introduced into it from a gasometer instantly produced a considerable deposit. Moreover, the standard of this half-normal liquid was so slightly altered during the three months, that 1-10th c.c. of a tested normal muriatic acid was scarcely less saturated by 50 c.c. of it, than would have been necessary by an exact standard.

It follows from these experiments that the half-normal ammonia liquid is at least as useful in acidimetrical work as the best caustic potash solution; besides which, the former has the advantage of being conveniently preserved, and of being easily obtainable chemically pure.

With respect to the importance of the appearance of a blue colouration of the litmus by a liquid reddened by free acid, so as to fix the final reaction in analysis by saturation, the following is worthy of remark:—

Cold diluted (to at least 1 : 10) solutions of neutral sulphate or nitrate of ammonia scarcely produce any perceptible change in blue litmus paper—at any rate, much less than that produced by the introduction of two bubbles of carbonic acid. Sal-ammoniac reacts, under these circumstances, as neutrally as chemically-pure chloride of potassium, or chloride of soda; and a single drop of half-normal ammonia produces in such litmus-coloured solutions a strong and lasting blue colour, slightly inclining towards violet.

Hot solutions of the ammoniacal salts in question, and especially sulphate of ammonia, act upon litmus in a somewhat acid manner, about the same as free carbonic acid; hence it follows that, in all estimations by ammonia, the liquid to be tested should be cold. Should it have been previously heated, it is advisable that it should be cooled as much as possible by first exposing it for some minutes to the air, and then setting it in cold water. If this be attended to, the distinctness of the tint will leave nothing to be desired. The objection may be raised, that ammonia cannot be employed, like potash or soda, as a normal, but only as a half-normal, liquid; the relation of the base to the acid as 2 : 1 is, however, more advantageous to the exactness of the determination than if both fluids possessed the same equivalents.

As all volumetric estimations, excepting those of such caustic liquids as caustic soda, potash, baryta, and ammonia, are finished by re-estimating the acid with ammonia, and, as 1 c.c. of normal muriatic acid corresponds with 2 c.c. of half-normal ammonia, the re-estimation is much more exact than if solutions were used containing equal equivalents. The usual 1-10th normal solutions may also hereby be dispensed with in almost all cases, if the experiments be carefully carried out. These remarks will demonstrate that I can specially recommend the employment of half-normal ammonia and of normal muriatic acid as standard liquids for analysis by saturation; at the same time, I may observe that, for testing acids combined with metallic salts, I employ normal potash, supersaturating with a measured quantity of muriatic acid the free potash present in an aliquot part of the filtrate, calculating the combined acid after removing the carbonic acid by heat, and re-estimating with ammonia.

The standard of the normal muriatic acid is ascertained by a weighed amount of pure carbonate of lime, slightly heated. The best way to preserve both liquids is in well-closed flasks, with glass stoppers. They should be placed in a cool place, free from dust. In hot summer weather, the flask containing the half-normal ammonia should be placed in cold water, which should be renewed daily, because a continued temperature of 25° C. will alter its standard, though only in a slight degree.

ON THE

EXAMINATION OF WATER FOR ORGANIC MATTER.*

By R. ANGUS SMITH, Ph.D., F.R.S., &c.

(Conttnued from page 282.)

Let us now consider what does take place during putrefaction. In all cases known to me, the first thing that occurs is the diminution of oxygen in the air absorbed by the water, and, to a more or less extent, the production of sulphuretted hydrogen, which, however, may exist in the water to a very small extent at a time, being rapidly converted into combined sulphuric acid when oxygen can be found for the purpose.

In Loch-Katrine water, the oxygen found in the absorbed air, by Dr. Peany, was equal to 31·69 per cent; that of the Manchester water is equal to 27 per cent. In the Liverpool water, at the bottom of the reservoir, the amount fell to 12 per cent, being equal on the surface to the Manchester. In the first case, as well as in the second and similar cases, the amount of oxygen is too great to allow of putrefaction; and in the third case it was very clear that the oxidation was a process of decolourisation, at least in part, whatever else may have occurred. This decolourisation is caused by the oxidation of the *humus* and its removal as carbonic or other acid.

The gases of pure water contain nearly 34 per cent. of oxygen.

Dalton found cistern-water almost entirely deprived of its oxygen; and I have found every percentage of oxygen from 34 downwards.

I go further into this point in my chapters on water, which I hope to bring out soon. Meantime I may say that the examination for oxygen is a very important one.

Another important feature in putrefaction is the occurrence of carburetted hydrogen. The carbonaceous or organic compound, having lost the ties that bound it together, is broken up into fragments. The carbon, when it can find oxygen, goes off in its company, but otherwise it leaves with hydrogen; separate, however, it must, and that with considerable violence. When there is a great amount of oxygen these decompositions of organic matter do not take place; and even if the Loch-Katrine and other water were largely supplied with organic matter, putrefaction would be entirely absent, as it now is, as long as the high amount of oxygen was kept up in continual presence.

That organic matter does exist in peaty water to a larger extent than in streams not peaty, but still offensive, may be taken for granted. A very brown water contains about four grains per gallon. It is extremely dark, indeed, if there are six grains; but, without peat, putrefaction, or, what is still worse, the development of mischievous germs, may occur, whilst in the other they seem stifled. How far this disinfecting and preserving quality of peaty matter will act in weak solutions I cannot tell; but in its greatest strength (that is, surrounded by the matter of the peat itself), preservation may exist for an indefinite time; and the non-occurrence of putrefaction in weaker solutions may be considered sufficient to show that there is abundant antiseptic power for the amount of matter to be preserved in these waters.

But the question still arises, what is this organic matte containing nitrogen? If it is albumen it is disinfected, if the peat is great in amount; and it is incapable of putrefaction, if the oxygen is great.

We are not perfectly sure that these ammoniacal humates of Mulder's actually exist in the form he mentions. It may be that the nitrogen is otherwise combined, giving another mode of explaining the conditions of the water. If they are combined, as Mulder believes, we have only to allow oxygen to enter the brown water and be absorbed, a process which readily occurs; the *humus* is bleached, and the ammonia is free to combine with carbonic acid, and readily to dissolve a fresh portion of the same salts of which it formed a part. If the nitrogen be otherwise combined, whether as albumen or any similar substance, the oxygen would still play a corresponding part.

By this view of the subject, the brown waters would be giving off carbonic acid, freeing and losing some carbonate of ammonia. When oxidation takes place, a certain acidity is found, coupled with a little bitterness, a quality possessed by great portions of the waters of the hills. This, I believe, occurs in those waters which have not been purified by descending deep into the earth (where thorough oxidation and sweetening take place), but which have passed only over the surface, and been partially oxidised. The complete oxidation produces carbonic acid; the restricted oxidation an acid that is not volatile, and is extremely bitter. I have prepared so little of this, that I am unable to give a good account of it. It was formed from extremely brown water, chiefly from the river Avon, in Lanarkshire. By its formation, the water became very bright; when boiled down, the acid became stronger to ordinary tests, and its bitterness became more intense.

I may remark, by the way, that in all the bottles in which this occurred there was a deposit of very fine flakes of silica, leading me to think that, by our usual modes of estimating that substance, we were apt to make the amount too small. I believe this acid to be the origin of that bitterness which I have so often observed on the hills; and even in the very brilliant water from the hills, the two processes have been going on at the same time—the formation of carbonic acid and the formation of the non-volatile acid.

Apparently there are times, perhaps flood-times, when the water does not become oxidised so much as usual; and then we find the bitterness as a result in a greater degree. Although I had observed this for many years, I had not known that the effects might be hurtful to those who drank the waters. I met this year, accidentally, at Oban, Professor Frankland, who told me of some gentlemen who had been very much inconvenienced and who actually took supplies of spring water with them to Inverness, at which place they had found the river to cause diarrhœa. I am not aware that this disease is more frequent at Inverness than elsewhere; but the water, or at least the substance in it, to which I allude, seems to be unwholesome to those who have not been accustomed to use it.

Chloride of calcium is observable in water from the clay slates of the west of Scotland, at least in some places. It is found also in Loch-Katrine water, although I have not seen it mentioned.

For some years I was inclined to believe that the bitter taste was owing to these salts, until I found it increased by oxidation. I am not prepared, however, to say that they are incapable of modifying the taste, although they exist in quantities very minute.

Taking this view of the case, water collected in the mountains is very different from that which has run down into the plains. The age of the water also is a matter of importance, and if kept long in deep reservoirs or in shallow reservoirs.

If in shallow reservoirs, the water may be uniform throughout; if in deep reservoirs, the oxygen may never be able to permeate to the bottom. At a depth of twenty feet I have found more than twice as much organic matter than was to be found on the surface, whilst the lower specimen was of a much deeper brown. This was in the Rivington reservoirs, as already said.

Water that comes down very rapidly may never be able, in a practical period, to have the organic matter thoroughly

* From vol. iv., 3rd series, of the *Memoirs of the Literary and Philosophical Society of Manchester*. (Communicated, with emendations and alterations, by the author).

oxidised. Water which purls down rather slowly, falling, nevertheless, over many rocks, is always clearer, although the reason partly of this is, that such water is not surface only, but has drained through the soil.

Peat itself, if distilled with fixed alkalies, gives out ammonia. I suppose there is no doubt that some of this arises from the decay of vegetable albumen, some of which may be retained in the peat; but its mode of decomposition is still a problem; it seems to take place chiefly by oxidation, not putrefaction. I was inclined to think that a notable amount of the ammonia might be taken by the acid waters direct from the atmosphere.

But the smoke of peat, or rather the oily matter deposited by the smoke, contains nitrogen compounds, very probably the bases obtained by the decomposition of that vegetable albumen, which will not enter into fermentation, or expand itself into the lower and dreaded organised forms, although compelled to yield to the action of fire. This shows that all the nitrogen does not exist as ammonia. Although Mulder is highly to be honoured for the work performed in endeavouring to elucidate the subject, and especially the question relating to *humus*, it is not easy to agree with him. If, however, any one would begin where he has left uncertainty some reward would be found.

I give a few quotations from Mulder's "Physiological Chemistry," first German edition:—

"I repeat that the ammonia in the soil, as in the natural saltpetre-grottos of Ceylon, is formed from the atmospheric air, the oxygen of which, instead of forming nitric acid, changes the organic substances into ulmic acid, then into humic acid, geic acid, apocrenic acid, and into crenic acid.

P. 158. "This formation of ammonia from the constituents of the air and water is of the highest importance for the growth and success of the plant. It is the cause which converts the insoluble organic constituents of the soil into soluble substances, and thus presents them to plants as organic food, even when no ammoniacal manures are added besides to convert the five mentioned acids into soluble salts of ammonia."

P. 166. "Ulmic, humic, and geic acids, however formed, possess the power of absorbing ammonia and water to the extent of several per cent. The quantity given out (at 140° C.) is between 8 and 16 per cent. It requires 195° to free them from water."

P. 167. "The power of ulmic, humic, and geic acids to condense ammonia is so strong, that the acid made by acting on sugar with hydrochloric acid almost always contains ammonia if air is not kept away."

P. 169. "These acids combine so intimately with ammonia, that they have the character of an organic compound of four elements; by treatment with potash at a higher temperature they lose the ammonia completely."

In the "Handwörterbuch der Chemie," under "Humus," it is said that by constant digestion with hydrochloric, acid, ammonia was not removed. It is also added that, boiled with an alkali, the ammonia is not removed.

This accounts for the opinion held by Berzelius and others, that nitrogen existed in these earth acids; and certainly it is not clearly shown that they are only ammoniacal salts.

Berzelius gives Hermann's old analysis of crenic acid as containing nitrogen; and until we can finally settle the composition of these substances, we may be allowed to doubt. Whatever the compound be which contains nitrogen, its disinclination to putrefy must lead us to believe that even the organic nitrogen is not a measure of the dangerous quality of water, whether that nitrogen exist in a non-putrescent condition or association of the albumen, or in a substance removed a step from albumen and passing downwards to a condition more allied to the idea of an inorganic body. My own belief is that part of the ammonia is in combination with earth acids, and part of that which we find is obtained by destroying an albuminous substance rendered non-putrescible by its surroundings.

I have given my reasons for believing that neither the nitrogen of ammonia nor the other nitrogen found in peaty water can be taken as the indication of the amount of putrescible matter. At present, I believe, we have no idea of the actual relation in which it stands to health. It will be interesting to know now if the nitrogen of the nitrates and nitrites is at all similar. These salts are not formed when putrefaction is going on rapidly. The reason is very simple: the water is then deprived of its oxygen. We do not know all the conditions of the formation of these salts; but one is essential, that oxygen shall be present.

In the Thames water, at least two miles below and above Hungerford, there was nitric acid in considerable abundance in 1848. It is mentioned, in evidence given in a parliamentary inquiry twenty years before that, that red fumes rose on heating the deposit. I quote from memory.

In 1848 this was certainly the case. In later analyses, by Dr. Hofmann, the nitric acid was not mentioned. I considered this at the time a mistake; and I examined the water again, finding, however, extremely little nitric acid, and, I believe, in some cases none.

Having examined other putrid streams, and found no nitric acid, I conclude that it had disappeared from the Thames also when it became more impure than previously.

During the time that river was so offensive near the Houses of Parliament, the organic matter must have wholly, or nearly deprived of its oxygen the air in solution. Running streams, however, do not, so far as I know, contain much nitric acid; that substance is formed in greatest quantity by the action of porous bodies. The oxidation is assisted by the pressure to which the gas is exposed by being brought in contact with a great amount of surface, as well as of numerous surfaces contributing to the result. For these reasons nitrates are found best in soils through which azotised matter in solution is slowly passed.

I had occasion to make experiments on this point, and showed, in a paper to the British Association, in 1848, that a filter might be made to form nitrates from putrid matter.

An interesting question arises—Does the nitric acid indicate the amount of organic matter which was previously in solution?

If nitrates are put on land, they are decomposed by vegetation, and the nitrogen is retained. These salts act both as food and air to plants. The water which flows from drained land may contain nitrates, but they are not a measure of the amount put on the land; and if they result from the organic matter there, they are still not in proportion to its amount, as, even after they are formed from vegetation, they may be decomposed by it.

Nitrogen, therefore, may be removed from water either as ammonia, or organic matter, or nitric acid, every trace of it finally disappearing. Those nitrates, however, which do remain indicate that at least an equivalent of albuminous matter or sewage matter did exist.

Another interesting question occurs—Is the nitric acid removed without vegetation? I believe that it is so.

In water from drained fields vegetation is generally found, though frequently in very small quantities. In the soil around drains it is found in considerable quantities; but after putrefaction has occurred in the Medlock, at Manchester, I have not found it. The oxygen seems to be removed as the oxygen of the air is, probably leaving nitrogen to pass off as gas.

As the nitric acid indicates an equivalent of albumen, I have put it down as telling us of the previous presence of organic matter; in other words, of old organic matter. The word "old" has no relation to time, except so far as to mean older than that from which the nitrites are formed, and the original organic matter. The nitrites,

not being fully oxidised, are supposed to be in the process of becoming nitrates. They have been taken, therefore, as indicating recent organic matter,—the word "recent" meaning only that they stand between the organic matter and the nitrates. I do not know that nitrates are converted into nitrites in water. Still it may be found to be so.

It may be asked,—If the nitrates are not a proof of albuminous matter, whence do they come? If it is said from the air, as Mulder would bring them, we need a proof; if from ancient remains, we need a proof; but we need no proof that they can come from albuminous substances. I believe they come from both animal and vegetable matter, so that decomposing roots and plants will send out some; but animal matter is the richest source. We have animal sewage and vegetable sewage. The latter is capable, as is well known, of doing much evil—perhaps not so much as the former, although this is uncertain. It does not seem proved that grass itself will not give nitrates. Yeast produces them. If vegetable and animal albumen are equally bad, we need not care as to the distinction of source; if nearly equal, we may care but little.

In looking for organic matter, I think it quite unsafe to trust either to chemistry or the microscope, without giving time for the development of all possible germs; but this is a point which demands a good deal of inquiry. Microscopists have given us details of appearances; but these have not been sufficiently classed; and the conclusions drawn have, therefore, not been valuable to the desired extent. To trust to the microscope without time for development, is to believe that the germs of disease can be seen. The use of allowing water to stand is not that the germs of disease may be seen, as we do not know them if we see them, but to see if the matter is active. The value of this must be tested.

The loss of the oxygen with peaty matter and no vegetation indicates, as already said, the formation of carbonic or a bitter acid. The loss of oxygen with the evolution of sulphuretted hydrogen indicates putrefaction; but there are two conditions which externally resemble each other very much, namely, the growth of vegetable matter with diminished oxygen, and the growth of vegetable matter with excess of oxygen. Water in the first of these conditions, too, may contain, as I imagine, the most dangerous ingredients: germs of all diseases may exist in such waters; we do not know to what extent; and, as we are very ignorant on the subject, it is well to be alarmed at the conditions, until we have examined them and made distinctions.

We do not know very much about the second of the two; and if I think it less dangerous, it is perhaps more from a prejudice in favour of the abundance of vital air, and of those hill-waters which do not contain bitter peat than from any accurate knowledge which has been attained.

Weighing the Organic Matter.

If nothing apparently organic is seen, or if there be no time to allow it to germinate, we may try the following method. About half a gallon of water is boiled down in a platinum vessel; or if there are no soluble carbonates it may be boiled in porcelain and transferred with care, when only a few ounces are left, to a platinum or even to a small porcelain capsule. The residue is dried and weighed. It is then burnt so as to oxidise the carbon, and weighed again; the difference gives the organic and volatile matter of the residue. 212° F., or 100° C., is not sufficient to remove all water; but as it is a temperature so easily obtained, it is convenient to consider it enough, especially as we cannot obtain the organic matter by weighing with absolute exactness. We may obtain an excess of water by the use of 212°, on one side; but, again, organic matter begins to be given off from some residues even at that temperature; Professor Miller and others advise about 300° F. It is, at any rate, well to state the temperature in the account of the analysis. Both temperatures appear to me wrong, and so is every other I can think of. The results, however, of this method are very useful.

The burning must not be effected at a very high heat, or several salts will be decomposed or evaporated; but at best some will suffer; and the use of a little carbonic acid and water, or carbonate of ammonia, to restore the lost amount is advisable. A little distilled water and a few expirations into it through a glass tube will be sufficient for most cases; of course after this the ash must be heated again.

Professor Miller advises the addition of 0·3 gramme of carbonate of soda to a litre of water, or 20 to 25 grains to a gallon, making allowances in the weighing.

It is needless to remark that I consider Frankland's mode of obtaining carbon and nitrogen far superior to any weighing, when hands sufficiently delicate are found. By using larger quantities, there seems no reason for supposing that the process cannot be undertaken by men who cannot advance beyond average refinement of touch. Since this paper was read, about a year and a half ago, the Wanklyn process for nitrogen has been gaining favour in my laboratory, as the results obtained have been very constant.

(To be continued.)

PROCEEDINGS OF SOCIETIES.

CHEMICAL SOCIETY.

Meeting held at the Royal Institution, June 17th, 1869.

Dr. A. W. Williamson, F.R.S., President, in the Chair.

The minutes of the previous meeting were read and confirmed, and the following certificates read:—

For the first time—E. A. Blackwell, Analytical and Consulting Chemist, 6, St. Sacrament Street, Montreal, Canada.

For the second time—John Morrison, Analytical Chemist, County Wicklow, Ireland; W. G. Lewis, Fellow of Oriel College, Oxford; Alfred Dudley Keightley, Gatcheck Gunpowder Mills, Old Hall, Milnthorpe, Westmoreland.

The President then addressed the meeting as follows:—

The Society is here assembled to inaugurate what would be inadequately described as a monument in honour of Faraday. The Faraday Lectureship has been founded by the Council of the Chemical Society in the hope that it will promote the advancement of human knowledge, and surely no higher tribute of respect could be paid to a great man than to do in his name what he would have loved best to see done. Now, among the arrangements which are made for the promotion of interchange of ideas—ideas which are so essential to those who are working in the investigation of nature—there is one particularly important defect and shortcoming. We have books and papers which circulate throughout the length and breadth of the civilised world, and in each country there are Societies where men meet together to consider and discuss questions relating to science, and to aid and encourage one another in various ways. But these books and papers give but the skeleton of a science without that life and interest which is imparted to facts when communicated by a discoverer himself. And, on the other hand, Societies, although they do much for the promotion of science, leave still more undone. It is an essential of truly philosophical work that questions be viewed from various sides; and those who have followed with any attention the recent history of our young science, must have been struck with the variety of lines of thought followed simultaneously by independent workers—lines of

thought which finally converge in certain general truths; their convergence serving to corroborate the evidence of those truths, and to establish more perfectly the conclusions which are thus arrived at. Now, the greatest difficulty which is experienced, and the greatest defect which one observes, is this, that workers in one line of thought are too frequently ignorant, or insufficiently cognizant of what others are doing; and the defect shows itself chiefly between those who are working in different countries, more than between those who are working in the same country. Now, imagine that we could induce to come among us a man possessed of one of those master minds which forms a focus of light throughout science, and amongst all those who are interested in science: suppose that he were to tell us the thoughts which are uppermost in his own mind, and—best of all—that he were to make us for a time think with him in the very words of his own language: imagine that such a highly gifted man combined in his own person the genius of a discoverer, the breadth of intellect of a philosopher, and the lucid fluency of an orator. I am sure that you would agree with me, that his visit would inaugurate something which Faraday would truly have rejoiced to see. Imagine, I say, those things: accurately fix in your mind's eye the image of such a man—and Dumas is before you! [Loud applause.]

M. Dumas, La Société vous reçoit comme le plus illustre representant du progrès de notre science. Nous sommes heureux et fier de vous avoir parmi nous,—heureux de vous voir et de vous entendre, fier de ce que vous êtes venu au nom de Faraday. Je vous presente cette medaille qui a été frappée en commemoration de votre visite, et je vous prie de conserver avec elle le souvenir de cette réunion.

M. Dumas's lecture* commenced with a brief *éloge* of his friend, the late Professor Faraday. The Lecturer then, with admirable eloquence, passed to the consideration, first, of what he termed "*la matière brute*," and of its forces; and, secondly, of organic matter and the forces special to it. He traced the origin of some of the more important modern chemical doctrines to the labours of the Greek philosophers, and identified the principle of the ancient classification into fire, air, earth, and water, with that of Lavoisier's chemical elements. He acknowledged his great admiration of the labours of Dalton and Prout, and in a most lucid manner pointed out relations between the atomic weights of the now received elements which led him to infer the probability of many of them having a common basis. The audience was reminded that many years ago M. Dumas had contended that organic bodies are constituted in a manner similar to mineral bodies, and he took occasion to show how the progress of chemical research had confirmed the truth of this view, he himself being disposed to limit the term "organic substance" to those very few compounds which take part in the growth of organised beings.

Professor Tyndall then spoke as follows:—Fellows of the Chemical Society, Ladies, and Gentlemen—It becomes my duty to ask you to return your best thanks to M. Dumas for the noble discourse which you have just heard; and I sincerely thank the President of our Society for giving me this opportunity of testifying to the respect and high regard which I personally entertain for our first Faraday lecturer, both as a man and as a philosopher. [Applause.] It is now, Sir, [turning to M. Dumas] one and twenty years since, in company with the gentleman who now sits at my side, I first heard your voice. It was in your own *College de France*, and to this hour I have not forgotten the impression that you then made upon me with regard to your clearness, your power, and your eloquence as an expositor of scientific truth. You then, Sir, were celebrated as an investigator, and, as I thought, you were in the very blossom of your strength; but, Sir, I was wrong. You have this night shown a vigour and a depth and a capability of grappling with great questions, such as I doubt whether you possessed in equal vigour twenty-one years ago. You have to-night, Sir, grappled with some of the weightiest questions which underlie both chemistry and physics, and which constitute, if I might be allowed the term, the very solder of the material universe; and you have, moreover, vindicated the claims of science to a higher recognition than that which may be fairly based upon the material results that flow from it. You have shown how it can connect itself with philosophy, and with the general culture of the human mind. Sir, the walls which here surround you are associated with immortal memories. For more than sixty years they have been accustomed to hear voices which have gone forth into all lands. They have heard the voice of the great Thomas Young, of Humphry Davy, and of Michael Faraday; and we, Sir, bid you welcome to the scene of their teachings and of their triumphs. [Loud applause.] We, Sir, wish with all heartiness that you may long preserve the vigour which you have here displayed to-night, employing it as you have just done, for the delight of your hearers, the honour of science, and the good of mankind. [Applause.]

Professor Odling: I feel it a great privilege, and at the same time a great difficulty, after the eloquent remarks of Dr. Tyndall, to second the vote of thanks to M. Dumas, which he has proposed. As an old officer of the Chemical Society I may say we all felt that we could not find a more fitting or more able inaugurator of the Faraday lectureship than M. Dumas; but we also found that we could not find anyone more willing—I might say more desirous—to make the sacrifice of time and convenience that was demanded of him in order to do honour to the memory of that great man whose name we are this night met to commemorate. I think, however, that our vote of thanks to M. Dumas for his eloquent address, and for his coming over among us to deliver it, must not be lessened by the consideration that it was impossible for him to surprise us, or at any rate those of us who know him, by any display of eloquence and any display of kindness, however extreme. I call upon you then, with every mark of enthusiasm, once more to show M. Dumas how much you appreciate his kindness in coming among us, and how much you feel the honour of his presence, and the benefit to be derived from his most eloquent address. [Loud and prolonged applause.]

The President: It is unnecessary to put the motion for it has been carried by acclamation.

M. Dumas replied in a short but eloquent speech, and the President announced that another meeting of the Society would take place at Burlington House, on the 1st of July, when papers will be read by Mr. R. H. Smith and Dr. Phipson.

* We have purposely given only a short notice of Professor Dumas's oration, as a verbatim report will appear in our next number.

CHEMICAL SOCIETY DINNER

On the occasion of the Inaugural Faraday Lecture by M. Dumas, June 18th, 1869.

In another part of this number we have given an account of the magnificent lecture by M. Dumas. We have here the pleasing duty of giving a brief account of the banquet given to the eminent philosopher and chemist on the evening after the delivery of his inaugural Faraday discourse. As may be supposed, there was a large attendance of Fellows of the Society, all of whom were anxious to do honour to the memory of Faraday, and also to show their esteem and admiration for one who was a personal friend of Faraday, and who occupies one of the highest p laces amongst our continental scientists, The chair was occupied by the President of the Chemical Society, Dr. A. W. Williamson, F.R.S. The following is the list of stewards:—F. A. Abel, F.R.S.; T. Andrews, M.D., F.R.S.; E. Atkinson; J. Attfield, Ph.D.; J. Lowthian Bell; J. H.

Brazier; Sir Benjamin C. Brodie, Bart., F.R.S.; A. Bernays, Ph.D.; D. Campbell; F. C. Calvert, Ph.D.,F.R.S.; E. T. Chapman; A. H. Church, M.A.; F. Claudet; W. Crookes, F.R.S.; H. Debus, Ph.D., F.R.S.; Warren De la Rue, Ph.D., F.R.S.; F. Field, F.R.S.; G. Cary Foster, F.R.S.; R. Galloway; J. P. Gassiot, F.R.S.; J. H. Gilbert, Ph.D., F.R.S.; J. H. Gladstone, Ph.D., F.R.S.; T. Graham, D.C.L., F.R.S; G. Griffith; F. Guthrie, Ph.D.; A. V. Harcourt, F.R.S.; D. Hanbury, F.R.S.; C. Heisch; F. C. Hills; T. H. Hills; Dr. Holzmann; Sir Robert Kane, M.D., F.R.S.; J. B. Lawes, Ph.D., F.R.S.; G. D. Longstaff, M.D; A. Matthiessen, Ph.D., F.R.S.; J. Mason; H. Medlock; W. A. Miller, M.D., LL.D., V.P.R.S.; T. Morson, jun.; H. Müller, Ph.D., F.R.S; S. Muspratt, Ph.D.; E. C. Nicholson; H. M. Noad, Ph.D., F.R.S.; W. Odling, F.R.S.; J. D. Perrins; W. H. Perkin, F.R.S; Lyon Playfair, C.B., M.P., Ph.D., F.R.S; D. Price, Ph.D.; E. Ronalds; E. Schunck, Ph,D., F.R.S.; E. Schweitzer; P. Spence; R. Angus Smith, Ph.D., F.R.S.; J. D. Smith; J. Stenhouse, LL.D., F.R.S; A. Smee, F.R.S.; A. Smee, jun.; J. C. Stevenson; C. Tomlinson, F.R.S.; J. L. Thudichum, Ph.D.; R. V. Tuson; J. Tyndall, LL.D., F.R.S.; J. A. Voelcker, Ph.D.; P. J. Worsley; G. F. Wilson; J. Williams; Col. P. Yorke, F.R.S. After the usual loyal toasts, the Chairman eloquently proposed the toast of the evening, "The Health of Professor Dumas," and spoke of his high scientific skill and attainments in terms which were enthusiastically received by the company; and the health of the guest was drunk with the usual honours and amidst tremendous applause. M. Dumas replied in a fluent and brilliant speech, in which he alluded with great pathos and feeling to Faraday, and also spoke of the pleasure it gave him to accede to the invitation of the President and Council to deliver the inaugural Faraday Lecture. Several other toasts followed, which were appropriately acknowledged, and the speeches were interspersed with a selection of music performed by the band of the Coldstream Guards. The arrangements were exceedingly good, and the way in which they were carried out reflects great credit on the executive committee. The evening was a most agreeable one to all present, and we hope that M. Dumas will long remember the delight and enthusiasm with which he was welcomed to the scene of Faraday's labours. We are certain that the Society will never lose the remembrance of his grand and stirring oration, which will always be associated with the courtesy and kindliness displayed by the Master of the French Mint during his short visit amongst us. It only remains for us to hope that for many years we may gain as much pleasure and profit from the Faraday Lectures as we have from this—the inauguration of our memorial to England's great philosopher.

PROPOSED MEMORIAL TO FARADAY.

On Monday last, a public meeting was held in the theatre of the Royal Institution, Albemarle Street, for the purpose of considering what measures shall be taken for the promotion of a memorial to Professor Faraday, whose voice was so often heard as a lecturer within those very walls. The chair was taken at half-past three by his Royal Highness the Prince of Wales, who was supported by M. Dumas, Count Strelecki, General Sabine (the President of the Royal Society), Sir Henry Holland (President of the Royal Institution), Sir Roderick Murchison (President of the Royal Geographical Society), Sir Charles Wheatstone, Professor Williamson, Admiral Manners, Colonel Yorke, Professor Frankland, Mr. De la Rue, Mr. Frederick Pollock, Dr. Gladstone, Mr. Cæsar Hawkins, Dr. Holtzmann, Dr. H. Bence Jones (Secretary to the Committee), Dr. Lyon Playfair, M.P., Professor Tyndall, Professor Graham (the Master of the Mint), Sir John Lubbock, Sir Benjamin Brodie, Mr. Gassiot, Professor Miller, and a number of other distinguished personages, both English and foreign. The Astronomer Royal, Sir John Herschel, the Marquis of Salisbury, Mr. Layard, and other gentlemen who had been expected, sent letters to apologise for their absence.

The proceedings were opened by His Royal Highness, who, in a few well-chosen words, expressed the pleasure which it gave him, both on public and on private grounds, to preside over such a meeting as the present, and reminded his hearers that, although he whom they had met together to commemorate had been dead for nearly two years, yet nothing had been done by the public as yet to perpetuate his memory. Early in 1868, the Council of the Royal Society requested the President to take measures for the holding of a meeting to promote a monument to Faraday, and, with that view, the Secretary was instructed to write to the presidents of the following societies:—The Royal Society, the Geographical, the Linnæan, the Geological, the Royal Astronomical Society, and the British Association. On the 24th of March, a meeting of the presidents was held, and it was thought desirable, before proceeding further, to learn the views of Her Majesty's Government as to the erection of a monument as a recognition of his pre-eminent services to science and mankind. On the 22nd of June, Mr. Disraeli desired his secretary to say that he considered a monument to Faraday a proper object; but he suggested that its consideration should be left till next year. In the present year, the present Chancellor of the Exchequer wrote saying that he had no doubt of the signal merits of Faraday, and he thought that a monument ought to be erected; but he could not consent to devote public money to a monument for a private citizen, however illustrious. He did not make this rule; he found it. On the 8th of June, it was resolved to hold a public meeting at the Royal Institution. Under these circumstances, the Council of the Royal Society, and the presidents of the various other learned societies, had resolved to take the matter seriously in hand without further loss of time, and the result was the present meeting, at which it gave him the greatest pleasure to take the chair.

The first resolution—"That it is desirable that measures should be taken to provide a public memorial to the late Professor Faraday"—was proposed in a short speech by General Sabine, who said that the Royal Society, over which he had the honour to preside, felt a pride and a pleasure in reckoning Michael Faraday as one of its members, and bore his testimony to the fact that, out of all its long list of Fellows, none had contributed such a valuable collection of papers to the *Philosophical Transactions*.

This resolution was seconded by M. Dumas, Senator, Member of the Academy of France, and Permanent Secretary of the French Institute. M. Dumas began by reminding his audience that Faraday, whose genius achieved so much in the cause of science, and, therefore, of civilisation generally, was one of the eight Foreign Associates of the Academy of Sciences of the Institute of France. He also said that it was with pleasure he himself had crossed the Channel to do homage to his memory, and that it was with a feeling of profound emotion that he now found himself standing in the place where his late great contemporary had stood so often. M. Dumas declared that in France Faraday commands as many admirers as in England, and that among these admirers the Emperor of the French stands foremost—so much so, indeed, that his Imperial Majesty never loses an opportunity of evincing his regard for the name of the great *savant*, after whom Paris had named a street, and whose discoveries have not only done honour to England, but have been of incalculable service to the interests of the world at large. M. Dumas then proceeded with great eloquence and perspicuity to touch in detail upon some of the scientific achievements of Faraday, and took occasion to observe that his genius, in its various applications of science to practical purposes, was distinguished by originality, not less than by profundity, instancing his condensation of gas into liquids, his manufacture of steel

and of glass, his magneto-electric currents which encircle the world in the telegraph wires, and his magneto-electric light, to be seen in the most important lighthouses of England and of France. M. Dumas wound up his speech by expressing, in a tone of deep emotion, his own personal regard for a man who was singularly distinguished by his virtues in private life. There were many present who sympathised with M. Dumas when he added that the world at large had cause to lament the loss of Faraday as one of the greatest philosophers who ever shed light upon it by the force of genius, but that he himself had still greater cause to lament in his death the loss of a friend.

Sir Henry Holland moved the second resolution,—"That the following gentlemen be a committee to take the necessary measures for the provision of the said public memorial in honour of Faraday: General Sabine, President of the Royal Society; Sir Henry Holland, President of the Royal Institution; Sir Roderick Murchison, President of the Geographical Society; Dr. Williamson, President of the Chemical Society; Mr. George Bentham, President of the Linnean Society; Mr. T. H. Huxley, President of the Geological Society; Admiral Manners, President of the Astronomical Society; Dr. W. J. Hooker, President of the British Association; the Right Hon. A. H. Layard, M.P., Mr. J. Fergusson, Mr. Gassiot, Dr. Tyndall, Mr. Grove, Dr. Frankland, Mr. De la Rue, and Dr. Bence Jones, with power to add to their number."

The resolution was seconded by Sir Roderick Murchison, who referred to the fact that in that very theatre, more than 60 years ago, he had seen Sir Humphry Davy make some of those experiments in electricity which now formed the basis of modern science; and that, standing on the very spot where the Prince now sat, Faraday year after year had carried on those experiments after his master's death, training two successive generations of disciples in the study of the laws of nature. He bore willing and grateful testimony to the extreme modesty and humility of the great man who for more than half a century had made that institution his home, and adverted to the fact that Faraday had first shown marks of his high genius within the walls of the Institution in the year 1823, when, Mr. Brande being taken ill and unable to lecture, the duty of lecturing suddenly devolved on his assistant, whose simplicity, sincerity, and genuineness of character even then had begun to make themselves felt, and were but an augury of his after life.

Professor Owen moved the third resolution, to the effect "That a subscription, not exceeding five guineas in amount from any one person, be made for the provision of a public memorial to Faraday." He prefaced this resolution by a few remarks, to the effect that the theatre in which they were assembled was redolent of Faraday and seemed haunted by his spirit. Great and deep as was the learning which he displayed as a lecturer, still his profound and subtle generalisations were almost exceeded by that playfulness of wit by which he raised the intelligence of his hearers without lowering himself from the height of his professional dignity. Of his genius they had heard already from M. Dumas; but enough could scarcely be said of his personal merits, his singular modesty, and that unconsciousness of genius which is so often combined with genius of the highest order, as in Wellington. Like him, Faraday sought no honours, and all that he gained came to him unsought; but Englishmen feel that they all have a share in the achievements of both, and the reputation of the great philosopher, like that of the great warrior, is reflected on all his countrymen. Those, therefore, who are devoted to science have a right to call upon not only men of science, but Englishmen in general, to acknowledge and to pay the debt which we owe to Faraday. Let us think what will be the feelings of a future generation who will look back to him as we look back to Newton. His discoveries of the grand secrets of nature have added to our stores of wealth and ministered to our comforts, and hereafter there will arise the feeling that we have not done as much as we ought for one who has done much for us. He then urged that Faraday and the Royal Institution were standing proofs of the results which could arise out of the voluntary system as opposed to State establishments. Faraday served a voluntary body—a "joint-stock company founded for the purpose of diffusing intellectual pleasure," and this body whom he served gave him a home in which he might carry out his experiments in the field of science. Late in life had come a public recognition of his services in the shape of a pension and a house at Hampton Court—the latter a free gift for life from his Sovereign. He observed that, as the introduction of the electric telegraph and gas had added to the conveniences and comforts of life, and had helped to diminish crime, the discoverers of such secrets of nature at the very least deserved some reward at the hands of those to whom they ministered—if not from the nation in its collective capacity, at least from its individual members; and he concluded his speech by remarking that, if any member of either House of Parliament should chance to be present there, he ought to take note of the right relations of the nation to men of science.

The resolution was seconded in a few brief but telling sentences by Dr. Lyon Playfair, M.P.

The three resolutions were severally put to the meeting by his Royal Highness, and declared to be carried unanimously.

A vote of thanks to the Prince for his kindness in presiding over the meeting and for his conduct in the chair was proposed by Sir Henry Holland and seconded by Professor Tyndall, who spoke with great feeling of the loss which both himself and the nation had sustained in the death of Faraday, and alluded to the fact that on that occasion the Prince had been among the first to write to condole with his widow. The motion was carried with great applause.

Dr. Bence Jones then read a letter from Sir John Herschel, excusing his absence on the ground of illness; it ran as follows:—

"I grieve to say that I can only be present in spirit at the meeting of next Monday, the state of my health being such as to preclude my leaving home for many months, most anxious though I should naturally be to show every possible reverence and honour to the memory of such a man as Faraday, whom I have always regarded as the "blameless prophet" of British science—so clear and far-reaching was he in his views, so indefatigable in their pursuit, so single in his objects, so blameless in his life, so genuine, candid, and unaggressive in all his relations with his brother *savans*."

The Prince briefly acknowledged the vote of thanks, and assured the meeting that he should be proud to lend his aid to the cause which they had met to promote, and it was announced that subscriptions to the "Faraday Memorial Fund" might be paid in at the Bank of England, Western Branch, Burlington-gardens; the London and Westminster Bank, St. James's-square; to Mr. William Hughes, at the Royal Institution, Albemarle Street; or to any members of the committee.

LABORATORY NOTES.

BLOWPIPE REACTION OF THALLIUM.

When either oxide of thallium is melted with borax, it gives a clear, colourless bead; but when this is kept for some time at a heat much below redness, the outside turns deep brown, owing to the formation of thallic oxide. On raising the temperature, it is again reduced to thallous oxide, small bubbles of oxygen are set free, and the bead again becomes colourless. I am not aware that any other substance behaves in the same manner.

H. C. Sorby.

CORRESPONDENCE.

ARTIFICIAL MANURES:

A COMMON SENSE VIEW OF THE PRECIPITATED PHOSHATE QUESTION.

To the Editor of the Chemical News.

Sir,—I have perused Mr. Hughes's paper with some interest, but more of astonishment. Is it or is it not the fact, that the greater part of the soluble phosphate of lime supplied to the soil in superphosphates is very speedily converted into precipitated or reduced phosphates, *i.e.*, insoluble in cold water? If it be a fact (and Mr. Hughes will hardly dispute it), why does he ask the manufacturer to make the farmer a present of some 3 to 6 per cent of valuable phosphates, for all intents and purposes of agriculture equal to soluble phosphates? Doubtless, Mr. Hughes is a very good chemist; but, in his zeal in combating the unfair use of oxalate of ammonia as a solvent for *reduced* soluble phosphates, he has rushed off to the other extreme. In his hot haste, and fresh from his "half-hours" of stewing coprolites, first with half their weight, and then with double their weight of oxalate, he rashly seeks to *rob* the manufacturer of his hardly-earned soluble phosphates! and, no doubt, the next farmers' club that sends a set of samples to Mr. Hughes for analysis will get them analysed on this principle. Nearly all superphosphates in good condition, from having lain long in the pile, contain more or less of this reduced soluble phosphate. Will Mr. Hughes or Dr. Voelcker contend that, because Mr. Chesshire has used a faulty process (if it be so), and, by boiling for half-an-hour, may have obtained more soluble phosphate from his samples than their respective bulks contained, that therefore the manufacturers are to be fined half-a-crown (or some such sum) per ton for every unit of soluble phosphate which has become reduced in the pile? This is a matter of very serious importance to manufacturers, and one which it behoves chemists, and especially so-called agricultural chemists, to settle.

May I venture to suggest that, if Mr. Hughes will abjure hot water in his examinations for soluble phosphates, he will get more correct results, and, if he had used a cold and very dilute solution of the oxalate, his experiments would then have been of more value. Again—for his own satisfaction, and by way of testing this matter—will Mr. Hughes perform an analysis of the clear solution obtained by pouring distilled water on to superphosphate on a filter; and then let him take another portion of this solution, and *reduce* the whole of the soluble phosphate by precipitating it with ammonia or lime-water. He will then have some precipitated phosphates on which to operate, and, if he will send you his results, I doubt not they will be of some practical value. He will then be able to say the minimum of oxalate of ammonia required to re-dissolve this phosphate, which he now wishes the manufacturer to give to the farmer for next to nothing.—I am, &c.,

Fair Play.

London, June 14th, 1869.

MISCELLANEOUS.

Death of M. Bérard.—We learn from the *Messager du Midi*, a daily paper published at Montpellier, that M. J. E. Bérard died in that city on the 10th inst., at the advanced age of nearly 80 years. The deceased, a celebrated chemist, was born at Montpellier on the 12th of October, 1789. He was first Professor of Chemistry of the Faculty of Sciences at Montpellier, and held simultaneously the Professorship of Chemistry of the Ecole de Pharmacie established in that city. For about the last twenty-five years he has been, first the active, afterwards honorary, Dean of the celebrated Faculty of Medicine of the University of Montpellier—a post of honour and influence—and he has been well known in various scientific circles. He was a member of several learned societies, the owner of large chemical works, and a man of independent means—a very courteous, but yet somewhat haughty, scientific diplomatist; he was a staunch upholder of the rights of the Université de France, and, at the same time, in politics a constitutional liberal. Those who have been personally acquainted with him, like the writer of these few lines, can testify that he was an eloquent and highly accomplished lecturer, an eminently successful experimenter, kind and forbearing with the students of his class, who, on an average, numbered from 1100 to 1800.

London Institution.—We have received the report of the above Institution, from which we find that it is proposed to adapt the chemical resources of the Institution to the practical teaching of chemistry. The following is an abstract of Professor Wanklyn's "Laboratory Report for the Session 1868-9":—"In addition to the annexed list of papers [a list of eleven papers follows, abstracts of which have appeared in our columns] from the Laboratory, it should be mentioned that a very elaborate memoir on the alcohols of fermentation, by my friends Messrs. Chapman and Smith, has been laid before a recent meeting of the Chemical Society, and is in course of publication in the "Journal." Much of the recent investigation has consisted in an elaborate confirmation of M. Wurtz's results—a circumstance which is not unimportant, regard being had to the great improvements in method which have been introduced since the date of M. Wurtz's investigation of butylic alcohol. The recent discovery of isomeric forms of the alcohols, and the exceedingly interesting structural differences presented by these isomers, give additional value to a careful study of a natural alcohol, such as butylic alcohol. The Royal Society has testified its approval of investigations such as this by making a grant of £50 to Mr. Chapman for the prosecution of researches of this character. In the paper entitled "*Researches on the Ethers*," read at the meeting of the British Association in Norwich, there is recorded a work in contradiction of a very important set of results published by eminent English chemists a few years ago. The result contradicted is, that an acetic acid had been produced in which part of the *radicular* hydrogen had been replaced by the metal sodium, so as to yield sod-acetic acid, or, more correctly, sod-acetic ether. It has been shown that, contrary to the assertion of two English chemists, there is no driving out of hydrogen by the action of sodium on acetic ether. As a consequence of the disproof of the elimination of hydrogen, a huge superstructure of unsound chemical theory has been destroyed. In conclusion, I would just call attention to the very interesting set of compounds—the salts of the new organo-metal, ethylene-sodium—which have been recently discovered in the laboratory of the Institution, and which are being investigated at the present moment."

Quantity of Water contained in Illuminating Gas.—During the months of February and March of the current year, the author (A. Vogel) instituted on various days, and at different hours during the day and night, experiments with the gas taken directly from the mains of the Münich Gas Works. By causing a slow current of the gas to pass through chloride of calcium tubes, the author found that the quantity of water contained in the gas varied from 0·06 to 0·11 grm. to the cubic foot; it is evident that this quantity may, and naturally will, vary according to circumstances. Dr. Vogel next made a current of gas pass through glass tubes placed in a freezing mixture; in this manner he obtained a quantity of ice formed by the freezing of the water contained in the gas; the water obtained on melting this ice had no action upon test papers. By means of Nessler's test, after previous addition of some caustic potassa to the water, ammonia was very clearly indicated to be present. Cyanogen was found therein by means of Schönbein's test-paper for this substance. When tested with indigo-carmine and sulphuric acid, the decolouration of indigo is observed, while an odour of nitrobenzol is emitted. It hence appears that there is nitrate of ammonia present, and that this is one of the products of the distillation of coal.—*Berichte der Deutschen Chemischen Gesellschaft zu Berlin.*

Testing Bees'-Wax.—It appears that both yellow and white bees'-wax is met with in the trade largely adulterated with paraffin. In order to detect this, the following process is recommended:—2 grms. of the wax to be experimented upon are placed in a test-tube; and there is added a solution, consisting of 1·5 grms. of solid caustic potassa in about 5 grms. of distilled water, and the mixture boiled, care being taken to shake the test-tube now and then, whereby a thorough though not quite clear mixture is produced. When the fluid has cooled so far down as nearly to reach the point of solidification of the wax, from 6 to 8 grms. of light oil of petroleum is gradually added, and this thoroughly incorporated with the entire mass, so as to form an emulsion, from which, if well made, the light oil does not separate. Next, an excess of an aqueous solution of acetate of lead is added, which is mixed with the mass by stirring with a glass rod. The addition of this lead salt causes the separation of the light oil of petroleum, and in it will be dissolved any paraffin present in the wax. The same operation is twice repeated with the contents of the test-tube, that is to say, petroleum is again and again added, and allowed to separate; the separated petroleum is placed into a retort, and the light oil removed by distillation. Pure yellow wax loses, by this process, from 14 to 16 per cent; but wax has been met which lost 57 per cent in weight; the specific gravity of the residue of adulterated wax was 0·88. When it is desired to obtain the paraffin in pure state freed from any dissolved wax, this may be effected by cautiously decomposing the wax supposed to be adulterated with paraffin, by means of fuming sulphuric acid, which does not affect paraffin.

The Zirconia Light.—The oxygen process of M. Tessie du Mothay, according to the Paris correspondent of the *British Journal of Photography*, consists in heating, in iron retorts divided in two by a horizontal grating, a quantity of manganate of soda. This is heated to a dull red, and a current of superheated steam is made to pass over the mass. Oxygen is given off in abundance, and passes along with the current of steam into a refrigerator, where the steam is condensed into water, and the oxygen is afterwards collected in a gasometer.

When no more gas comes off, the manganate is exhausted. The next operation is to re-oxygenise the exhausted manganate. This is accomplished by passing heated *air*, not steam, over it, when the manganate absorbs the oxygen, and becomes as ready as ever for yielding it again to the vapour of water. Thus, the two operations can go on for an indefinite time, the air being the source of supply of oxygen. It has been found that carbonic acid gas is detrimental to the production of oxygen, and so the air is deprived of this before it acts upon the manganate of soda. One advantage claimed by the advocates of the zirconia cylinders, besides their durability, is that a mixture of *equal* parts of oxygen and carburetted hydrogen can be used instead of a mixture in which oxygen is in excess, as is usual. The magnesia for the magnesian cylinders must be very pure, and free from silica, or they will not be durable under heat.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

In accordance with the generally expressed wishes of our friends and readers, we are endeavouring to effect arrangements to enable us to give, under the above heading, notices of EVERY CHEMICAL PAPER IN THE WORLD, *as soon as possible after publication. Whenever possible, these notices will appear in the form of carefully prepared, although necessarily brief, abstracts; as respects papers either too long or too abstruse to render condensation possible, their titles will be chronicled; and in all cases accurate reference will be made to the original publication. The two half-yearly volumes of the* CHEMICAL NEWS, *with their copious indices, will therefore be equivalent to an English edition of the "Jahresberichte," with the additional advantage of keeping the readers week by week on a level with the latest advances of science.*

Comptes Rendus des Séances de l'Académie des Sciences, Monday, June 14, 1869 (No. 24).

This periodical is entirely filled with the reports about the prizes and the distribution thereof. The greater part of the speaking at this meeting of the Académie devolved upon the eminent and eloquent speaker who honoured the Chemical Society with his excellent speech on the night of Thursday (June 17) at the Royal Institution in London, M. Dumas; and his eminent *confrère* as Sécrétaire Perpétuel, M. Elie de Beaumont, read the eulogium on the late M. Puissant, an excellent geodesist and late member of the Académie. Among the prizes distributed we notice the Jecker prize, which has been granted to M. P. A. Favre for his researches on the heat set free by chemical combination; a sum of 2000 francs (£80) has been granted to M. A. Gautier for his researches on hydrocyanic acid, the nitriles, and a new class of substances isomeric therewith.

Bulletin de la Société d'Encouragement pour l'Industrie Nationale, No. 196, April, 1869.

Omitting the papers on subjects connected with mechanics and engineering, we meet with a report—

On the New Method of Purifying Oils invented by M. Michaud, of Honfleur; the report is from the hand of M. A. Chevalier. After having reviewed the different processes in use from the middle of last century, to render fatty oils, such as rape-seed and colza oils, more suitable for use in lamps of a more complicated construction, the author of the report states that M. Michaud's process consists of a defecation of the raw oil, by the simultaneous introduction therein of jets of air and thin streams of sulphuric acid, whereby those substances contained in the raw oil, which are injurious to its properties for use in moderator and carcel lamps, are coagulated and brought to the surface of the oil as a scum, which can be easily removed; the oil is next washed with water, afterwards heated by steam to 100° C., and lastly filtered through cotton and a layer of clean and pulverised marble, at a temperature of 40° C., yielding an excellent material for use in lamps.

This number also contains a lengthy treatise—

On Electricity and its Application to the Construction of Electrical Apparatus for Medical Use.

And a lengthy treatise—

On the Cultivation of the Mushrooms known as Truffles.—To this paper are added analyses of twenty-four different kinds of soil taken from various parts of France, but it does not, after all, appear that there is distinct relation between any kind of soil and its capability of growing these dainties, which, as appears from this paper, were largely cultivated in France, for the use of the wealthy Romans, at the time Cicero and Horatius lived. Curiously enough, those parts of France—the native country *per excellentiam* of truffles—which produce good wine, do, as a rule, also produce these cryptogamics in excellent condition.

Annales du Génie Civil, No. 5, 1869.

This periodical contains the following short notices concerning matters of interest to our readers, in addition to its valuable papers relating to mechanical science:—

Artificial Ebony.—This material is prepared on the large scale in the following manner:—60 parts of charcoal, obtained from seaweeds, and previously treated with dilute sulphuric acid, and dried, are ground to powder, and mixed with 10 parts of liquid glue, 5 of gutta-percha, and 2½ of caoutchouc, care having been taken to mix the two latter substances with coal-tar oil, and thus to render them gelatinous; next 10 parts of coal tar, 5 of pulverised sulphur, 2 of pulverised alum, and 5 of powdered resin are added, and the mixture heated to 300° F. After having been cooled, a substance is obtained, which, in every respect, is equal to genuine ebony wood, but is far less expensive, and takes a finer polish.

Vulcanisation of Caoutchouc.—In a great many instances, especially when a superficial vulcanisation only is desired, bisulphide of carbon and chloride of sulphur only are applied. Since the bisulphide is very inflammable as well as very volatile, and is, beside this, injurious to the health of the workmen, it is desirable to desist from its application; instead of it, petroleum is now used, after having been submitted to a peculiar process of refining; it is for that purpose mixed with sulphuric acid, thoroughly stirred, and, after having been left quiet for some time, the supernatant oil is withdrawn by means of a syphon, and placed in distilling apparatus along with some caustic potassa, and submitted to distillation. The refined petroleum thus obtained is, however, a less good solvent for caoutchouc than the bisulphide of carbon, and hence the vulcanisation process may, by the use of petroleum, become less complete and less penetrating than by the use of the bisulphide of carbon.

Manufacture of Phosphorus.—M. Brison proposes to apply for this purpose, on the large scale, a furnace not unlike a blast furnace as used for the reduction of iron ore. Through a kind of throat or mouth, which can be hermetically closed, coke and phosphate of lime, either apatite, coprolites, or any other, are introduced, along with a sufficient quantity of a suitable flux to liquefy the lime of the phosphate and the ashes contained in the coke. A blast-pipe, connected with a blowing engine, introduces a sufficient supply of air to keep the coke, after having been ignited at a high temperature, while a tube, plunging into a tank, filled with cold water, is intended to carry off the vapours of phosphorus set free by the reducing action of the coke upon the phosphate; the slag is run off in a peculiar manner, somewhat akin to that in use with blast furnaces at iron works, but so as to prevent phosphorus escaping. According to a note by the editor of the paper at the head of this notice, the results obtained with this furnace are very satisfactory.

Les Mondes, June 3, 1869.

Newly-Invented Gunpowder.—A Bavarian chemist, named M. Hahn, has brought to Paris a proposal to sell his invention of a new kind of gunpowder, which, according to his statements, is so readily prepared, that one workman, while engaged for ten hours a day, can mix 200,000 kilos. (200 tons) of the materials the powder is to consist of, which are substances readily procurable in any country. This powder, on being ignited, gives off no smoke, and is neither affected by damp nor dryness, and can be safely stored anywhere. We refrain from quoting more about this subject, as we fear *le bon* Père Moigno has been taken in somewhat, as would appear from the statement that this powder, while floating on water, yet explodes in contact therewith, and is not after all affected by damp (*sic*).

Boiling of Sugar.—M. Woestyn.—The only noteworthy point in this rather practical paper is the observation, made by the author, that, notwithstanding the use of the vacuum pan, by the application of steam of 1, 2, 3, 4, or 5 atmospheres over and above the atmospheric pressure, and corresponding to temperatures of 100°, 122°, 134°, 143°, and 152° C., an increase of colouration, averaging 2, 4, 8, 12, and 16, is obtained, while, at the same time, research with the *saccharimètre optique* proves analogous quantities of inverted sugar in the product previous to the boiling free therefrom.

Among the books of which receipt is acknowledged we notice an Italian monograph, by M. A. Raffaelle Drago, which bears the title—"*Resumé* of the Theory of the Rev. Father Angelo Secchi, S.J., on the Relation existing between the Meteorological Phenomena and the Variations of Terrestrial Magnetism." This book is highly spoken of in the above-named periodical, which contains a lengthy paper, "On the Phosphorescence and Luminosity of Gases under Reduced Pressure," translated from the Official Gazette of the Kingdom of Italy, this paper, however, does not contain anything on this subject which is not already known to our readers.

June 10, 1869.

The only communication we briefly notice from this number is:—

Localities of Rock Salt.—Dr. A. Boué.—The author says: The ten or twelve large sites of rock salt at present known belong, in a geological sense, to either secondary or tertiary formations; those of the Devonian and Silurian deposits appear to have been formed by the evaporation of their existing seas, by the action of the heat of the interior of the globe. The saline deposits and beds of gypsum of triassic period are neither due to evaporation or sublimation, and appear to have been rather formed by saline waters, saturated solutions of salt, from springs, running into then existing seas, and causing such a supersaturation as to bring about a deposit of chlorides and sulphates. The saline springs, salt springs of the cretaceous period may be the result of fresh water which has become saturated with salt while traversing deeper lying beds thereof, and being afterwards forced up by hydrostatic pressure. It may be said that a continuous diminution of sea-water has been taking, and is yet actually taking place, from the first existence of a sea on our globe, either by chemical action, or by infiltration.

PATENTS.

Communicated by Mr. Vaughan, F.C.S., Patent Agent, 54, Chancery Lane, W.C.

GRANTS OF PROVISIONAL PROTECTION FOR SIX MONTHS.

1523. W. Benson, Hexham, Northumberland, "Improvements in treating or reducing ores, and in apparatus employed therein."—Petition recorded May 18, 1869.

1632. F. A. Barrow, Glasgow, N.B., "Improvements in purifying or bleaching mineral oils."—May 27, 1869.

1642. J. Brönner and H. Gulzkow, Frankfort-on-the-Maine, "An improved method of obtaining anthracen out of asphaltos—that is to say, pitch produced from coal-tar—and of preparing two colouring matters from the anthracen."

1652. A. T. Fairgrieve, West Street, Sunderland, "An improved paste or composition adapted for coating the bottoms of wood and iron ships."—May 28, 1869.

1668. P. Kirk, Workington, Cumberland, "Improvents in puddling furnaces, and in other furnaces employed in the manufacture of iron and steel."—May 31, 1869.

1691. H. Browning, Salmon Lane, Limehouse, Middlesex, "Improvements in compositions suitable for use as varnish or paint."—June 1, 1869.

1700. G. V. Turnbull, C. Salvesen, and R. Irvine, Leith, N.B., "Improvements in the manufacture or preparation of lubricants or softeners, and the application of the same to the treatment of hemp, jute, flax, and other like fibrous materials."

1706. H. Larkin, Torriano Cottages, Leighton Road, and W. White, Thurlow Road, Hampstead, Middlesex, "Improvements in the manufacture of magnesium, and in the preparation of its anhydrous chloride."

1710. A. L. Simpson, Stowmarket, Suffolk, "Improvements in compositions suitable for treating sheep attacked by fly, and for other similar purposes."—June 2, 1869.

NOTICES TO PROCEED.

318. W. J. Palmer and W. P. Goulding, Reading, Berkshire, "Improvements in evaporating and calcining alkaline solutions which have been used to boil vegetable fibres."—Petition recorded February 2, 1869.

362. J. Halford, Kingswinford, Staffordshire, "Improvements in puddling furnaces used in the manufacture of iron, and in other reverberatory furnaces."—February 5, 1869.

419. P. Taysen, Leith, "Improvements in the manufacture of stearic and oleic acids."—A communication from J. C. A. Bock, Copenhagen, Denmark.—February 10, 1869.

460. A. H. Lewis, Fenwick Street, Liverpool, "Improvements in extracting copper from its ores."—A communication from T. S. Hunt, Montreal, and J. Douglas, jun., Quebec, Canada.—February 15, 1859.

510. E. Dorsett, London Street, London, "Improvements in means and apparatus for heating, smelting, and working metals, and in furnaces employed therein, which improvements are also applicable to heating and otherwise operating upon minerals and other substances."—February 19, 1869.

699. J. P. Budd, Ystalyfera, near Swansea, Glamorganshire, "Improvements in the manufacture of iron and steel."—March 8, 1869.

727. G. Spencer, Cannon Street, London, and J. Barker, St. Leonards, Mortlake, Surrey, "Improvements in preserving animal substance, fruits, and other substances, made from corn, grain, or other vegetable matter."—March 9, 1869.

1044. W. T. Rickard, Crown Court, Threadneedle Street, London, "Improvements in the preparation of cements."—April 7, 1869.

1418. H. R. Lumley, St. John's Wood, London, "The treatment of molten iron in order to free it from all impurities."—May 10, 1869.

1568. G. Johnston, San Francisco, California, U.S.A., "Improvements in the distillation of spirituous liquors, and in apparatus to be employed therefor."—May 20, 1869.

NOTES AND QUERIES.

Superphosphates.—Probably some of your chemical correspondents would tell me if, in superphosphates, a chemist can say whether it has been made from bone material or mineral phosphate, either wholly or mixed. I am in the way of selling and buying such, and buy according to the quantity of soluble and insoluble phosphates present. I wish to buy nothing but bone material. According to Dr. Anderson and other agricultural chemists, the phosphates in mineral is of much less value than in bone this last season; the phosphate in mineral was sold at 10d. per unit per ton, while that in bone-ash was 1s. 5d. per unit per ton. I buy at the rate given for phosphates in bone-ash. I have sent to a number of chemists for analysis samples of my manure, and get often very irregular results from the same lot; but in no case can I be informed whether the manure has been made from bone-ash wholly, or only partly, and how much of the one and the other. Is this problem within the range of ordinary analysis? If not, what guarantee have farmers that they are not paying for an article they do not get.—A Constant Reader of The Chemical News.

Albumen.—It frequently happens that among the dried albumen met with in commerce a variety is met with which is soluble in water, but not coagulated by the application of heat. Dr. Monnier, at Lyons, has succeeded in preparing this modification, and has studied its properties. When white of eggs is slowly evaporated by exposure to the heat of the sun, or rapidly evaporated to dryness on a water bath, after having been previously exposed to strong daylight for a considerable length of time, a modification of albumen is obtained, non-coagulable by heat. A dilute aqueous solution of this non-coagulable albumen is not precipitated by addition of acetic, formic, or tartaric acid, but the addition of these acids (a few drops) restores its coagulability by heat. In order to restore to 0·20 grm. of this dry albumen dissolved in 10 c.c. of water its coagulability by heat, it was sufficient to add 5 milligrammes of solid crystalline acetic acid, dissolved in 0·5 c.c. of water. If as much ammonia was added as exactly suffices to neutralise the acid, the albumen thereby again lost its property of becoming coagulated by the application of heat.—*Deutsche Industrie Zeitung.*

Rendering Walls Impervious to Damp.—This is not a very simple question; well-built walls of proper construction ought not to be damp: the causes of dampness may be—(1) bad foundation in a wet or ill-drained soil too impervious for water, and the use of unsuitable building materials, *i.e.*, too porous bricks or natural stone; (2) walls may be damp because on being exposed to rain, and made of materials which greedily absorb and retain water, they slowly but surely allow it to evaporate where the heat is greatest, viz., on the inner side; (3) damp walls may be due to the infiltration of water from drains, as well as from improperly-constructed gutters along the roof, and rain-water pipes. Really sound building materials, well-seasoned stone and sound bricks, laid in a proper cement and upon a suitable foundation, concrete if necessary, and application of coal tar or even asphalt will insure against defects of soil wherein foundation is laid, especially if care be taken about proper drainage pipes. As to covering, coating rather, walls inside with materials to resist damp there are various means at hand. Supposing due care to have been taken in building the wall, and good materials to have been used, it may be coated with a thin layer of good Portland cement, mixed with a little plaster of Paris, and, after this is thoroughly dry, it may be hardened, and rendered impervious to water by painting it with boiled linseed oil and red-lead mixed together. If it is required afterwards to have a kind of stucco laid on, it not being intended to paper the wall, such stucco may be made up—(1) of gypsum, plaster of Paris mixed with a thin glue solution, to which a small quantity of sulphate of zinc has been added, constituting, after drying, a hard surface, which can be rubbed smooth with pumice-stone; (2) or a paint is used, made of 50 parts of fine white sand, similar to that used in glass-making, 50 parts of marl, 9 of massicot, litharge, and 9 of red-lead, mixed with 4½ quarts of boiled linseed oil. Water-glass, or silicates of soda or potassa, have not been found to answer well: perhaps Szerelmey's silicate zopissa might answer the purpose.

TO CORRESPONDENTS.

*** *In consequence of the enlargement of our journal by the introduction of abstracts of all the foreign periodicals, the index is much larger than it has hitherto been; we have therefore decided to issue next week a supplementary number, which will contain the title-page, preface, and a copious index to the present volume. The price will be the same as for an ordinary number. Unless advised to the contrary, that number will be forwarded to subscribers with the first number of the next volume, to be published on Friday next.*

A. B. E.—Our correspondent will find in No. 488, April 9, 1869, p. 178, the information he asks for.

Communications have been received from Robbins, Lane, and Pinniger; G. W. Buckley; R. Laurie; B. Nightingale; A. S. Herschel; W. Blench; Ritchie and Sons; J. H. Richardson; W. Wotherspoon; A. Wuth; J. Wallace; M. Prentice (with enclosure); H. Bassett; Maclachlan and Stewart; H. Greenwood; J. C. Major; J. Thorn (with enclosure); E. G. Tosh; T. Morson and Son; W. and H. M. Goulding (with enclosure); P. Squire; S. R. Muspratt; A. N. Graham; W. Bailey and Son; J. Cliff; J. Tilley; F. W. Whiffin; H. Cole, C.B.; R. Gregson; J. C. Brough; J. Barclay; J. Jones; Dr. Bedford; E. F. Teschemacher; and J. Denham Smith.

NEW WORK BY DR. W. ODLING, F.R.S.
Just published, in crown 8vo., Price 4s. 6d., cloth,

Six Lectures on the Chemical Changes of Carbon, delivered before a Juvenile Auditory at the Royal Institution of Great Britain. By William Odling, M.B., F.R.S., Fullerian Professor of Chemistry, Royal Institution. Reprinted from the Chemical News, with Notes by William Crookes, F.R.S., &c.

London: Longmans, Green, and Co., Paternoster Row.

Just published, demy 8vo., price 6d.

On English and Foreign Alkalimetrical and Chlorimetrical Degrees, by John Pattinson, F.C.S. Read before the Newcastle Chemical Society.

London: Chemical News Office, Boy Court, Ludgate Hill, E.C.

INDEX.

ABEL, F. A., F.R.S., &c., contributions to the history of explosive agents, 196

Des Cloizeau, M., crystalline form, &c., of gadolinite, 247
Designolle, M., explosive powders, 159
Desulphuration of chemical combinations, 69
Dexter, W. P., sulphates of oxide of antimony, 63
Dextrin, sugar, gum, and glucose, testing glycerine for, 71, 167
Diabetes, bread for, 252, 263
Diamonds, detection of, 192
Mr. Sorby's researches on, 132
Diaphanometer to determine transparency, 287
Dichlorbenzoic and paradichlorbenzoic acid, identity of, 251
Dichlorphenol, 10
Diethylconia, conia, and ethylconia, physiological action of iodides of, 82
Dimethyl, researches on, 33
Dinner, complimentary, to Dr. Odling, 201
of the Chemical Society, 307

Disinfectants and disinfection (review), 105
Dissociation, 84
Distillation of dense hydrocarbons at high temperature, 182
Doda, J., laboratory pump, 296
Dresler and Stein, Drs., on hydroxyl urea, 261
Dumas, M., inauguration of the Faraday lectures, 306
Dust, microscopical examination of, 116
Dutch liquid, 191
Dyes, new aniline, 181
from ochella weed, 108, 119
poisonous, 106

EAR, human, cerumen contained in the, 211
Ebony, artificial, 311
Ecole Pratique des Hautes Etudes, Paris, 107
Edinburgh, chair of chemistry at, 190
Eghis, A., on polymeric cyanobromide, 274
Electric light and phosphorescence in rarefied gases, 247
spark, action of on marsh gas, 81
Electricity, application of to naval and military purposes, 218, 241
and phosphuretted hydrogen, 204
Electro-capillary actions, 81
Electromotors, vegetable, 193
Element, a new, 118
Ellagic acid by means of gallic acid, formation of, 41
Ellershausen process for refining iron, 230
Elliot, Arthur, determination of carbon in cast-iron, 152
Enamel, photographing on, 82
Equivalence and quantivalence, 211, 225, 236, 249, 272
Ergot, sulphate of potassium in, 103
Erlenmeyer, M., on the melting point and relative constitution of succinamide, 252
Ether, formation of alcohol from, 10
orthoformic, 262
Ethers of propylic alcohol, 176
Ethylconia, conia, and diethylconia, iodides of, physiological action of, 82
Ethyldimethylcarbinol, 286
Ethyldiphenol, 251
Ethylen, biniodide of, action of corrosive sublimate on, 176
Ethylenchloride of iron, 275
Ethyl-iodate, 10
Ethyl, sulphocyanate, and sulphuric acid, 69
Every, C. E., nitrate of silver test for arsenic acid, 263
Experiments, lecture, note on, 130 154, 166, 191, 204, 215, 227, 275
Explosive agents, contributions to the history of, 196
Explosion, fearful, 131

FACTORS, constant, employment of in the calculation of analyses, 265, 300
Faraday as a discoverer (review), 140
lecture of the Chemical Society, 306
memorial to, 296, 308
Fermentation, on propyl compounds derived from, 176, 198
Fermented liquors, new alkaloid in, 71
Fever, scarlet, to prevent the spread of, 215, 228
Field, F., F.R.S., on the artificial formation of atacamite, 46
Figures, cohesion, exhibition of to a lecture audience, 21
Filter, the syphon, 169
Fischer, F., on dichlorphenol, 10
Fittig and Hoogewerff, MM., new compounds derived from mesitylen, 251
Fittig, Prof. R., constitution of coumarin, coumaric acid, and mellilotic acid, 73, 193
synthesis of hydrocinnamic acid, 251
Fleck, Dr. H., on the substitution of sodium for phosphorus in lucifer matches, 148
Fleischer, Dr. E., contributions to analytical chemistry, 169, 206, 265, 290
employment of constant factors in the calculation of analyses, 265
separation and estimation of copper in the presence of other metallic salts, 206
Fleury, A. L., reducing aluminium, 162
Flour, wheaten, researches on, 203
Flückiger, M. F. A., on the ground nut, 288
Fluids, means of preventing the bumping of when boiling, 297
Fluorides, decomposition of silicates by, 270
Fluosilicic acid for sugar refining, 250
Food, on, 30, 75, 90, 108, 138, 150
Forbes, D., F.R.S., &c., chemical examination of Oriental jargon, 277
estimation of titanic acid, 3
Forbes, J. E., F.R.S., &c., death of, 22
Formic acid, acetone of, 249
Formula, chemical, of alizarine, 193
Frangulin, 191
Frank, M., methods for the detection of arsenic, 288
Frankland, Dr. E., F.R.S., &c., and J. N. Lockyer, F.R.A.S, on gaseous spectra, 158
Friction, luminosity of Geissler tubes by, 176
Friedel, M., on iodide of silicium, 273
Fruits, soluble hydrates of carbon met with in, 143
Furnace, chemistry of the blast, 232, 243
Furtenbach, Dr., colour of wafers, 286

GADOLINITE, crystalline form, optical properties, and chemical composition of, 247
Galena, on a new thermo-electric battery made with, 298
Gallic acid, formation of ellagic acid by means of, 41
Galvanic batteries, substitution of graphite by antimony in, 203
Gardenia grandiflora, 156
Gas, coal, to burn oxygen or air in, 154
examiner for the City of London, 118
illuminating, quantity of water contained in, 310
inspectorship of the City, 142
marsh, action of electric spark on, 81
natural, 239
olefiant, and Dutch liquid, 204
oxygen, preparation of pure, 190
purification, 167
sulphuretted hydrogen, action of on oxide of iron, 178
supply of the City, 23
Gases, liquefaction of in relation to the state of dryness of these gases, 299
Gautier, M., hydrates of hydrocyanic acid, 273
Generator, new carbonic acid, 215
Glaser and Buchanan, MM., on the synthesis of hydroparacoumaric acid, 261
Glasgow Philosophical Society, 35, 60, 81, 116, 140, 165
Glass, action of sunlight on, 226
aventurin, analysis of, 213
diaphanometer to determine transparency of, 287
cryolite, or hot-cast porcelain, 287
frosting, 12
optical, 71
Glauber's salt, on solutions of, 200
Glucina, constitution of, 227
Glucose, sugar, dextrin, and gum, testing for, 167
Glutz and Schmitt, sulphuric acid and ethyl sulphocyanate, 69
Glutz, Dr. L., on oxysulphobenzid, 250
Glycerine, testing for sugar, dextrin, gum, and glucose, 71, 167
crystallisation of, 34
its history, &c., 287
its uses and abuses, 120
Glycolic and lactic acids, destructive distillation of, 251
Gold discovery in Uist, 202
platinum, iridium, osmium, rhodium, and palladium, atomic weights of, 302
Gore, G., F.R.S., on hydrofluoric acid, 74
Graebe and Liebermann, MM., artificial preparation of alizarine, 157
on the colouring matters of the anthracen series, 237
Graham, T., F.R.S., on the relation of hydrogen to palladium, 52
Grange, M. E., acetic derivatives of mannite, 299
Grape sugar, decomposition of by oxide of copper, 250
Graphite, substitution of by antimony in galvanic batteries, 203
Grapes, analysis of, 204
Grease, recovered, 288, 300
Green, aniline, 136
chrome, 131
Grenelle artesian well, water of, 273
Griess, P., on new bases, 70
derivatives of hippuric acid, 70
Grimaux, M., cinnamate of benzile, 9
Ground nut, 288
Guaiacol, synthesis of, 10
Guanidine from chloropicrin, 69
Guano, biphosphated Peruvian, 106, 118, 130, 142
of Mexillones, 132
Peruvian, preparation of uric acid from, 215
Gulf stream, 227
Gum, sugar, dextrin, and glucose, testing glycerine for, 167
Gummic acid and combinations, 203
Gunpowder, newly-invented, 311
Gypsum, water saturated with, 276

HAGER, M., non-identity of caffeine and theine, 288
Hahn, M., newly-invented gunpowder, 311
Hamy, Abbe A., discovery of the weight of the air, 189
Hart, P., rapid determination of oxygen, 253
Hayes, Aug. A., and S. Dana, influence of the oxides of chromium and titanium on the composition of pig-iron, 163
Heat, action of on peroxide salts of iron, 211, 228
action of on sulphate of strontia, 190
action of on tartaric acid, 143
action of on zircons, 156
contraction of caoutchouc by, 276
decomposition of disulphide of carbon by, 287
dilatation of petroleum by, 167
effect of on electromotive force of galvanic battery, 226
Heat, influence of on regeneration of sulphide of iron, 273
utilisation of waste, 84, 108
Heaton's steel and iron process, 83, 85, 96, 106
Herschel, A. S., spectrum analysis, 157
Hervé-Mangon, M., mud and slime carried down by rivers, 274

Hints to purchasers of jewellery (review), 106
Hippuric acid, derivatives of, 70
Hirsch, J., Ph.D., carbolic acid a therapeutic agent, 97
Hofmann, Dr. A. W., guanidine from chloropicrin, 69
Hoogewerff and Fittig, MM., compounds derived from mesitylen, 251
Horsford, Professor E. N., source of free hydrochloric acid in the gastric juice, 229
Household poisoning, 47
How, Prof., non-precipitation of manganese by sulphide of ammonium, 137
oxalate of manganese, 41
Huggins, W., F.R.S., further results of spectrum analysis, 187
Hugo, M. L., construction of a synoptic pyrheliroscope, 223
Hutton, W. R., igniting point of vapours of some commercial products, 41
Hydrate of phenyl and carbonic acid, combination of, 237
Hydrates of hydrocyanic acid, 273
Hydriodic acid, action of on organic chlorides, 203
preparation of, 191
preparation of an aqueous solution of, 297
preservation of, 132
Hydrobromic and hydrochloric acids, action of upon nitrobenzol, 261
Hydrocarbons, distillation of dense at high temperatures, 182
sulpho-acids of the, 22, 286
Hydrochloric acid, action of cyanogen on, 84
action of on codeia, 302
and hydrobromic acids, action of upon nitro-benzol, 261
electrolysis of, 289
in the gastric juice, source of, 229
solubility of silico-fluoride of potassium in, 180
Hydrocinnamic acid, synthesis of, 251
Hydrocyanic acid, detection of minute traces of, 180
detecting minute traces of, 167
hydrates of, 273
Hydrofluoric acid, on, 74
Hydrogen, adhesion of to metals, 261
and carbon, expansion, by heat, of some compounds of, 262
and palladium, 299
bottle, 227
carbides of, oxidation of, 273
phosphuretted, 204, 285
reduction of oxides by, 179
relation of to palladium, 52
silicated, 132
sulphuretted, action of different bodies on, 288
experiments with, 44
varying behaviour of iodine towards, 297
to burn oxygen or air in, 154
Hydroparacoumaric acid, synthesis of, 261
Hydroxyl, 143, 156
urea, 261, 298
Hypophosphorous acid, action of air on, 190
Hyposulphurous acid, constitution of, 253

ICE house, 60
Igniting points, uniformity in taking, 70

Ilse, Dr., amylendisulphinic acid, 275

Oxygen, extraction of, from the air, 225
to burn in hydrogen or coal-gas, 154
free, rapid determination of, 253
natural water containing excess of, 276
Oxyhydrogen light, 226, 249
Oxysulphide of carbon, 273
Oxysulphobenzid, 250
Ozone, 35
detection of in the atmosphere 179
Ozone, determination of the density of, 104
Ozonisation of hydrocarbon oils, 260

PAINTING, use of tungstate of baryta in, 225
Palladium, gold, platinum, iridium, osmium, and rhodium, atomic weights of, 302
and hydrogen, 299
on the relation of hydrogen to, 52
Paper, carbolic, 143
pulp, bleaching, 250
test, for determining minute traces of hydrocyanic acid, 167
Paradichlorbenzoic and dichlorbenzoic acid, on the identity of, 251
Paraffin, 156
Paramonochlorobenzoic acid, synthesis of, 226
Paris, explosion at, 154
Patchouli, essence of, 156
camphor of, 169
Patents, 132, 155, 227, 238, 263, 275, 300, 312
Pattinson, John, F.C.S., on English and foreign alkalimetrical and chlorimetrical degrees, 111
Paul, Dr. B. H., connection between the mechanical qualities of malleable iron and steel, and the amount of phosphorus they contain, 58
on Heaton's steel and iron, 106
on spurious guano, 106, 130,
Peat, compressed, from Switzerland, result of analyses of, 214
Peckham, S. F., distillation of dense hydrocarbons at high temperatures, 182
Pélissard, Jolyet, and A. Cahours, MM., physiological action of conia, ethylconia, and iodide diethylconia, 82
Pelouze, M. E., solubility of sulphur in coal-tar oils, 262
Perchloride of phosphorus, vapour density of, 273
Perkin, W. H., F.R.S., on some new aniline dyes, 181
Patellaric acid, and its existence in the Parmelia scruposa, 275
Petrequin, M. J. E., cerumen contained in the human ear, 211
Petroleum act, the new, 72, 82, 84, 96
American, new products obtained from, 143
dilatation of, by heat, 167
solubility of iodine and sulphur in, 213
Pharmacopoæ Recentiores, Anglica, Gallica, Germaniæ, Helvetica, Russiæ, inter se collatæ (review), 271
Phenaconic acid, constitution of, and transformation of benzol into tartaric acid, 191
Phenitolsulphuric acid, salts of, 299
Phenol, on some molecular combinations of, 191
researches on the ethers of, 299
Phenomena of opals, on some optical, 205
Phenomenon, extraordinary, 286
Phenyl, hydrate of, and carbonic acid, on a combination of, 237
Phlobaphen, 203
Phonoelectroscope, 167
Phosphates of lime, magnesia, iron, and alumina in superphosphates, estimating the reduced, 229, 266
Phosphoric acid, researches on the, present in that proportion of arable soils which is insoluble in aqua regia, 262
acid and urea, combination of, 261
Phosphorus, action of ammonia on, 191
combinations of, 275
detection of by means magnesium, 179
Phosphorus, estimation of in iron and steel, 71, 95
holder, 285
in iron and steel, 58, 71, 95, 117
manufacture of, 311
penta-chloride of, action of upon saccharine substances, 215
perchloride of, vapour density of, 273
substitution of sodium for, in lucifer matches, 148
Phosphuretted hydrogen, 285
Photographing on enamel, 82
Physical Society, proposed new, 296
Physiological action of conia, ethylconia, and iodide of diethylconia, 82
Picrate of quinine, 108
Picrates, 288
Picrotoxin in beer, detection of, 179
Pipes, water, lead *versus* tin for, 104
Pitchstone of the Island of Arran, 181
Pitcoal, on some changes of when heated, 143
Plants, living, excretion of carbonic acid by, 229
Platinising copper, yellow metal, and brass, 226
Platinum, discovery of in Scotland, 154
compounds, new series of, 179
gold, palladium, iridium, osmium, and rhodium, atomic weights of, 302
Playthings, arsenical, 103
Poisoning, household, 47
Poisons act, sale of, 23
Pollack, M., cement for iron and stone, 287
Polymeric cyanobromide, 274
Polytechnic, the Royal, 11, 177
Popoff, M. A., on ethyldimethylcarbinol, 286
Positive or negative, 156, 167, 168
Potassium, action of upon Dutch liquid, 211
chloride of, and chloride of sodium, decomposition of, 298
cyanate, action of upon amidoacids, 10
silico-fluoride of, solubility of in dilute hydrochloric acid, 180
and sodium, chlorides of, behaviour of in presence of metallic vapours, 9
or sodium, detection of sulphur by means of, 179
sulphate of in ergot, 103
Pott, Dr. R., hydroxyl derivative of cymol, 261
new method for preparing cymol from camphor, 261
Powder, Austrian non-explosive blasting, 108
Powders, on new explosive, 159
Precipipate, white, 103
Precipipates, washing of, 160, 173
Priestley's letters to Canton, remarkable passage in, 235
Prize, chemical, 190
Products, commercial, on the igniting point of some, 41
Propane, on the derivative of, 194, 298
Propyl compounds, derived from the propylic alcohol of fermentation, 198
Propylic alcohol, on the existence of a normal, 203
of fermentation, propyl compounds derived from 198
Proximate analyses of coals, 282
Pulp, wood, 204, 263
on the bleaching of, 9
Pump, laboratory, 259, 295
Putrefaction, creatinine an index of, 8
Pyrheliioscope, synoptic, on the construction of a, 223
Pyruvic acid, on 191

QUARTZ, gold, assay of, 132
Quantivalence and equivalence, 211, 225, 249, 296
a plea for the word, 236, 296
Quinine, on a certain reaction of, 152, 253
citrate of, 103
picrate of, 108, 132
sulphate of, testing, 238

RACEMIC ACID, formation and constitution of, 22
Rayet, A., on the refrangibility of the brilliant yellow ray of the solar atmosphere, 158
Rees and Co., biphosphated Peruvian guano, 118, 142
Refining sugar, on the chemistry of, 78, 96, 130, 153, 166, 177
on a new method of manufacturing and, 197
Researches into the chemical constitution of narcotine, and of its products of decomposition, 197
on materials for resisting high temperatures, 226
Resin, on a constituent of the, from the Ferreira spectabilis, 237
Reynolds, Dr. J. F., isolation of the missing sulphur urea, 7
laboratory pump, 259
Rhodium, gold, platinum, iridium, osmium, and palladium, atomic weights of, 302
Richter, Dr., experiments on the direct decomposition of sulphide of calcium as met with in soda waste, by means of chloride of manganese, 287
Ritthausen, M., on cholesterine in wheat and rye, 104
Rivers, experiments on the quantity of mud and slime carried down by, 274
Roccella tinctoria, some varieties of, 203
Rochleder, M., on isocitric acid, 287
Rodwell, G. F., note on Aristotle and the discovery of the weight of air, 123, 189, 209
Rosette metal, estimation of suboxide of copper occurring in, 238
Roux, M. Le, behaviour of chlorides of sodium and potassium in presence of metallic vapours, 9
phenomena of electric light and phosphorescence in the midst of rarefied gases, 247
Rowan, Thomas, on the examination of the "flame" of the Bessemer converter, 170
Royal Institution of Great Britain, 142, 223
Royal Society, 189, 213
Rye, cholesterine in 104

SACC, Dr., detection of some fatty oils, 252
Saccharine substances, action of penta-chloride of phosphorus upon, 215
Salicine, researches on the derivatives of, 298
Salicyl, aldehyde of, history of the, 274
Salt deposits at Stassfurt, 64, 77
deposit near Berlin, 288
Glauber, on solutions of, 200
new, containing tin, cæsium, and chlorine, 262
rock, localities of, 311
Salts, Epsom, taking away the bitter taste of, 260
in water, lowering of temperature due to the solution of, 214
metallic, separation and estimation of copper in the presence of other, 206

Scheibler, M., percentage of water in starch, 297
Schiff, M. Hugo, researches on the derivatives of salicine, 298
Schmeltzer and Birnbaum, MM., on the combination of phosphoric acid and urea, 261
Schmitt and Glutz, MM., on sulphuric acid and ethyl sulphocyanate, 69
Schneider, M. R., on new sulphosalts, 287
Schorlemmer, Dr., constitution of hyposulphurous acid, 253
Schorlemmer, C., derivatives of propane, 194
Schunck, Dr. E., chemical formula of alizarine, 193
Schwanert and Limpricht, MM., on the toluylen group, 274
Science and art department, 11
and violence, 61
applied, in Italy, 202
Scientific blue books (review), 45
Review, the (review), 58
Scotland, discovery of platinum in, 154
Secchi, Rev. Father, on the spectroscopic phenomena of the sun's spots, 223, 247, 298
Sewage of the city of Melbourne, report on the, 178
contamination, previous, 213
Dr. Letheby on the methods of water-analysis and on, 230
question, a chemist's view of the, 253
Sharples, S. P., on a new salt, containing tin, cæsium, and chlorine, 262
Siam, 36
Silicates, refractory, decomposition of by fluorides, 270
Silicium contained in aluminium, 274
iodide of, 273
Silk, spontaneous combustion of, 84
Silver, chloride of, action of light upon, 226
coinage, alloy for, 119
compounds, modifications of the method of assaying in the wet way, 3
nitrate of, test for arsenic acid, 263
reduction of chloride of, 178
Silvering cast-iron, 274
glass specula, 12
Soap, bleaching, 299
Smalt, analysis of, 214
Smith, Dr. R. Angus, on the examination of water for organic matter, 278, 304
Smith, E., M.A., on vegetable electromotors, 193
a phonoelectroscope, 167
Smith, M. H., and E. T. Chapman, on propyl compounds derived from propylic alcohol of fermentation, 198
Soap, adulterated, 226
notes on the manufacture of, 204
tablet stamping machine, 84
Socks, coloured, 83
Soda, caustic, Bachet's process for the manufacture of, 262
dithionate of, new preparation of, 178
Sodium, chloride of, and chloride of potassium, decomposition of, 298
combustion of, 275
ethylate, composition of the crystals of, 22
and potassium, chlorides of, behaviour of in presence of metallic vapours, 9
or potassium, detection of sulphur by means of, 179
how to preserve untarnished, 119
substitution of for phosphorus in lucifer matches, 148
Solar protuberances, 48
Soldering without fire, 252
Solution, saline, action of upon minerals, 190
Sorby, H. C., new applications of the microscope to blowpipe chemistry, 124
blowpipe reaction of thallium, 309
researches on jargonium and the Ceylon jargon, 205
Soret, M., determination of the density of ozone, 104
Sow, composition of the milk of the, 217
Spectra, gaseous, researches on, 158
Spectroscope, new pocket, 142
use of to distinguish a feeble light with a stronger light, 299
phenomena of the sun's spots, 223, 247
Spectrum analysis (review), 284
artificial, with a Fraunhofer line, formation of an, 40
analysis as applied to the heavenly bodies, 187
a new element accompanying zirconium discoved by means of, 121
methods and recent progress of, 157
binocular, microscope, new arrangement of, 205
the lines in the, 12
Spence, P., sulphurous acid in the air of Manchester, 139
Spiller, J., the non-precipipation of sulphide of manganese, 166
Spirit from lichens, 115
Sprague, J. T., chemical affinity and electricity, 82
Stanethyl and stanmethyl, physiological effects of, 299
Stanford, E. C. C., a chemist's view of the sewage question, 253

meteoric, fallen from the sky, 299
Storm, sand, 191
Strecker, A., formation and constitution of racemic acid, 22
Strontia, sulphate of, action of heat on, 190
baryta and lime, estimation of, 289
Strychnine, detection of, 34
Sublimate, corrosive, action of on biniodide of ethylen, 176
Succinic and benzoic acids, 276
Succinimide, melting point and relative constitution of, 252
Suez, climate of, 274
Sugar, aqueous solutions of, solubility of difficultly soluble compounds in, 226
boiling of, 311
dextrin, gum, and glucose, testing glycerine for, 71, 167
grape, on the decomposition of, in alkaline solution by oxide of copper, 250
manufacture, substitution of alum-shale for bone-black, 249
manufacture of, 302
Sugar, on a new method of manufacturing and refining, 197
refining, on the chemistry of, 78, 96, 130, 153, 166, 177
fluosilicic acid for, 250
scum, composition of, 190
Sulphate of aniline a test for nitric acid, 104
of manganese, 263
of potassium in ergot, 103
Sulphates of oxide of antimony, on the, 52, 63
and sulphuric acid, a new volumetric process for, 116
Sulphide of carbon light, 215
of iron, influence of heat upon the regeneration of, 273
Sulpho-acids of the hydro-carbons, 22, 286
Sulphobenzylic acid, 10
Sulphocyanate, ethyl, and sulphuric acid, 69
Sulphocyanides, quantitative estimation of, 270
Sulpho-salts, new, 287, 300
Sulphur, action of aqua regia on, 132
adulteration of precipipated, 103
detection of by means of potassium or sodium, 179
and iodine, solubility of in petroleum, 213
obtaining coke quite free from, 215
detecting in organic substances, 179
recovery of from alkali waste, 234
solubility of in coal-tar oils, 262
urea, isolation of the missing, 7
Sulphuretted hydrogen, experiments with, 44
Sulphuric acid, adulteration of, 227
aromatic, 103
and ethyl sulphocyanate, 69
and sulphates, a new volumetric process for, 116
volumetrical determination of, 287
Sulphurous acid, 103, 129
for dissolving bones, 249
in the air of Manchester, 139
Sunlight, action of on glass, 226
on bisulphide of carbon, on the action of, 29
Sun, researches on gaseous spectra in relation to physical constitution of the, 158
spectroscopic observations of the, 28, 169, 217, 223, 247, 298
Superphosphates, 312

THE FARADAY LECTURE,

DELIVERED BY

M. J. DUMAS,

Sénateur; Président de la Commission des Monnaies et Médailles; Member, and one of the Perpetual Secretaries, of the Institut; Inspecteur Général de l'Enseignement Supérieur; President de la Société d'Encouragement pour l'Industrie Nationale; Grand Croix de la Légion d'Honneur, &c., &c.

BEFORE THE

CHEMICAL SOCIETY OF LONDON,

IN THE

THEATRE OF THE ROYAL INSTITUTION,

THURSDAY, JUNE 17TH, 1869.

GENTLEMEN,—You have desired that the memory of Faraday should be handed down to posterity; you have summoned together men of science, all to celebrate, in a solemn manner, his great and beneficial labours; and, calling upon France to take the lead in this solemnity, you have chosen me to be his panegyrist, no doubt on account of the long and constant friendship with which I was honoured by Faraday.

I am the bearer of the acknowledgments of the scientific men of France, as well as my own. My country—I am proud to say it—can offer representatives of science much more worthy of your approbation; but I know no one, at least, who feels more intimately the sentiments of profound gratitude for the noble welcome which England has accorded for so long a time, nor do I know one who bears so sincere a veneration for Faraday.

The name of your illustrious fellow countryman is not one which any single nation can claim as its exclusive property; his labours and discoveries are as widely recognised in France, in Germany, and in America as in England. Faraday belongs to the whole world. There is not a spot on this earth to which civilisation has penetrated, that does not claim the right of partaking of the respect and gratitude you entertain for him.

Faraday was identified with the scientific movement of the first half of this century; he was one of its principal leaders, and drew in his train a whole host of thinkers, engineers, men of enterprise, and capitalists. Ever contemplating the chaste beauties of nature, and searching into her most hidden recesses, this disinterested philosopher, this deep thinker, scattered broadcast on his path the seeds of the most extraordinary and unheard-of results—such are the electric currents of Faraday that bear our messages, furrowing Europe and traversing the Atlantic—such are those lights, rivalling the sun in brilliancy, which shine forth from our principal lighthouses; and it is even to the gases which he liquefied that hot countries owe the luxury of ice.

In the pursuit of truth alone, he was able to satisfy, as if by accident, the boldest demand of a refined civilisation; and, devoted to the ideal, he sowed the seed of riches, not for himself, for he despised them, but for the profit of trade, which has gathered the fruit.

Faraday is the type of the most fortunate and most accomplished of the learned men of our age. His hand, in the execution of his conceptions, kept pace with his mind in designing them; he never wanted boldness when he undertook an experiment, never lacked resources to ensure success, and was full of discretion in interpreting results. His hardihood, which never halted when once he had undertaken a task, and his wariness, which felt its way carefully in adopting a received conclusion, will ever serve as models for the experimentalist.

The study of nature entirely puts aside conjecture, and places a guard on vague hypotheses; it begins with facts, ascends to laws, and raises itself, as far as the limits of man's intellect will permit, to the knowledge of causes, by the triple means of observation, experiment, and logical deduction. A long familiarity with the exact detail of phenomena can alone give to a man, as to Faraday, the right of being bold; he is, like Faraday, restrained when he has a thorough appreciation of the limits of man's knowledge. It is two centuries ago since Europe received this system of philosophy from Galileo and Newton, characterised at that epoch by the establishment of the Academy of Naturæ Curiosorum, in Germany, which represented the art of observation; in Italy, by the Academia del Cimento, the school of experimental science; and in England and France, by the Royal Society of London and by the Académie des Sciences de Paris, which adopted mathematical science as one of the means most conducive to the knowledge of truth in the domain which is accessible to us.

What an awakening for Europe! After two thousand years, she found herself in the same position to which she was raised by the profound intellect of India, and the acute genius of Greece, by Aristotle, Plato, Archimedes, and their emulators, from which, during those long ages, she was permitted to fall, whilst the work of the assimilation of races

was being carried on under the political influence of Rome.

What would have been the result if the learning of the Greeks, continuing its development from the third century before Christ to our own days, had pursued its triumphant march without hindrance? We do not know; no more than we can forecast the material resources of the human race after twenty centuries, nor to what heights the science of nature will have risen, should no social revolution create a breach in its tradition or retard its progress.

Greek art presents inimitable models; Greek philosophy has forestalled the modern schools in all their fearless opinions; and Greek science, not less prolific, paved the way which Europe has followed after long hesitation.

It is not difficult to connect Leucippus, a contemporary of Alexander the Great, who first clearly enunciated the philosophical doctrine of atoms, and the illustrious physicist of Manchester, Dalton, who, at the commencement of this century, founded, upon experiment, the atomic theory of modern chemists. Between these two points, so far removed, there is no intermediate link. Dalton is the son of Leucippus. Thus Cuvier, too, whose inventive genius was greater than that of Aristotle, was the sole inheritor of his spirit of order, his love of method, and his strength of judgment. In the same manner, we may ascend directly from Galileo and Newton, to Archimedes and Plato; the ideas of Faraday, too, on matter, atoms, force, and motion, were those of a Greek philosopher. The Romans did not receive this inheritance from the Greeks; given more to practical pursuits, they did not recognise the fact that these owed their progress to pure theory.

Truth is so beautiful that it deserves every effort a man can bestow to gain it; it is so fruitful that it carries along with it its own recompense. In placing before our mind the end, without occupying ourselves with particulars, we find the ordinary details of well-being and riches fall into their proper places.

Has not the atomic theory of Dalton, in assigning limits to phenomena, renewed the whole art of chemistry? Has Lavoisier's theory of combustion ever ceased to direct agriculture, the useful arts, health, and therapeutics? Did not these two philosophers contemplate abstract truth in all its splendour, and after receiving it from above, was it not sufficient for them to cast their eyes upon the earth, to reflect its light, and to spread far and wide its fruitful and exhaustless seed?

Let us, then, continue faithful in the cultivation of science for itself, and trust, without anxiety, that it will bear practical fruit for itself. Our remembrance of the life of Faraday teaches us that moral truth, when implanted in a man's heart, develops, at the proper time, each virtue that life exacts. His labours show us that the same holds good with scientific truth. At the proper time, it produces, as well as many spontaneous fruits, each of those discoveries which civilisation demands.

To a nation ambitious of becoming famous in history, it should be said "Despise conquest, abandon the pursuit of riches, and seek Truth, for by that your memory will be perpetuated." In like manner it may be said to a people who desire war or fear it, who wish to remain agriculturists or seek the advantages of commerce; "Search for Truth; it will create your means of defence or attack, maintain the fertility of your plains, and furnish your manufactories with resources against competition." The princes of bygone times considered themselves enriched and assured of prolonged youth, if they could obtain an alchemist capable of making gold, and possessed of a panacea against mortality. The nations of the present day, better advised, seek the aid of chemistry, and place in its counsels their hopes of well-being and honest gain: they know the value of artificial soda, chlorine, gas illumination, stearine candles and aniline dyes, and are grateful for the labour and care which these discoveries have cost.

Everything must give way to the laws of nature, and he only who has mastered those laws can control her processes. But the mastery cannot be obtained without a struggle; the fable of Proteus is a true picture of the combat between man, eager for knowledge, and the stubborn guardian, charged with the preservation of the secrets of destiny. Proteus changed himself into a thousand shapes before speaking, and yielded only to the hero who, far from being moved by his transformations, bound him with bands of increasing pressure. Such is nature herself, her answers are always true, but like the ancient shepherd of Neptune's flocks, before allowing Truth to shine forth, she arrays herself in the garments of error, or hides herself behind the phantoms of illusion; and will only assume her proper shape under the determined pressure of a resolute disciple of Science. This indomitable courage was possessed by Faraday in the highest degree.

The struggle for mastery is often prolonged. The whole life of a man does not suffice; the meeting of many philosophers animated by the same idea, or even the labours of different generations devoted to one pursuit, are required for the attainment of success; hence free associations for the cultivation of physical science and laboratories, where young men full of faith and ardour, working under one head, unite in the execution of such plans as he may invent or approve. Private study, which was perhaps best adapted to Faraday's temperament but which prevented him from establishing a school, has been succeeded by the labours in common of learned societies, and work carried on simultaneously by pupils in the same laboratory. Enlightened countries at last comprehend that all scientific research is a battle to be won, and that every victory increases national power. Intelligent nations no longer deny to scientific men, worthy the name of captain, either arms for the contest, soldiers devoted to their cause, or subsidies for their maintenance. Science is no longer an unrecognised power of which, nevertheless, much is expected; to day, every government which does nothing for it must expect to be vanquished by rivals, and to receive the censure of posterity for its want of forethought.

When Christopher Columbus set out for the conquest of the New World, did he not require ships, sailors, provisions, and ammunition? How then can the new world of science be conquered without assistance?

For textile manufactures there must be raw material, machinery, workpeople. The best workman in England, left to his own resources, would be unable to make an inch of cloth. It is the same with scientific discoveries; to weave the weft, there must be raw material, laboratories, apparatus, and reagents. The more eminent a scientific man may be, so much the more is he powerless to resolve unaided all the questions which arise in his mind,

and to develope all the views suggested to him by the new aspects of nature, which his penetration has reached.

How many *chefs-d'-œuvre* might have been lost to us if Raphäel, protected by an illustrious Pope, had not been the centre of a brilliant and devoted school, capable of sparing him the actual labour required to develope his ideas! What discoveries will be made when scientific masters of all countries, raised to their true position, are no longer limited in their resources, confined as to their means of execution, and obliged to do everything with their own hands!

The high position held by Faraday allows of such a comparison, and we may regret the loss of the discoveries which might have been added to those with which he has benefitted the world, if, like Raphäel, he would, or could, have founded a school. Learned societies formerly chose as a subject for their solemnities, an encomium on those monarchs or ministers whose protection they enjoyed. This meeting presents a spectacle more in conformity with the dignity of science: Faraday indeed raised himself above his fellows like a prince, but as a prince of thought; he exercised his power like a minister, but as a prime minister of the power and forces of nature.

His life is likewise an epoch of intellectual progress; and our immediate posterity will speak of such and such discoveries as having been made in the time of Faraday; sure of being as well understood as if referring to events in history, as being of the time of Elizabeth or Charlemagne.

But the life of Faraday is known to you, and you are familiar with his labours. I cannot fail of rendering that homage to his memory which he would have desired himself if, together with you, I review the progress of those sciences to which he was devoted.

Since the commencement of this century, three nations, animated with a noble spirit of rivalry—England, Germany, and France—have been contending for the first place in the study of physical science. Warranted, by turns, in claiming superiority, no one of them has dreamed, for one instant, of abdicating its claims. From this generous strife have sprung innumerable labours, the boast of our age, which will imprint a character upon it in history.

I do not wish to review, nor even to point out, the advantages that these nations have received from the liberal hand of science, but to bring before our minds the acquisitions to our knowledge of matter and force, to point out those fundamental ideas which have been brought to light, and to call to mind the part we must attribute to Faraday in this wonderful movement. I propose, then, to examine what we have learnt with regard to—1st, the nature of concrete matter; 2nd, the forces which it obeys; 3rd, the nature of truly-organised matter; 4th, the force which animates it.

The Greeks considered all matter divisible into four irresolvable elements, viz., earth, water, air, and fire, which are concrete representations of the abstract ideas solidity, liquidity, gaseous state, heat. So far they were guided by their senses; but they were of opinion that, finally, matter was made up of inaccessible atoms, and that variety, in the number or the arrangement of the latter, accounted for all the varieties in natural substances.

At the present day, with Lavoisier, we give the name of elements to all substances which we cannot break up or resolve; but hold, with Dalton, that these elements are themselves made up of atoms which unite in different proportions, and with varying arrangements, to form different compounds.

To sum up, matter can be reduced to substances which no longer admit of reduction, and these substances are the elements of modern chemists; matter has only three forms, the solid, the liquid, and the gaseous, which stand for the elementary substances of the Greeks; matter is agitated by different motions, which may be all represented by one alone—heat—as all the rest may be transformed into it.

Lavoisier demonstrates that these are substances which cannot be resolved into simpler parts, and these he calls elements; Dalton asserts that the latter are substances combined in unvarying proportions, and he gives the name of atoms to these proportions reduced to their simplest form. Are not the elements of Lavoisier subject to decomposition in their turn? Cannot the methods recognised by Dalton be brought under a more general statement? May not chemistry be in the same state as astronomy with Kepler's laws, and is it not waiting for its Newton?

We are inclined to believe in the absolute simplicity of Lavoisier's elements when we consider,—1st, that, since the commencement of civilisation, no power at man's disposal, no natural action observed by him, has been able to break them up; 2ndly, that when converted into gas, their atoms occupy the same space as before; 3rdly, that in the solid state their atoms have the same volume when we deal with analogous elements; 4thly, that in the last case their forms are identical, so that they can replace and displace one another mutually in their compounds, without any great change of properties; 5thly, that the heat required by atoms for a change of temperature, is the same, no matter how they differ in weight; lastly, that in order to separate them when united, any atom whatever requires the same amount of electricity as any other. But, with the exception of inalterability, all these properties, not excepting the last, one of Faraday's best discoveries, are found in all compounds of the same order; we have, then, only a right to say that Lavoisier's elements are substances of the same order, and if we may say that they *cannot* be resolved, it is only because they *have not* been resolved.

We are inclined to think Lavoisier's elements further reducible from considering—1st, their number, which has risen in less than a century from thirty-one to sixty-five, and which grows rapidly; 2nd, their natural classification by families, the different numbers of which approach gradually, like terms in a continous series; 3rd, their indubitable analogy with organic radicals, which are compounds.

In this way, Faraday's idea, that the atoms composing simple substances are collections of centres of force diversely arranged, may be defended. Chemical atoms would be the starting point of the analysis; mechanical atoms its last stage.

However, the question has entered upon another phase since the most recent discoveries. Natural philosophy has enabled us to determine the elements which are in incandescent matter, by means of the character of the spectrum formed by the latter.

The fact that Lavoisier's elements have resisted for the millions of years that they have been on the earth all the efforts of nature and of man to reduce them, is a characteristic of simplicity. Now we can

say that these elements have resisted every effort at destruction in space as well as in time. We find in the sun, in the fixed stars, in the nebulæ, and in comets themselves—that is, within our system and without our system—the elements which we have known on earth; we find the same metals, hydrogen, nitrogen, &c.

When we are taught by the beautiful discoveries of Messrs. Janssen, Lockyer, and Frankland, that the protuberances on the sun are only incandescent hydrogen, we ask, How shall it be possible to reduce this element if the temperature of the sun do not suffice for its reduction?

As far as man can go back in time, as far as man can reach by observation in space, the concrete elements of matter present the same character as Lavoisier's elements.

In their abstract forms, reduced to mere centres of force, these elements, if such be the name for matter in its final state, belong to an immense tract, and soar up into a region of thought, inaccessible to man both in space and in time.

The examination into the modifications which have taken place in our ideas on the subject of force authorises us in going back to an age long before the commencement of this, for from thence the changes in our ideas take their date. Then matter used to be placed under the dominion of universal attraction, of motion, of light, of heat, of electricity, of magnetism, of chemical affinity, of cohesion, of the force of solution, of capillary attraction, and, later, of endosmose, &c.

It was no longer the philosophy but the mythology of Greece that served as a model. Natural forces occupied the position with regard to modern science that the divinities of old did with respect to Olympus, and people came to attribute to the former, as they had done to the latter, distinct and inalienable personalities.

At the present day, we know that light and heat have many properties in common, that electricity can be changed into magnetism, and *vice versa*, and that mechanical action can produce heat, magnetism, electricity, light. This correlation of physical force, as Mr. Grove calls it, the data for which were given by Ampére, Melloni, and before them by Sady Carnot, and confirmed by the crucial experiments of Faraday, remove all doubt. These forces are different modes of motion, and all these modes of motion can be transformed one into the other.

The man with vulgar cravings sought for the transmutation of matter, and failed to find it; he had little care for the transmutation of forces, the deep meaning of which none but the philosopher understood, and as a reward for the disinterestedness of the latter, the truth was revealed to him.

One of my most eminent fellow-labourers, one of my countrymen who has many friends here, and whom you have heard in this theatre, M. Henry Ste. Claire Deville, has just proved the existence of a close alliance between affinity and mere physical attraction, by the discovery of dissociation, which will influence the progress of chemistry materially.

We cannot deny that there exists close relationship between affinity on the one hand, and mechanical force on the other, when we see the decomposition of a body, such as marble when submitted to the action of a steady heat, come to a stand in the same way and from the same causes as the vaporisation of a liquid *in vacuo*.

This is the first step that has been taken to bring chemical phenomena under the laws of mechanics, and to justify Newton's view that chemical attraction was a particular case of universal attraction.

Has not Mr. Graham, in turn, reduced to causes purely mechanical the manifold effects of diffusion, of endosmose, of capillarity? Has not this illustrious philosopher been led by his latest researches to manifest, not only the metallic character of hydrogen by a memorable discovery, but to seize the very moment at which the phenomenon of the mechanical condensation of a gas by a porous body changes into a truly chemical combination?

There remains, then, universal attraction which, acting on heavy bodies, guides the motion of the stars as well as that of atoms; a motion which produces heat, light, electricity, and magnetism.

The study of matter leads us to the knowledge of an ever-increasing number of elements, and of simpler and simpler forces. Matter which was always believed to be conceptible and susceptible of transmutation, has resisted the efforts of man; whereas physical forces which were considered to be beyond his reach are shown to be ephemeral, and change one into the other readily.

But what relation connects gravitation with the other forces in nature? We know not; and Faraday, who has meditated on this point all his life, and who has thrown such vivid light on all its surroundings, has not made one step towards the solution of the problem.

What is the cause of gravity itself? We now know no more than was known two hundred years ago, in Newton's time.

What is meant by organic matter? If one were influenced by the views of the old chemistry, there would be no difficulty in replying. All organic matter originated in plants or animals; it was destructible by heat; it contained, generally, carbon and hydrogen, often oxygen, sometimes azote. Thus it was a compound of which carbon formed the fundamental element, destruction by fire the chief characteristic, but which, above all, derived its organic character from the circumstances of its origin.

At that time, no one thought of confounding organic chemistry and mineral chemistry. At the present day, this fusion exists in all purely chemical substances; only the terms of this assimilation are not understood. We are dazzled by a quibble. My age, and the share I have had in this movement in science, compel me to explain clearly my opinion, and to endeavour to put an end to the misconception.

The first studies we pursue on the chemical phenomena of life teach us that plants create, and animals destroy, organic matter. The sun appears as the agent by whose means this matter is produced, and combustion by the air that animals breathe, as the process that destroys them, in order to restore their elements to the state of "brut" matter.

The chemical forces placed at the disposal of life, descending on the earth under the forces of light, disappear by radiating off into space under the form of heat. An equilibrium obtains between the vegetable and animal kingdoms for receipts and disbursements, represented by these two forms of motion—light and heat; and the amount of animal life which may be developed on the globe is measured by the amount of food that vegetable life has prepared for it. The dark rays of heat appear to carry off from the earth that which radiant and brilliant light has spread over it.

On looking more closely into it, however, it was found that matter of organic origin was divided into two groups; one so rich in species that it surpasses all that has ever been imagined of the very numerous species of plants or animals described by naturalists; the other containing but a very few distinct species.

The first group constitutes the true organic species of chemists; that is to say, those which they have analysed, of which they have recognised the constitution, which they make by means borrowed from from their own sciences, and of which they can, consequently, define the nature by analyses and syntheses.

Let us first attend to these matters. At what moment can they be characterised as organic?

Their origin does not suffice. In fact, carbon, hydrogen, oxygen, azote, can be withdrawn from plants or animals, and no one would find anything but mineral elements.

Oxide of carbon, carburetted hydrogen, cyanogen, water, and ammonia may meet in the produce of the constituents of plants or animals without anyone thinking of making organic substances from these binary compounds. But old chemists gave this name to alcohol, to vinegar, to the essence of bitter almonds, to urea, for example. Now, if there is any certain principle in science, it is this. Alcohol, vinegar, essence of bitter almonds, urea, although proceeding from plants or animals, have never lived, and will never live. They are subordinate products of life; they are not necessary instruments of life.

With regard to them, chemistry need no longer hesitate. This matter is formed in the manner of mineral matter. It shows all the conditions of its composition, its structure, and its properties. One circumstance only distinguishes it, and that, even, is not absolute. Generally, mineral matter is formed of simple elements, directly united. However, we perceive sometimes that certain composite groups may act like elements, may replace them or be replaced by them in combinations, without the latter changing their general character.

That which is the exception in mineral chemistry becomes the rule in organic chemistry. Lavoisier had the presentiment of this when he wrote—"Organic chemistry is the chemistry of compound radicals."

At this day, there is no longer any doubt. Cyanogen, cacodyle, the metallic radicals of Dr. Frankland, are well-known substances, offering all the chemical qualities of simple bodies, and nevertheless compound.

The substitutions admit of displacing and replacing one element by another, or even, at pleasure, by a compound radical in all the organic matter of chemists without changing its type. The converse is true: there is no impediment to replacing a compound radical by an element in a combination; and this change does not alter the type of it more.

Thus, the organic materials of which we speak are similar in all their conditions or qualities to mineral materials; 1st, they contain certain compounds which play the part of elements; 2nd, they assimilate with the oxides, sulphides, chlorides; with acids, bases and mineral salts in all their properties; 3rd, their radicals can replace the mineral elements, and be replaced by them; 4th, they can replace each other reciprocally.

Like "brut" bodies, these materials are susceptible of crystallisation, of volatilisation, without becoming decomposed; they form definite combinations, are incapable of life, and never have lived.

They thus resemble mineral matter in every respect, and where they differ from it is only that they have the general principles of compound radicals, whilst the mineral species have generally the principles of elements.

Analogies are even apparent in some numerical relations known to the elements of mineral chemistry, and to the radicals of organic chemistry. These relations are manifest in the two cases, for all elements susceptible of being arranged in series or natural families.

Thus, lithium, sodium, potassium, whose respective atomic weights are 7, 23, and 39, form a series of which the difference is 16. Magnesium, calcium, iron, whose respective atomic weights are 12, 20, 28, form a series whose difference is 8.

Thus all organic radicals offer the same condition. Methylium, ethylium, propylium, butylium, &c., give a series whose difference is 14, their respective atomic weights being 15, 29, 43, 57.

It seems natural to conclude from all this evidence, not that substances thus endowed and composed are organic because they are derived from organised beings, but rather that the elements of mineral chemistry may be complex.

In any case, the assimilation of the two chemistries becomes more and more near.

This picture would be incomplete if we did not add a few more features.

The radicals of mineral chemistry formerly numbered 30, and the combinations known in nature raised the number to some hundreds; at this day we count 65 elements, and some thousands of compounds or natural mineral species.

The chemist of the last century might study them one by one, and become acquainted with them all. Such is not the mission of the chemist of the present day; the species being realised, he tries to study them in groups; the potential species he tries to create. In nature, every element produces, on an average, eight or ten species. In the laboratory, every element may form thousands of the same order as the known mineral species.

The contrast is still more striking in organic nature. The animals and plants which cover the surface of the earth are counted by hundreds of thousands, and yet their tissues and their juices, submitted to chemical analysis, resolve themselves into no more than a few hundreds of distinct chemical species.

But the power of combination is such, among the special elements which form them, that it is by thousands that they have arisen; and if we calculate the number of combinations of this kind which may be realised, it seems as easy to count the grains of sand on one of the great shores of the sea as to say to what number of figures may be raised the organic species which the chemist has to produce.

Thus mineral or organic species, counted formerly by hundreds, are now counted by thousands for the first and by millions for the second.

Whence comes this fecundity for the formation of the so-called organic substances? Many circumstances contribute to it; but the first results from the almost incalculable number of the compound radicals which it can realise. Each of them being able to give birth to a prodigious number of combinations, organic chemistry counts a very great number of heads of tribes, and each tribe an infinite number of species. The latter, already multiplied in fact for simple ra[illegible]

cals, are much more so by the consequences of the fertile discovery of Mr. Williamson, which has taught us to unite two different radicals to each other, to bring them into a single system, and to produce with the latter as numerous compounds as were obtained from each of the isolated radicals. In consequence of the first and fundamental discovery of Mr. Graham, on the triple functions of phosphoric acid, which has been extended to the domain of organic chemistry,—for acids by M. Liebig,—for bases by M. Berthelot,—for alcohols by M. Wurtz, the result of this harmony of work, of which the immensity alarms the imagination, is that the atomic compounds with which we were chiefly engaged forty years ago, have not only been multiplied, but that they have been repeated by counterproofs. One might say, without forcing a metaphor, that we had visited and described all the rooms of the ground floor of the building; that Messrs. Graham and Liebig have revealed to us the existence of a first and second story, which repeated all their arrangements, and that Messrs. Berthelot and Wurtz have shown us that it was the same case in the basement and in the cellars. Thus five times more chambers or species have been produced at pleasure.

But, from all the sources of multiplication of substances with which organic chemistry is concerned, the most fertile is that of substitution; in fact, the discovery of the compound ammonias by M. Wurtz, and the labours of M. Hofmann which resulted from them, have produced a multitude of combinations, in which the atoms of hydrogen contained in ammonia are replaced by compound atoms performing the function of elements—that is to say, by organic radicals. If we apply the calculation to this special case, we even see that, with the known radicals employed to replace entirely, or in part, the hydrogen, or to replace each other mutually, we should henceforth be able to produce compounds derived from ammonia by hundreds of thousands or by millions.

How if we were to apply the same calculation, and the same prevision to all the types?

There is yet more. The chemist is not now, as formerly, obliged to derive all the substances that he produces by these means from those yielded by animals and vegetables; he creates them at will; he no longer needs, for his starting point, the action of solar light on plants. When he wishes to produce organic substances, he obtains his force by employing heat, formerly regarded as the true means of destroying them.

Not that he has succeeded in directly uniting carbon, hydrogen, oxygen, and nitrogen, so as to form organic substances; but, by the aid of heat alone, he first combines them two and two, and he thus forms carburetted hydrogen, carbonic oxide, cyanogen, water, and ammonia. Afterwards, by subjecting these first compounds to the action of suitable substances, and by the necessary artifices, he succeeds in regenerating, little by little, all the definite compounds of organic chemistry.

There is not a chemist who has not performed syntheses of this character; but the most striking is that of urea, by M. Wöhler; and the first, which have been grouped in a systematic manner are those which have been performed in Germany, by M. Kolbe; and especially those performed in France, by M. Berthelot, who has worked at them with great success, being the first to reproduce formic acid, and to combine directly carbon and hydrogen.

The function of the chemist changes, and becomes elevated. In presence of the numerous substances that his power evokes from the regions of the unknown, he owes his first attention to order, method, classification, and to nomenclature. But, once this first duty is fulfilled, he contemplates this innumerable host of forms, raised by his conceptions, or realised by his hands; and he applies to mathematics for a definition of the harmonies of numbers therein revealed; to mechanics, for a statement of the laws which their structures obey, or those which determine the stability of the material systems which they represent.

The Bible tells us that when God had formed, from dust, all the beasts of the earth, and all the fowls of the air, he made them pass before Adam, and that the name given to each by Adam is its true name.

In presence of this new creation, not of animated beings—whose appearance on earth depends on a power superior to his—but of harmonious forms which chemistry reproduces at will, always identical with each other, and always distinct from all others, man might sometimes forget that he has no longer merely to give names to the works of God, in order to remember that he has to name his own works.

If the discoveries which we have witnessed during the last half century do not justify pride, they at least excuse it. But, to bring back man to our appreciation of truth, it suffices to tell him that—if he has become more expert in the art of observing, if he employs with more certainty the art of experimenting, if the logic proper to the sciences leads him more surely to the discovery of the laws of nature—he has not as yet advanced one step towards the knowledge of causes.

Let us consider, in particular, what he knows on the subject of the materials which his life sets in motion in its development, and the contrast will be striking.

If I question the physiologist, on the subject of these millions, or milliards, of compounds, misnamed organic, of which the chemist transforms, reproduces, or creates at pleasure the species, he will reply to the three following questions:—Are these compounds living?—No! Have they lived?—No! Are they capable of living?—No!

If I ask the chemist himself if these compounds belong to mineral chemistry—to the chemistry of raw (brut) substances—he will reply, Yes!

Organised matter, not capable of being crystallised, but destructible by heat, the only matter which lives, or has ever lived—this matter, a subordinate agent of the vegetating power in plants, of the motion and sensation of animals, cannot be produced by chemistry; heat does not give birth to it; light continues to engender it under the influence of living bodies.

Let us not be disturbed by a quibble. The ancients admitted that nature alone produces organic matter, and that the art of the chemist is limited to transforming it. To-day we might, perhaps, even pretend that chemistry is powerful enough to replace, in all respects, the forces of life, and to imitate its processes; let us keep to the truth.

The ancients were mistaken when they confounded, under the name of *organic matter*, sugar and alcohol, which have never lived with the living tissue of plants or the flesh of animals. Sugar and alcohol have no more share of life than bone-earth, or salts contained in the various liquids. These remnants, or rubbish of life, placed amidst organic matter, are

true mineral species, which must be brought back to, and retained amongst, "brut" bodies. Chemistry may produce them in the same sense that she manufactures sulphuric acid or soda, without, for all that, having penetrated into the sanctuary of life.

This subject remains what it was—inaccessible, closed. Life is still the continuation of life; its origin is hidden from us as well as its end. We have never witnessed the beginning of life: we have never seen how it terminates.

The existing chemistry is, therefore, all powerful in the circle of mineral nature, even when its processes are carried on in the heart of the tissues of plants or of animals, and at their expense; and she has advanced no further than the chemistry of the ancients, in the knowledge of life and in the exact study of living matter; like them, she is ignorant of their mode of generation.

Where, then, is true organised matter, or matter susceptible of organisation? What is its chemical constitution? What is its mode of production? What is its manner of growth?

Instead of myriads of species, one would feel disposed to recognise but eight or ten at most, if one may be allowed to consider elementary types of organisation as chemical species. Be this as it may, in the origin of beings which have life we see cells appear, and in the heart of their types we find cells for organic elements, and, still beyond these, germs of cells.

In these cells, or in the spaces between them, we observe inert products, aliments, excretion, substances stored up. It is the cell, it is the germs which proceed from life, which live, which engender life, and then die. The substances which are contained in, or which surround these organs, are subordinate accidents, products rejected by organisation, or destined to its use, but distinct from life.

Every organised being is born of a germ; every plant from a seed; every animal from an egg. The physiologist has never seen the birth of a cell, excepting by the intervention or as the produce of a mother cell.

The chemist has never manufactured anything which, near or distant, was susceptible even of the appearance of life. Everything he has made in his laboratory belongs to "brut" matter; as soon as he approaches life and organisation, he is disarmed.

Thus, for a century past, the empirical elements of matter have been recognised and separated; their combinations have been multiplied to infinity; physical forces have been brought back to a common origin—motion—and one has been at pleasure changed into the other; and yet—

Is the intimate nature of matter known to us? No! Do we know the nature of the force which regulates the movement of the heavenly bodies and that of atoms? No! Do we know the nature of the principle of life? No!

Of what use, then, is science? What is the difference between the philosopher and the ignorant man?

In such questions the ignorant would fain believe they know everything; the philosopher is aware that he knows nothing. The ignorant do not hesitate to deny everything; the philosopher has the right and the courage to believe everything. He can point with his finger to the abyss which separates him from these great mysteries,—universal attraction which controls "brut" matter, life which is the source of organisation and of thought. He is conscious that knowledge of this kind is yet remote from him, that it advances far beyond him and above him.

No, life neither begins nor ends on the earth; and if we were not convinced that Faraday does not rest wholly under a cold stone, if we did not believe that his intelligence is present here among us and sympathises with us, and that his pure spirit contemplates us, we should not have assembled on this spot, you to honour his memory, I to pay him once more a sincere tribute of affection, of admiration, and respect!

ON JARGONIUM;

A NEW ELEMENTARY SUBSTANCE ASSOCIATED WITH ZIRCONIUM.*

By H. C. SORBY, F.R.S., &c.

AT the *soirée* of the President of the Royal Society, on March 6th, I exhibited various spectra, differing so much from those characteristic of any known substance that I considered myself warranted in concluding that they were evidence of a new element. Since this may be studied to the greatest advantage in the jargons from Ceylon, it appeared to me that, as the name *zirconium* has been adopted for the principal constituent of zircons, so that of *jargonium* would be very suitable for this constituent of jargons.

At the above-named *soirée* I gave away a printed account of the objects I exhibited; and in this I said that jargonia "is distinguished from zirconia and all other known substances by the following very remarkable properties. The natural silicate is almost, if not quite, colourless, and yet it gives a spectrum which shows above a dozen narrow black lines, much more distinct than even those characteristic of salts of didymium. When melted with borax it gives a glassy bead, clear and colourless, both hot and cold, and no traces of absorption bands can be seen in the spectrum; but, if the bead be saturated at a high temperature, and flamed, so that it may be filled with crystals of borate of jargonia, the spectrum shows four distinct absorption bands, unlike those due to any other known substance."†

I have since applied myself almost exclusively to the study of this substance, hoping to have been able to communicate to the Royal Society a full account of the subject this session; but so much still remains to be done that it is now impossible to do anything more than give a brief outline of the more important facts. The delay has not been because there is any difficulty in proving it to be a new substance, but because its properties are so unique, and have so much interest in connection with physics, that it appeared desirable to carefully examine all other known elements, in order to ascertain whether any of them exhibit analogous phenomena. That jargonium is quite distinct from zirconium is not only proved by the spectra, but also by other facts. Both myself and Mr. David Forbes have succeeded by entirely different processes in separating from jargons, zirconia apparently quite free from jargonia, and jargonia nearly, if not quite, free from zirconia; and, even if the separation be not perfect, it is, at all events, more than sufficient to prove that they are quite distinct. They are certainly very closely related, and are deposited from borax blowpipe beads in microscopical crystals of the same general form‡, quite unlike those characteristic of other known earths; but beyond this the

* Communicated by the author, having previously been sent to the Royal Society.

† For the further history of this subject, see Prof. Church's papers:—*Intellectual Observer*, 1866, vol. ix., p. 291; CHEMICAL NEWS, March 12th and 19th, 1869, vol. xix., pp. 121 and 142; *Athenæum*, March 27th; and also my own—CHEMICAL NEWS, vol. xix., p. 122; and *Athenæum*, April 3rd.

‡ See *Monthly Microscopical Journal*, June, 1869.

difference is as great as that between any other two allied elements. Judging from an analysis kindly made at my request by Mr. David Forbes, and from a comparison of the spectra, the amount of jargonia in jargons varies up to about 10 per cent. The entire or comparative absence of jargonia from the zircons of Miask, Fredericksvärn, and various other localities, appears to explain some of the facts which led Svanberg* to conclude that zircons contain more than one earth. He was so far correct, but failed to establish the existence of any substance with special chemical or physical properties; and if, as is probable, the Norwègian zircons, which, according to his views, contain such a notable quantity of this supposed new earth, as to have led him to give it the name *noria*, were from Fredericksvärn, and if the Siberian were from Miask, his norium cannot be looked upon as equivalent to my jargonium, which is almost or quite absent from those zircons.

The most remarkable peculiarity of jargonium is that its compounds may exist in three different crystalline states, giving spectra which differ from one another as much as those due to any three elements which give the most striking and characteristic spectra. Several substances can be obtained in two different physical states, giving different spectra, but usually only one of them is crystalline. The other is the vitreous or colloid condition. Crystalline minerals coloured by oxide of chromium do indeed show spectra of two different types; but, as far as I have yet seen, they never occur in the same mineral. In the case of jargonium, however, there are no less than *three* types of spectra, which are all met with in different crystalline modifications of the *self-same* compound.

The most characteristic test for jargonia is the spectrum of the borax blowpipe beads seen with a spectrum microscope, which enables us to detect it in zircons apparently

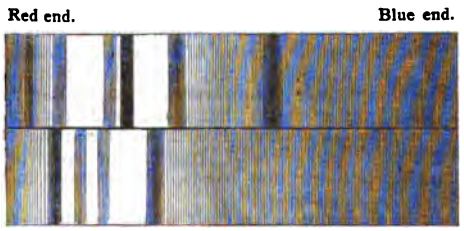

FIG. 1.

FIG. 2.

containing less than 1 per cent. As much of the earth or natural silicate as will completely dissolve should be melted in a circular loop of platinum wire about ¼ inch wide, with a mixture of borax and boric acid, and a strong heat kept up till crystals begin to be deposited, owing to the loss of the solvent by volatilisation. On removing the bead from the flame it remains clear and shows a few acicular crystals, but gives no absorption bands. On reheating to a temperature just below dull redness, the bead turns white, and so very opaque that no ordinary light will pass through it. When, however, a small and very bright image of the sun is formed in the centre by means of an almost hemispherical lens of ¼ inch diameter, and a cap is placed over the object glass, with a round hole of less diameter than the bead in the focus, so as to prevent the passage of extraneous light, the bead is seen to be illuminated by transmitted light of about the same brilliancy as that of a bright cloud, so that it gives an excellent spectrum without being at all dazzling.

In the case of beads conaining jargonia, the character of the spectrum differs completely according to the temperature at which the included crystals are deposited. As already mentioned, the clear glassy bead gives no absorption bands; and when the crystals of the borate are deposited at as low a temperature as possible, much below dull redness, and only just sufficiently high to soften the borax, there may be scarcely any trace of bands; but if the clear bead be quickly raised to a temperature just below that of very dull redness, it suddenly becomes very opaque, and shows a spectrum with a number of remarkably distinct absorption bands (Fig. 1). The most distinct and characteristic is that in the green, then one in the red and one in the blue, and there are three others fainter, one in the orange and two in the green. On raising the temperature to bright redness, all these vanish and four others appear, none of which coincide with any previously visible (Fig. 2). Three are situated in the red and orange and one in the green, so as to give rise to a spectrum of an entirely different character.* In this state the bead is of a pale straw colour. and not almost white as before. In the case of nearly pure jargonia the beads should not be above 1-25th of an inch thick, or else they would be too opaque. Pure zirconia gives no bands whatever in any state, and the beads are white, and sufficiently transparent when two or three times as thick as just named. It might be thought that these three different spectra were due to different compounds of boric acid and jargonia, if it were not that there is a similar series in the case of the natural crystalline silicate. Some of the jargons from Ceylon have a specific gravity very little inferior to that of pure zircons (4·70), and contain very little jargonia; but those of low gravity (4·20, or thereabouts) contain perhaps nearly 10 per cent, in a state which gives scarcely any trace of absorption bands. After keeping such at a bright red heat for some time, the specific gravity increases from about 4·20 to 4·60; and, judging from the imperfect data now known, this indicates that the volume of the silicate of jargonia is reduced to about one-half. The hardness becomes somewhat greater, and when examined with the spectrum microscope, the spectrum is found to be entirely changed. Instead of a mere trace of bands, a spectrum is seen which is more remarkable than that of any clear and transparent substance I have ever examined, with thirteen narrow black lines and one broader band.† No such changes occur in zircons free from jargonia like, those from Miask—no absorption bands are developed, and there is no increase in their specific gravity. In all cases this varies simply and directly as the amount of jargonia which passes from one state into the other; and if the bands are very distinct before ignition, the gravity is high and not much altered by heat.

Zircons, in their natural condition, from various localities, vary much in both the absolute and relative amount of these two modifications of jargonia; and there is good reason to believe that this difference in physical state may assist us very materially in determining the temperature at which certain rocks have been formed. Fortunately, I have met with one example of the third form of spectrum. A brown-red zircon, from Ceylon, was so dark in one part that I was not able to ascertain what sort of spectrum it would give in its unaltered condition. On heating to redness, the whole became a clear pale green; and, without examination with the spectroscope, no one would have suspected any difference between the different portions. That which was originally pale then showed the spectrum usually characteristic of heated jargons, whilst that which was originally very dark showed one entirely different, corresponding exactly with that of the borate deposited in blow-pipe beads at a medium temperature. It also corresponds in general character, but not in detail, with that of the blue spinels from Ceylon, which I believe contain a small quantity of jargonia. That part of the zircon which gives this spectrum appears to have had the same remarkably low specific gravity of about 4·0, both before and after ignition, as though the volume of the silicate of jargonia in this state were even greater than in that which gives no bands.

* *Pogg. Ann.*, 1845., vol. lxv., p. 327.

* June 30th.—I have since been able to examine these spectra with unusually good light, and have found another band in the blue in spectrum Fig. 1, and another in the extreme red in spectrum Fig. 2.

† CHEMICAL NEWS, vol. xix., p. 122.

These various spectra of jargonium are all of a very marked character, quite unlike those due to any other element in similar conditions.

The change produced by heating the jargons is, to some extent, analogous to what occurs on heating arragonite, but yet differs in many most important particulars. When arragonite is thus changed into calcite, it becomes an opaque mass of small crystals, the specific gravity and hardness are diminished, and there is no difference in the spectra of these two different modifications of carbonate of lime; whereas, after heating, the jargons are still as simple and transparent crystals as at first, the specific gravity and hardness are increased, and the spectrum totally changed. Iodide of mercury is an excellent illustration of a difference in the spectrum due to a change in the crystalline state, produced by heat; but there are only two modifications—the scarlet and the yellow. The existence of three crystalline conditions is, in some respects, analogous to what occurs in titanic acid. Anatase, brookite, and rutile are three distinct crystalline modifications of the same substance; but they do not differ very much in specific gravity, and their spectra do not present any characteristic differences. On the whole, the different states of carbon—charcoal, graphite, and diamond—are, perhaps, the best illustration of the existence of three distinct modifications, which differs much in specific gravity and optical characters; since one is black, the second has a metallic lustre, and the third is colourless and transparent; but these are variations in the element itself, and not, as in the case of jargonium, modifications of its compounds. So far as I am aware, there is indeed, no substance which shows strictly comparable facts.

There cannot, then, I think, be any doubt whatever that jargonium is not only a new elementary substance, but is, also, one likely to throw much light on several important physical questions. By the time that the Royal Society resumes its meetings, I trust that I shall be able to send a complete account of the whole of my investigations, including such facts connected with other substances as may serve to illustrate the very peculiar properties of this hitherto unrecognised element.

POSTSCRIPT (June 16th).

Since Professor Church has published some papers on the existence of a second earth in some zircons, it may perhaps be well to give a short account of what he has done. He was the first to observe the absorption bands, and gave an account of them in the *Intellectual Observer* for May, 1866 (vol. ix., p. 201). In that paper he said nothing about a *new* elementary substance, and does not even seem to have been convinced that they were not due to zirconia, since he speaks of silica as "the other constituent of zircons," as though there were but two constituents—silica and zirconia. However, since he had found that some zircons show the bands much better than others, he said that he was "induced to hazard the conjecture that it may be, after all, the presence of Svanberg's *norium* which determines the difference." I have now shown that jargonia may exist in very considerable quantity in zircons in such a physical condition as not to show any bands, and it was quite as probable that their presence or absence might have been due to a similar variation in the physical state of zirconia itself; and therefore no fact described in Professor Church's paper can now be looked upon as proof of the existence of a second earth. His paper does not appear to have attracted much attention and I was quite ignorant of it until after I had printed, for distribution at the *soirée* of the Royal Society on March 6th, an account of the characteristic peculiarities of jargonia. Up to that time he had never so much as even suggested the existence of a *new* earth, and the first time that he did so was in his paper subsequently published in the CHEMICAL NEWS of March 12th, manifestly written because he had "heard, when in London, that Mr. Sorby had discovered a new set of black absorption bands in certain zircons, and had attributed their occurence to the presence in the stones examined of a new element accompanying zirconium." In this paper he suggested that the name *nigrium* might be appropriately adopted, but did little more than recapitulate the arguments previously brought forward by Svanberg in proof of the existence of *norium*, viz., a difference in the specific gravity of the zircons, in the atomic weight of the earths, and in some obscure and doubtful chemical properties; but he never proved that the bands might not have been due to several well-known elements, and that the above-named differences depended on the substance which gives the peculiar spectrum. I therefore maintain that I was the first, not only to suggest, but also to prove, the existence of a new element by my blowpipe methods, and to show that the earth may be separated from zirconia and obtained in a state of approximate purity.

POSTSCRIPT (June 18th).

I here subjoin a brief account of tbe methods employed by Mr. David Forbes* and myself in separating zirconia and jargonia from one another. He separated apparently pure zirconia by means of strong hydrochloric acid, which dissolved the chloride of jargonium, but left chloride of zirconium undissolved, and obtained the approximately pure jargonia by adding to the solution excess of ammonia, and then considerable excess of tartaric acid, which left most of the tartrate of jargonia insoluble, but dissolved what may turn out to be a mixture of zirconia and jargonia with a third substance not yet sufficiently studied—perhaps Svanberg's noria. My own analysis was only qualitative. I fused powdered jargon with several times its weight of borax, which gave a perfectly clear glass, completely soluble in dilute hydrochloric acid. After separating the silica in the usual manner, a slight excess of ammonia was added to the hydrochloric acid solution of the earths, and then some oxalic and hydrochoric acids, which left undissolved apparently pure zirconia that had passed into an imperfectly soluble state. To this solution so much ammonia was added as to give a very copious precipitate, but yet to leave the solution with a very decided acid reaction. After removing the precipitate, which was chiefly oxalate of zirconia, almost or quite free from jargonia, excess of ammonia was added to the solution, and the washed precipitate digested in dilute hydrochloric acid to remove per oxide of iron. The insoluble portion must have been approximately pure oxalate of jargonia, for it gave the characteristic spectra described above in remarkable perfection. Though this method succeeded far better than I anticipated, I do not yet understand the exact conditions requisite to ensure success, and have been prevented by absence from home from making further experiments.

Jargonium.—We learn from the *American Journal of Mining*, of June 12th, 1869, that, at a meeting of the Polytechnic Association of the American Institute, held on June 3rd, a note was read "*On Jargonium*," which referred to the exhibition of jargonia by Mr. Sorby at the *soirée* of the Royal Society, and also to the communication by Professor Church in the CHEMICAL NEWS for March 12th. After the reading of the note, Dr. Isidor Walz spoke as follows:—"It will be remembered that, at a meeting of the New York Lyceum of Natural History, Professor Loew announced the discovery of jargonium before the number of the CHEMICAL NEWS which contained an account of Mr. Sorby's discovery had reached this country. The discovery was, undoubtedly, made by the English and American discoverers quite independently of each other."

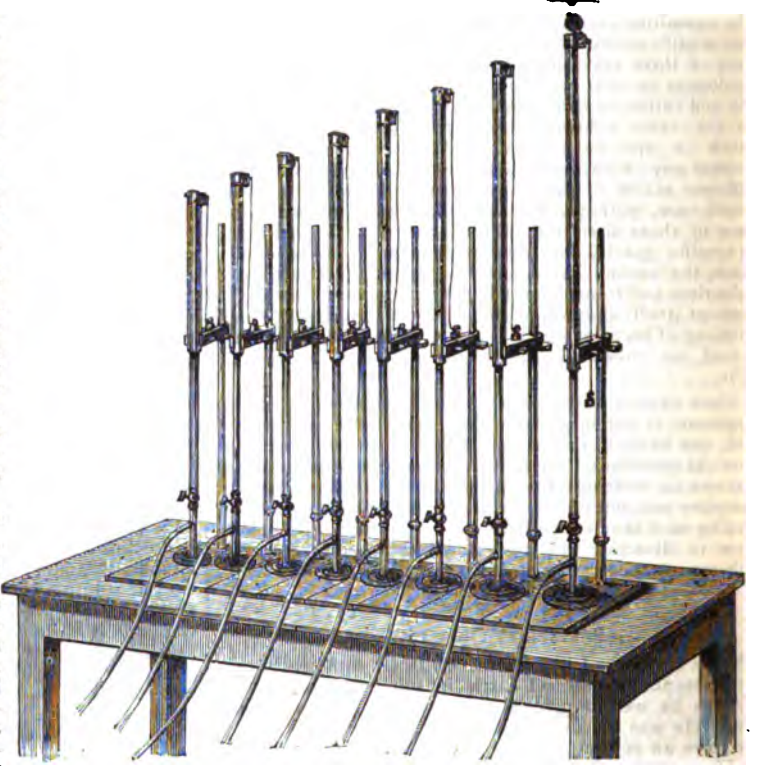
NOTICES OF BOOKS.

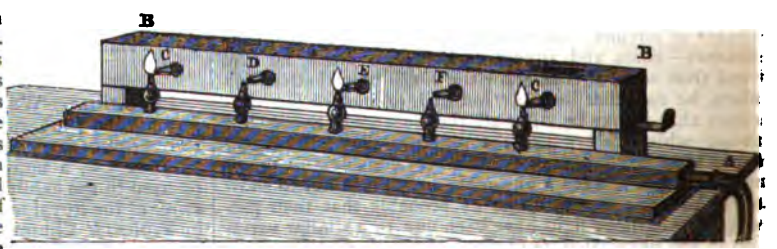
Cyclopædic Science Simplified. By J. H. Pepper. London: Frederick Warne and Co. New York: Scribner, Welford, and Co. 1869.

Of a verity this book is a small cyclopœdia of science; the variety of subject matter is astonishing, and six hundred woodcuts lend their aid to the simplification. Within the memory of most of us the only source of very popular science for boys was to be found in the "Boy's Own Book," where the science was bounded on the right by perhaps Cricket, and on the left by Boating, and the dominant experiment was the "Lead tree," while examples of chemical combination were ordered to be made somewhat after this fashion:—"Take a sixpence, put it in a small tea-cup, and pour upon it about a wine-glass full of aqua fortis; it will immediately dissolve; now add a pinch of salt, and the silver will fall down as a white powder," and so on. Now, for having led boys from such science as this, and given them sound science resulting from the labours of sound men, and often accompanied by their own explanations, we think every school-boy ought to thank Mr. Pepper. He cannot open this book without having his mind simultaneously opened, and it is his own fault if he ever closes it again.

As for subject matter, we have light, heat, electricity, magnetism, pneumatics, acoustics, and chemistry. In the article on Light, a detailed account, accompanied by woodcuts, is given of the celebrated ghost delusion, which surprised us all so much a few years ago, and of which M. Marion has given such a capital account in his *Merveilles de l'Optique*, one of that admirable series well called "Bibliothèque des Merveilles," from whatever point of view we may consider it.

If we specialise at all we may perhaps mention the chapter on Acoustics as being well illustrated. The accompanying figure represents the "gas flame organ," by means of which, we are told, simple tunes have been played; while in the second figure, we have the apparatus of Pichler for showing the position of the nodal points and ventral segments in a vibrating column of air. When the column of air in the tube, B B, is caused to vibrate, the gas jets, D and F, which are opposite to the centres of ventral segments, are blown out, while the jets, C, E, G, remain lighted, because they are opposite to nodal points—that is, points where the column of air is at rest.





Mr. Pepper also tells us lots of scientific "dodges," explains the talking head of Albertus Magnus, and indicates the true position of the "invisible girl," who, being in communication with "a sort of ornamental bedstead," yet all unseen, answers any questions addressed in the neighbourhood thereof. But there is much severer science than this; we would refer to the accounts of magnetism and dia-magnetism specially, also to the account of the Atlantic cable; in fact, we recommend all young fellows with any glimmer of a taste for science, to take the book home with them at the approaching summer holidays, to read it carefully, and, as far as is possible, experimentalise for themselves.

Endowment of a School of Practical Chemistry.—Mr. James Young, the late proprietor of the extensive works at Bathgate, near Glasgow, and manufacturer of paraffin and paraffin oils, whose name, in fact, is intimately associated with this manufacture as the discoverer of the process by which these valuable products have for many years been produced from certain varieties of coal, is stated to have presented the sum of £10,000 to the Andersonian Institution, Glasgow, for the endowment of a school of practical chemistry.—*Pharm. Journ.*

LABORATORY NOTES.

ACTION OF SODIUM ON WATER AND NITRIC ACID.

I send a few facts which you may perhaps consider worth a place in some corner of the CHEMICAL NEWS.

When sodium is thrown upon water, the hydrogen does not kindle, as we all well know, unless the water be warmed, or the metal confined to one spot by blotting-paper. If sodium, however, be dropped upon nitric acid of specific gravity 1·36 (ordinary commercial), the hydrogen burns with ease; but if the acid be diluted this result ceases. I thought it of interest to ascertain the point of dilution, which was conducted in the following way:—The concentrated acid, to the extent of 680 grains, was placed in a beaker, which again was placed in a vessel of water; a fragment of sodium of equal size was then added, the acid being diluted with 25 grains of water before each addition of sodium. The rise of temperature consequent upon this dilution (always two degrees) was allowed to fall back to that of 66° F., at which the experiments were commenced. Seventy-two experiments gave as the result, that the hydrogen ceased to kindle when the acid was diluted to specific gravity 1·056. The residue contained a fair amount of ammonia. I have used this dilute nitric acid with advantage, when showing the preparation of hydrogen by potassium and sodium as a lecture experiment, as the results then appear similar. No doubt the rapid oxidation of the sodium into nitrate is the explanation.—I am, &c.,

THOMAS BLOXAM,
Lecturer on Chemical and Natural Philosophy, Cheltenham College.

CORRESPONDENCE.

THE FARADAY MEMORIAL.

To the Editor of the Chemical News.

SIR,—I read with regret that the proposed memorial to Faraday is to be in the form of a statue in St. Paul's Cathedral. I am very sorry to differ from those who, doubtless knowing Faraday better than I did, though they could not have loved him more, support this proposal. Government has refused to contribute anything to the memory of this great man on the ground that he did not hold the position of a public servant. Had he been a fighting man, doubtless a statue would have been raised to his honour. But why should we attempt to rival Government in erecting a statue in a state church? Ought we not rather to make our memorial take a scientific and beneficent form, such as Faraday himself would have approved? England can do many things well, but she cannot make an artistic statue. Why then should we waste this splendid opportunity of doing good in the production of a wooden figure at great cost? And the good I would propose, is the creation of a permanent fund for the encouragement of poor students in science, and poor investigators. Many would give—I for one—their five guineas to such a fund, who would withhold it if the money is to be spent on stone. There are poor boys in poor schools who display an unusual amount of talent, but for want of means or patronage have no opportunity of rising. Could not such boys be collected in a Faraday College, and trained up in science? We might thus get the pick of undeveloped talent throughout these islands.

Faraday, who shunned empty titles, does not want a statue. His kindly feeling was always extended to workers in science. I have several times received a word of encouragement from him, either written or spoken, when it was most refreshing because most needed. I will mention an example of his self-denying kindness which is not, I believe, known, although thousands of such cases might be collected, for no one came in contact with Faraday without receiving some benefit.

Mr. Weale, the publisher, told me that a scientific man having agreed to write a book for him, delivered the copy and then had to go abroad. Mr. Weale read the proof-sheets. In one sheet several difficulties occurred which he could not solve. Not knowing who to apply to, he bethought himself of Faraday, although personally unknown to him. The messenger arrived at the Royal Institution, delivered the parcel, and said he would wait. "It is of no use," said the porter, "Mr. Faraday is unwell and is ordered out of town; he is just going to start." While the messenger was remonstrating, Faraday appeared, carpet-bag in hand, took the packet, and read the letter. "O, yes," said he, "I will do this for Mr. Weale. I can go by the next train."

Can the memory of such a man be honoured by resorting to the worn-out custom of erecting an ugly statue?—I am, &c.,

F.R.S.

June 25th, 1869.

SUPERPHOSPHATES.

To the Editor of the Chemical News.

SIR,—I observe in the CHEMICAL NEWS of last week an enquiry regarding the possibility of distinguishing between mineral and bone phosphates in superphosphates. If your correspondent will take two samples, one of a bone-ash and the other a coprolite superphosphate, and precipitate the insoluble phosphate by ammonia, and burn the precipitates, he will see that there is such a marked difference in the appearance of the two as to render it very easy to distinguish the one from the other.

Should your correspondent desire it, I shall be most happy to give him any information I can on the subject.—I am, &c.,

ARTHUR E. DAVIES, Ph.D.

Analytical Laboratory,
St. Mary's Gate, Manchester,
June 30th, 1869.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

In accordance with the generally expressed wishes of our friends and readers, we have effected arrangements to enable us to give, under the above heading, notices of EVERY CHEMICAL PAPER IN THE WORLD, *as soon as possible after publication. Whenever possible, these notices will appear in the form of carefully prepared, although necessarily brief, abstracts; as respects papers either too long or too abstruse to render condensation possible, their titles will be chronicled; and in all cases accurate reference will be made to the original publication. The two half-yearly volumes of the* CHEMICAL NEWS, *with their copious indices, will therefore be equivalent to an English edition of the "Jahresberichte," with the additional advantage of keeping the readers week by week on a level with the latest advances of science.*

Comptes Rendus des Séances de l'Académie des Sciences (No. 25), June 21, 1869.

Omitting the purely astronomical, mathematical, and other memoirs and papers of no direct interest to readers of our paper, we notice a memoir—

On a Homologue and Isomer of Choline.—M. Wurtz.—The author says—Some time ago I pointed out that, when chlorhydrate of glycol fixes and combines with trimethylamine, the result is the formation of a new basis identical with neurine as obtainable from brain. Since the identity of choline, which M. Strecker has extracted from liver, and the base just alluded to, has been proved, I shall call neurine henceforward choline. The reaction above mentioned is represented by the following formulæ:—

$$\underbrace{(C_2H_3)_3N}_{\text{Triethyl-amine.}} + \underbrace{C_2H_4\left\{\begin{matrix}OH\\Cl\end{matrix}\right.}_{\text{Chlorhydrate of glycol.}} = \underbrace{\left.\begin{matrix}C_2H_4.OH\\(C_2H_3)_3\end{matrix}\right\}NCl.}_{\text{Chlorhydrate of hydroxethylentri-ethylammonium.}}$$

This salt is soluble in water and alcohol, crystallises in prisms, and yields, with chloride of platinum, a crystalline double-salt made up according to the following formula:—

$$\left[\frac{C_2H_4.OH}{(C_2H_5)_3}N.Cl\right]_2 + PtCl_4.$$

The hydrate of hydroxethylen of triethylammonium, $C_8H_{21}NO_2$, is evidently a homologue of chinoline, $C_9H_{15}NO_2$. The author's paper describes, at very great length, the preparation of many complex compounds like those named, and, lastly, promises a detailed account of this portion of his labours.

Some Isopropylic Compounds.—M. Da Silva.—Butyrate of isopropyl is a colourless liquid; odour disagreeable; boils at 128° C.; is inflammable, and burns with a bright flame. Its vapour density is 4·73.—Valerate of isopropyl is also a liquid, colourless, inflammable, of a disagreeable odour, and of less density than water. Its specific gravity, at 0° C., is 0·8702; vapour density, 5·004; and boils at 142° C.

Coal-Tar Oils which Boil at about 200° C.—M. Romier.—The author says—Having obtained, through the kindness of the chief engineer and chemist of the United Parisian Gas Works Company, M. Audouin, 16 litres of heavy coal-tar oil, I have therefrom obtained about 4 litres of oil, perfectly freed from naphthaline, phenol, and alkaloids, and boiling at between 170° and 225° C. Leaving out of the subject of his research all fluids contained in the aforesaid 4 litres boiling below 176° C., and which in bulk represented 3¼ litres, the author has obtained three oils of constant boiling point, respectively boiling at between 176° and 179°, at between 196° and 198°, and, lastly, at between 200° and 225° C. These oils are colourless, lighter than water, and exhibit an odour reminding one of that of oil of turpentine; they have been submitted to a series of experiments; and the author states that they are cymens and hydrides of formen.

Analysis of the Meteorite of Kernouve, near Cléguérec, Morbihan, Fallen on the 22nd of May last.—M. Pisani.—The entire weight of this mass, before it was broken up, was about 80 kilos.; the piece from which a portion has been applied for analysis weighed 16 kilos. The specific gravity of this meteorite is, on an average, 3·747. The result of the analysis, in 100 parts, was as follows:—Iron, 22·25; nickel, 1·55; sulphur, 2·15; copper, a trace; chromate of iron, a trace; silica, 32·95; alumina, 3·19; protoxide of iron, 11·70; magnesia, 23·68; lime, 1·89; soda, with traces of potassa, 1·41.

Polytechnisches Centralblatt, No. 9, May 1, 1869.

We do not propose regularly to quote this periodical, which is chiefly devoted to mechanics and engineering; but whenever it happens to contain, either original papers of interest to our readers, or, as now and then occurs, abstracts of interest from German, Swedish, or Russian periodicals, which from their limited circulation have not become generally known, we shall make the necessary abstracts.

Ready Method of Preparing Phosphuretted Hydrogen Gas.—Dr. H. Schwartz says, When the pulverulent metallic zinc which is deposited in the tubes of the Belgian (Vieille Montagne) zinc smelting furnaces, is mixed with amorphous phosphorus in powder, in the proportion of one part of zinc to two of phosphorus, and this mixture, after having been introduced into a hard-glass combustion tube, is gently heated therein, while, at the same time, a current of dry coal gas or dry hydrogen gas is passed through the mixture, phosphide of zinc is formed; it is necessary to cool the tube and mixture while the current of gas remains turned on. From the phosphide of zinc so obtained phosphuretted hydrogen may be readily prepared by means of dilute sulphuric acid, or by boiling with caustic potassa solution; the gas evolved is, however, the non-spontaneously combustible kind; the spontaneously combustible gas may be obtained by applying a larger quantity of the phosphide of zinc and warm dilute sulphuric acid.

Analysis of some Colouring Substances used for Staining Glass and Faience Ware.—Dr. H. Schwartz.—A bright brown colour was found to consist in 100 parts of—Oxide of chromium, 11·30; peroxide of iron, 21·00; alumina, 18·02; oxide of zinc, 50·90; this material may be prepared as follows: 71 grms. of chrome alum; 60 grms. of persulphate of iron; 160 grms. of alum, and 180 grms. of sulphate of zinc, are dissolved in water, and after having been mixed, precipitated by means of carbonate of soda, collected on a filter, washed, dried, gently ignited, and rubbed to powder in an agate mortar; a reddish brown colour consisted in 100 parts of—Oxide of barium, 19·82; oxide of chromium, 11·07; peroxide of iron, 7·70; alumina, 2·30; Silica, 10·40; Sulphuric acid, 5·47; carbonic acid and alkali, 3·81.

Bulletin de l'Academie Imperiale des Sciences de St. Petersbourg, Vol. xiii.

This periodical contains only one paper relating to chemistry—A memoir, or rather, and more correctly, a fresh instalment of a memoir:—

On Hydrocarbons.—M. F. Fritzsche.—(Read at the meeting of the 4th of February last). The author says, I call Photen the substance $C_{14}H_{10}$, fusing at 210° C.; in pure state it is always a somewhat yellowish coloured solid, soluble in very strong alcohol, exhibiting in solid as well as in a fused state a violet fluorescence. Phosen, another hydrocarbon, fuses at 193° C.; by the action of sunlight this substance is entirely altered in its properties, and the so altered matter is called paraphosphen by the author; by simple fusion this latter is again converted into phosen. The author describes at great length the preparation in pure state of the two substances alluded to, discusses their crystallographical properties; describes oxyphoten $C_{14}H_8O_2$; oxybinitrophoten, dioxyretisten $C_{14}H_{14}O_2$; but these descriptions and the record of the properties, and mode of preparation of these substances, are so lengthy, and, moreover, so interspersed with discussions on other, although not in this respect quite irrevelant, matter, that it is impossible to give a condensed abstract which will do justice to the author.

PATENTS.

Communicated by Mr. VAUGHAN, F.C.S., Patent Agent, 54, Chancery Lane, W.C.

GRANTS OF PROVISIONAL PROTECTION FOR SIX MONTHS.

1641. J. Wilson, Royal Exchange Buildings, London, "Improvements in the manufacture of wrought iron."—A communication from I. O. York, New York, U.S.A.—Petition recorded May 28, 1869.

1713. I. Hopkinson, Leeds, "Improvements in the manufacture of artificial fuel."

1717. F. Rave, Manchester, "An improved method of extracting colour from vegetable matter."

1719. W. V. Morgan, Cannon Street, London. "Improvements in the manufacture of crucibles and other refractory articles or vessels."—A communication from J. L. Hall, and J. V. Morgan, Montreal, Canada.

1721. J. H. Johnson, Lincoln's-Inn-Fields, Middlesex, "Improvements in the manufacture of iron."—A communication from J. Burt, Detroit, Michigan, U.S.A.—June 3, 1869.

1731. J. Duke, Mannamead, near Plymouth, "Improvements in the manufacture of plaster and cement."—June 4, 1869.

1742. T. W. Arkle, Liverpool, "Improvements in the mode and means for extracting, recovering, or collecting copper from water containing the same in solution, and in apparatus therefor."—June, 5, 1869.

1782. A. St. C. Radisson, Lyons, France "Improvements in the treatment of oleine and other fatty matters for the purpose of transforming them into solid materials suitable for the manufacture of candles."

1785. W. L. Wise, Adelphi, Westminster, "Improvements in the manufacture of artificial fuel and in apparatus for the purpose."—A communication from B. Le Quesne and Dumontier, St. Servan, France.—June 9, 1869.

1800. G. W. Oliver, Liverpool, "Improvements in the manufacture of explosive powder and in machinery to be used in such manufacture."—A communication from P. A. Oliver, New York, U.S.A.—June 10, 1869.

NOTICES TO PROCEED.

319. W. A. Smith, Manchester, "Improvements in the preservation of meat, fish, and other perishable articles of food during their carriage by railway, and in apparatus connected therewith."—Petition recorded February 2, 1869.

374. H. A. Bonneville, Chaussée d'Antin, Paris, "A new and improved compound for preparing jelly broth."—A communication from C. J. Desnoix, Paris.—February 6, 1869.

420. J. Clayton, Radcliffe, Lancashire, "An improved paste for fixing and brightening aniline and pigment colours in printing on cotton, woollen, silk, or mixed fabrics."—February 10, 1869.

442. W. E. Newton, Chancery Lane, "Improvements in the manufacture of explosive compounds."—A communication from A. Nobel, Paris.—February 12, 1869.

637. J. Townsend and P. Forbes, Glasgow, N.B., "Improvements in refining or purifying oils and fats."—March 2. 1869.

942. E. Morewood, Rock Cottage, Briton Ferry, Glamorganshire, "Improvements in coating metals."—March 29, 1869.

1317. A. Meredith, Newgate Street, London, "Improvements in the manufacture of iron and steel."—April 28, 1869.

1469. J. Townsend and P. Forbes, Glasgow, N.B., "Improvements in refining or treating oils and fats, and in apparatus therefor.—May 13, 1869.

1539. W. R. Lake, Southampton Buildings, Chancery Lane, "An improved process for obtaining gelatine and other products from animal substances."—A communication from D. K. Tuttle, O. Lingo, W. J. Hooper, and T. Hooper, Baltimore, Ma., U.S.A.—May 19, 1869.

1575. C. W. Siemens, Great George Street, Westminster, "Improvements in calcining and smelting ores, and in furnaces and apparatus employed in connection therewith, which furnaces are also applicable to other purposes."—May 21, 1869.

1642. J. Brömer and H. Gurzkow, Frankfort-on-the-Maine, "An improved method of obtaining the anthracen out of asphaltos, that is to say, pitch produced from coal tar, and of preparing two colouring matters from the anthracen."—May 28, 1869.

TO CORRESPONDENTS.

*** *In consequence of the enlargement of our Journal by the introduction of abstracts of all the foreign periodicals, the index is much larger than it has hitherto been; we have therefore issued with this a supplement, which contains the title-page, preface, and a copious index to the volume just completed. The price is the same as for an ordinary number.*

THE CHEMICAL NEWS.

VOL. XX. No. 502.

ON

HEAT TREATED AS A SCIENCE OF KINETICS.*

By G. F. RODWELL, F.C.S.

I.

WE are surrounded by actions which we cannot readily recognise. There are actions of the nature of those which constitute light—differing not in kind, and but slightly in degree—which are unseen; there are other actions, similar to those which constitute sound, which are unheard; and others, again, similar to those which constitute heat, which are unfelt. Vast ranges of phenomena are beyond the direct cognisance of the senses. The organs by which external impressions are received and conveyed to the brain, although admirably perfect,—I need not say far *more* perfect than our most delicate and refined instruments—are yet, be it remembered, exercised solely in regard to the welfare of the organism of which they form a part. They are devoted to that organism, and exist for the purpose of enabling it to resist adverse assaults, whether of external agencies, or otherwise; to comply with all the demands requisite for the conditions of life, and to transform the external actions of the material world into actions capable of being recognised under some definite form by the centre of perception—the brain. The actions, or motions, which are thus received and transmitted by the nerves, are such alone as are requisite for the well-being of the entire organism. Light, sound, and heat are varieties of motion; but the nerves of seeing, hearing, and feeling only transmit certain of those motions: if they pass a well-defined limit of quickness or slowness, they cease to be transmitted. But these same relatively quick and relatively slow motions, although incapable of being directly recognised by us, do not the less profoundly influence matter. It is the object of natural philosophy to investigate *all* the actions by which matter is influenced.

Thus our senses are limited in their capability of observation. Their operations are finite. Hence, when we pass from the influence of the so-called *physical forces*—light, heat, electricity, chemical action—upon ourselves to their influence upon matter external to ourselves, it is necessary for us to assist and exact the capabilities of the senses in the particular direction required, and to free the intellect from impressions produced by unaided observation, the bias so resulting, and from the *idola specus* of which Bacon speaks, for we have all of us in our minds "*specum sive cavernam quæ lumen naturæ frangit et corrumpit.*" It therefore behoves us when we study natural philosophy—specially any branch of it submitted to a mode of treatment more assimilable with reason, but less so, perchance, with unaided observation than some older and long-dominant system—it behoves us, I say, to receive with caution, and to carefully examine and analyse the impressions conveyed to us by our unassisted senses, and to put from our minds all preconceived notions, whether derived from directly-received impression, or indirectly from the authority of some older physical system; and this I will ask you to do at the outset. And when, as will frequently be the case, I shall have to speak to you of minute, invisible particles or molecules of matter, endued with functions, attributes, and influences, diverse in form, and varied in character, and such alone as we are wont to associate with larger masses of matter, capable of being seen, and handled, and weighed, I will ask you to grant me some faith, and some imagination. If you find difficulty in doing this in this particular direction, remember that every grain of sand upon the sea-shore is a microcosm, sharing in the innate motions which pulsate through the Universe; and remember, further, that there are specks, infinitely smaller than grains of sand, in which a heart beats, and blood circulates, and all the functions of an exuberant vitality are exercised; and thus, by comparing the unknown with the known, faith may be lessened, and imagination not too tensely stretched.

I had intended to have adopted a different name for the subject of this course from that which appears on the syllabus; to have replaced the word *heat* by some term which, as I thought, would better associate in your minds the idea of motion with that of heat; such as *thermo-kinetics* (from θερμος heat; and κινησις, motion), or *thermo-dynamics*; or to have spoken of it as *a certain motion appertaining to matter*. I had intended to have done this, when, on enquiring into the etymology of our word *heat*, I found that the term is peculiarly appropriate, although the science which it designates has, of late, undergone the most profound changes. The word *heat* is closely related to the Anglo-Saxon *haets*, the Gothic *haitan*, the Icelandic *hita*, and the old High German *eit*; and these words agree, by Grimm's law, with the Greek αιθος, fire, from αιθω, to kindle; mark, also, the related words αιθοψ, αιθυσσω, and (perhaps) αιθηρ. The celebrated philologist Bopp, carries back the derivation to a Sanskrit root—*indhi*, to shine; and traces it through the Greek αιθος, the Latin *æstus*, and the old High German *eit*, to our word *heat*. "*Æstus*," says Vossius, in his "Lexicon Etymologicon," *est commotio, vel in igne, vel in aqua, vel in animo. Omnis autem commotio fervorem gignit.*" Now, as it will be my object to show that heat *is* a commotion of the small particles or *molecules** of matter, I think you will agree with me that the term could not be changed with advantage.

From an early age, the idea of motion has, in some form or other, been associated with that of heat. I may remind you that, in αιθυσσω, to put in rapid motion, to kindle (from αιθω), we have distinct reference to this; and, moreover, that αιθηρ, from which we have our word *ether*, was sometimes used to express fire. From the supposed proximity of the sphere of ether to the sphere of fire, and the generation of the latter from the former, the ether was sometimes regarded by the ancients as a very pure fire; invisible all-pervading, and in perpetual motion; indeed, as a something approaching to the nature of what we now call heat. Now if, as Aristotle affirms, αιθηρ is derived from αει, always, and θεω, to move swiftly, we have here additional evidence that, at an early period, the idea of motion was associated with that of heat.

"*Æstus est commotio . . . omnis commotio fervorem gignit.*" I will define heat as a rapid motion of molecules of matter. This motion, when transmitted to the brain by the molecules of the sensory nerves, produces in us the sensation by which heat is familiarly known.

Let us now briefly trace the rise of the two theories which for so long a time prevailed in regard to the nature of heat. Epicurus regarded heat as an efluxion of minute spherical particles which, in virtue of their smallness, and of the rapidity of their motion, insinuate themselves into the densest substances, and thus expand, and eventually disintegrate them. Lucretius, who followed Epicurus somewhat closely, maintained that both light and heat are caused by the vehement motion of small primary particles—*primi minuti*, as he calls them. The majority of the ancient philosophers regarded fire (under which term was included both light and heat) as an element more divine than air, water, and earth; it was to them the acting agent of the Universe, the *force* exercising itself upon *matter*. The function of fire is well signified in the story of Prometheus, who, you will remember, is related to have stolen fire from heaven, and therewith

* A course of four lectures delivered at the London Institution.

* *Molecula*, a little mass; a Low Latin diminutive of *moles*, a mass; a mass of incommensurable minuteness.

vivified mankind. Fire was the *anima*, while tangible matter was the *corpus*.

The ideas of the ancients regarding the nature of heat were very generally adopted during the middle ages. Cardanus frequently speaks of *motus ignis* and *motus caloris*. Telesius, of Cosenza, a philosopher far in advance of his time, asserted that heat is the cause of motion, cold of rest, and that these principles together produce all the phenomena of the universe. Robert Fludd (also known as Robertus de Fluctibus), the founder of the Fluddists, affirmed that heat is the ultimate effect of the action of light, and that it results from the motion of material particles. Francis Bacon was one of the first to deny the elemental nature of fire, by asserting that it is "merely compounded of the conjunction of light and heat in any substance;" elsewhere he defines heat as "not an expansive motion of the whole, but of the small parts of a body." As an example of the production of heat by the transformation of visible motion, he mentions that a piece of metal when hammered becomes hot, and that if the hammering were continued, it would possibly become red-hot.*

About twenty years after the death of Bacon, the *Principia* of Descartes appeared. In it we find the development of one of the most comprehensive kinetic systems which has ever appeared in the history of science. (By *kinetic system* I mean a system in which the phenomena of the universe are accounted for on the supposition that they are caused by various motions). It is impossible at the present time to enter into any detail account of the Cartesian philosophy. I may mention, however, that Descartes supposed the existence of three elements, by the mutual interaction of which all natural phenomena are produced. The first element, the *materia cælestis*, corresponding somewhat to the *αιθηρ* of the Ancients, is a very subtle medium, possessing perpetual and vehement circular motion, and it is the cause of all the motion in the universe; the second element is more gross, and it embraces all gaseous matter, while the third element embraces all solids and liquids. Thus the first element, which actuates by its motion the second and third elements, corresponds somewhat with what we now call a *force*. Heat, according to Descartes, is a rapid circular motion of the particles of the third element, communicated by the materia cælestis. The particles of oils and fats, and of combustible bodies generally, are peculiarly adapted to the reception of this motion, and such bodies he designated "potentially hot." Among other passages which bear upon the kinetic theory of heat, I find the following in the fourth book of the *Principia*:—"A nail which is being driven into a block of wood does not become hot until after it has been driven home by the hammer, because heat is not a motion of masses, but of small particles, and so long as the nail itself is capable of moving, the force of the blow is expended in producing the motion of a mass, not in moving the small particles of the metal." The nature of heat, according to the Kinetic theory, received a very apt expression in the following definition given by John Locke:—"Heat is a very brisk agitation of the insensible parts of the object, which produces in us that sensation from which we denominate the object hot; so that what in our sensation is *heat* in the object is nothing but motion."

Towards the close of the seventeenth century, there arose a theory which endeavoured to trace the cause of a number of phenomena to the absorption or rejection of "*materia aut principium ignis, non ipse ignis*," better known as the theory of Phlogiston (from *φλογιστος*, burnt). This theory profoundly influenced the scientific world for more than a century, and it led to an extended theory of materialised heat.

We thus perceive that there had gradually arisen two distinct theories in regard to the nature of heat, for while some regarded it as a motion of the molecules of matter,—as a condition, or attribute of matter, others regarded it as matter itself, subtle indeed, and infinitely thin, but yet a kind of matter capable of being absorbed or rejected by other and grosser matter. The former of these is the *Kinetic theory of heat*, (*κινησις*, motion), and is now generally, if not universally, adopted; the latter is the *material theory of heat* (*materia*, matter), and it was almost universally adopted during the last, and far into the present, century.

According to the materialists, substances have heat stored up in them. A metal becomes hot when it is hammered because its particles are approximated, and the heat is, as it were, squeezed out of it, as water is squeezed out of a sponge. The metal, before being hammered, was said to possess a *greater capacity for heat* than the hammered metal. In a similar manner they accounted for the production of heat by friction and percussion; the possibility of producing new heat was denied, and the amount in the universe was considered incapable of variation.

In 1798, Count Rumford, while engaged in the boring of cannon in the Arsenal of Munich, observed, with surprise, the large amount of heat which was produced during the process, and the apparently unlimited extent of its production. Now, he reasoned, if the explanation of the materialists be correct, it follows that all the heat observed in the cannon, and in the separated borings, results from the altered capacity for heat of a few ounces of metal borings. But, on examination, they were found to possess precisely the same capacity for heat as an equal weight of the solid metal, hence the explanation offered by the materialists was clearly fallacious. Rumford afterwards constructed a special machine for the production of heat by friction. It consisted of a metal cylinder in which a blunt steel borer was caused to revolve by horse-power. The cylinder was surrounded by a casing, in which was placed about 2½ gallons of water. When the borer was caused to revolve, the temperature of the water gradually rose, until, in two hours and a half, the whole quantity of water commenced to boil—a conclusive proof of the unlimited production of heat by mechanical means. A few years later, Sir Humphry Davy conclusively proved the immateriality of heat, by demonstrating the liquefaction of two pieces of ice submitted to friction in a freezing atmosphere. Now, it was admitted—even by the materialists, who contested every inch of ground—that water possesses more heat than ice at the same temperature, hence, if their explanation were valid, ice ought not to liquefy when submitted to friction in a freezing atmosphere.

Although the fallacy of the material theory was thus proved early in the century, the theory was by no means abandoned, and it continued to be generally adopted (when *any* theory at all of heat was adopted), until it was shown that a definite relationship exists between heat and mechanical work, and that they are mutually convertible. This determination of the so-called *mechanical equivalent of heat* was made almost simultaneously by Dr. Julius

* Some time ago a correspondent enquired in this journal if iron could really be hammered until it becomes red-hot, and some discussion was elicited on the subject, the general conclusion appearing to be that it is one of the many things which are much talked of, but never seen. I recently asked a blacksmith if he could do it, and he replied that he had never seen it done, but would try. In the first place a piece of very tough iron was hammered with a moderately heavy hammer; it became hot, but scarcely sufficiently so to scorch a piece of paper upon which it was placed. It was then hammered by two men, one of whom used a sledge hammer, but the iron scarcely became hotter than before. Presently a man who was working in the shop said he had often lit his forge fire by the means when matches were less plentiful than now, and he accordingly took a nail, such as is used for shoeing horses, and after hammering with a light hammer for less than two minutes, part of the nail was brought to a bright red heat. It thus appears that there is a good deal of knack in the operation; the blows were light but frequent, and the nail was turned at each blow, with something of the alternating motion which is adopted in feathering an oar; that is, if we suppose the nail to be square, it was turned, so as to receive one blow upon a surface A, the second on a contiguous side B, the third on A again, and so on, these two surfaces being struck alternately. A few months ago I saw a heavily laden omnibus rapidly descending Pentonville-hill with a locked wheel; before reaching the bottom of the hill the bearing surface of the locked wheel was glowing with a bright red heat, and the adjacent woodwork was on fire.

Mayer, of Heilbronn, in Wurtemburg, and by Mr. Joule, of Manchester, in the year 1842. Mayer worked out his result rather by reasoning upon known facts than by direct experiment, while Joule instituted a lengthy and elaborate series of experiments, which were published in their entirety in 1850. Since this date, the kinetic theory of heat has been largely developed by the labours of Hirn, Helmholtz, and Sir William Thomson, and notably by Professor Clausius, of Zurich.

Let us now turn our attention to Joule's determination of the relationship existing between heat and mechanical work, or, more correctly, and in accordance with the definition of heat with which we started, of the amount of mass motion equivalent to and convertible into a definite amount of molecular motion. In this country, the unit of mechanical work (known as the *foot-pound*) is the mechanical force necessary to lift 1 lb. to a height of 1 foot *in vacuo*, and the unit of heat is the quantity of heat necessary to raise 1 lb. of water 1° F. in temperature strictly from 55° to 56° F. On the Continent, the unit of work (called a *kilogrammetre*) is the mechanical force necessary to lift 1 kilogramme to a height of 1 metre *in vacuo*, and the unit of heat is the quantity of heat necessary to raise 1 kilogramme of water from 0° C. to 1° C. Sometimes the quantity of heat necessary to raise 1 lb. of water from 0° to 1° C. is adopted as a unit of heat in this country.

Now the simplest and most definite form of mechanical force is the falling of a known weight through a known space under the influence of the force of gravity; and this form of force was employed by Mr. Joule to produce heat by friction. A falling weight was caused to communicate rotary motion to a paddle working respectively in water and in mercury, and to produce the revolution of cast-iron discs in contact; and the increase of temperature resulting from the friction was measured by thermometers which could be read to 1-200th of a degree Fahrenheit. The rise of temperature for each experiment was—in the case of water, 0·563° F.; mercury, 2·41° F.; and cast-iron, 4·3° F.+ By this method, Joule ascertained that a weight of 1 lb., falling from a height of 772 feet, produces, on its collision with the earth, an amount of heat competent to raise the temperature of 1 lb. of water 1° F. (that is to say, to generate one unit of heat). Mayer, by a perfectly distinct method, found the number to be 771·4 feet—a difference of less than 0·1 per cent; hence there can be no doubt concerning the accuracy of the determinations.

Let us next consider the various modes by which heat may be generated—the various causes which tend to produce a rapid motion in the molecules of matter; and this brings us at once to the subject of *energy*.

Energy (ενεργεια, action, operation) is a term used in physics to designate the power of doing work against or overcoming the action of force, whether it be—(α) the attraction of masses acting through a sensible space (*gravity*); (β) the attraction of similar molecules acting through an insensible space (*cohesion*); (γ) the attraction of dissimilar molecules acting through an insensible space (*chemical affinity*); (δ) the attraction of molecules in different electrical or magnetic conditions (*electrical and magnetic attraction*), or any action whatsoever which it may be possible to resist. In fact, we may attach to the term energy almost the same meaning as it possesses when applied to ourselves. Energy is competent to exist in two conditions; viz., as *potential energy*, or possible energy; and as *kinetic energy*, or actual energy; and these may be likened to energy of character, and to energy of action in ourselves.

Potential energy, or energy of position, or possible energy, or, as Helmholtz calls it, energy of tension, is energy existing in possibility, not in act, as in the case of a ball suspended above the surface of the earth, or an arrow resting upon a tense bow-string.

Kinetic energy, or energy of motion, or dynamic energy, or *vis viva*, or mechanical energy (for by these various names you will find it designated in different books), is the actual energy of a body in motion; as in the case of a ball falling to the earth's surface, or an arrow projected from a released bow-string.

Now, when the kinetic energy of a mass is suddenly arrested—as by collision with a larger mass—it is transformed into the motion of molecules—it becomes heat; and it has been found that the heat thus produced is dependent upon the mass of the moving body multiplied by the square of its velocity, that is, $h = mv^2$. From this, it follows that, if the velocity of a projectile be doubled, the heat developed on the stoppage of its motion will be increased fourfold; if trebled, ninefold; if quadrupled, sixteenfold; and so on. It has thus been calculated that a rifle-bullet, moving with a velocity of 1338 feet per second, develops, upon striking the target, sufficient heat to raise its temperature 1080° F., an amount more than sufficient to fuse it; but we must remember that this heat is shared between the bullet and the target. But, in the application of this law, we may pass from the arrested motion of a rifle-bullet to that of far larger masses of matter. Mayer and Helmholtz have calculated the amount of heat which would be produced by the stoppage of the earth in its orbit, and have determined that it would be sufficient not alone to fuse, but actually to vaporise the earth. The heat thus generated would be equal to that produced by the burning of fourteen spheres of coal, each equal to the earth in magnitude.

The amount of energy in the Universe is constant; we can neither add to it nor take from it; the only possible change is from one form to another; and this is called the principle of the *conservation of energy*.

Potential energy is constantly being converted into kinetic energy, and kinetic energy as constantly into heat. Friction, percussion, and compression, and the partial or complete stoppage of motion in any form, and by any means whatsoever, afford examples of this. (I.)—*By Friction.*—Lucretius tells us that fire was first made known to mortals, either by clouds meeting violently in collision and dashing out sparks of fire, or by the excessive friction of the branches of trees in a forest, induced by high winds, and resulting in fire. Friction has, from the earliest ages, been employed as a means of producing fire, and in our modern matches, although the labour is lessened, we still adopt the means. (The many experiments which illustrate this part of the subject are too well known to need detail here. Phosphorus may be readily ignited by the heat of friction (α) of a pointed piece of wood rubbed in a wooden groove; (β) of a gimlet which has been used for boring wood, or (γ) of a saw which has been used for sawing; (δ) by the heat resulting from the friction of the crystalline fibres of tin, by bending a rod of that metal repeatedly in opposite directions; and a number of examples will suggest themselves at once without further mention.) (II.)—*By Percussion.*—A piece of metal when hammered becomes hot, and may readily be brought to a red heat. When a pistol is cocked, potential energy is conferred upon the hammer; it is comparable to a raised weight: when the trigger is pulled, the potential energy becomes kinetic; when the hammer strikes the cap the kinetic energy becomes heat equal to that expended in raising the hammer. (III.) - *By Compression.*—A piece of wood, compressed in an hydraulic press, becomes warmer than before. In the rolling of the metals (as at the Mint), the bar, before passing between the rollers, is cold, but, after compression, it comes out so intensely heated that water assumes the spheroidal condition when poured upon it.

+ If water be violently shaken in a bottle for less than a minute, a rise of temperature of from 0·7° to 0·8° F. ensues; and, in the case of mercury, of from 1·3° to 1·5° F. Of course, in both cases, if the bottles are shaken by the hand, they must be surrounded by several layers of thick flannel, to prevent any communication of heat from the hand. Mr. Herschell has ingeniously shown the heating of mercury by agitation by communicating rapid reciprocal motion to a tube containing a small quantity of that metal, and then placing a piece of phosphorus on its surface: immediate ignition is the result.

(IV.)—*By Chemical Action.*—The production of heat by chemical action is probably due to the conversion of the kinetic energy of molecules into heat, as in the above instances, the heat resulted from the conversion of the kinetic energy of *masses*. (Instances of the production of heat by chemical action are too numerous to require notice here; take the combination of sulphuric anhydride with water, or of iodine with phosphorus, as examples.) Molecules, chemically separated, are in the condition of a raised weight, the energy which has been expended in separating them has overcome the force of chemical attraction, and removed the molecules out of its range; when they once again come within the range of the attraction, they rush together and unite chemically; their potential energy becomes kinetic, and the kinetic energy becomes heat. (V.)—*By Electricity in Motion.*—When kinetic electricity passes through a thin wire which offers some resistance to its passage, heat is copiously produced. (The production of heat by the energy of electricity in motion cannot be accounted for until we know more of the nature of electricity. Possibly, in the above experiment, the electricity so agitates the molecules of the conducting wire that, while transmitting its own motion, a collision of molecules results, and a consequent production of heat; or, in other words, the electricity may indirectly confer kinetic energy upon the molecules of the conducting wire, which energy is resolved into heat.)

The reverse of the above action also takes place. Heat is consumed—(α) in the production of mechanical work as in heat engines, the most prominent example of which is the steam-engine; (β) in the separation of molecules chemically united, as in any instance of decomposition by heat; and (γ) in the production of kinetic electricity, as in the thermo-electric pile. Mayer, writing in 1842, says, "A locomotive may be compared to a distilling apparatus; the heat applied under the boiler passes off as motion, and this is deposited as heat at the axles of the wheels."* Sparks may be frequently observed at the point of contact of the break-wheels and the rail at any of the "Metropolitan Railway" stations. The trains on this line keep up their speed until they are on the point of entering the station, hence their motion is more suddenly arrested than that of trains in general, and hence the above result. The loss of molecular motion (cold) which results from the performance of work, may be readily shown by causing a gas to perform work, as when the receiver of an air-pump is rapidly exhausted, the production of cold is shown by the deposit of moisture upon the sides of the receiver; it may also be readily shown by a Breguet's helix; or, again, when a cork is projected from a soda-water bottle, cold results. The condition of the cork at any moment can be clearly defined by bearing in mind that which has been said above on the subject of energy. At the outset the cork is in a condition of potential energy, for it has a greater pressure upon its under than upon its upper surface, and is hence competent to do work against gravity; when the string is cut, the potential energy becomes kinetic, and the cork is projected into the air. At any moment of its flight before attaining the final altitude, it possesses both potential and kinetic energy, for it possesses potential energy capable of causing it to fall through the space intervening between it and the earth, *plus* the kinetic energy which will raise it to the final altitude; when the latter is attained, the energy is obviously all potential, and the potential energy is not entirely transformed into kinetic until the cork reaches the earth; on its collision, heat is produced equal to that consumed in projecting it from the bottle.

Ink for Writing on Glass.—A solution of fluoride of ammonia is recommended as furnishing a ready means of writing with a pen of any kind upon glass, and is especially adapted for labelling bottles, cylinder-tubes, &c., in the laboratory, as well as for marking the degrees upon hydrometers and apparatus of similar construction.—*American Artisan.*

ADDITIONAL

OBSERVATIONS ON HYDROGENIUM.*

By THOMAS GRAHAM, F.R.S., Master of the Mint.

From the elongation of a palladium wire, caused by the occlusion of hydrogen, the density of hydrogenium was inferred to be a little under 2. But it is now to be remarked that another number of half that amount may be deduced with equal probability from the same experimental data. This double result is a consequence of the singular permanent shortening of the palladium wire observed after the expulsion of hydrogen. In a particular observation formerly described, for instance, a wire of 609·14 m.m. increased in length to 618·92 m.m. when charged with hydrogen, and fell to 599·44 m.m. when the hydrogen was extracted. The elongation was 9·77 m.m., and the absolute shortening or retraction 9·7 m.m., making the extreme difference in length amount to 19·47 m.m. The elongation and retraction would appear, indeed, to be equal. Now it is by no means impossible that the volume added to the wire by the hydrogenium is represented by the elongation and retraction taken together, and not by the elongation alone, as hitherto assumed. It is only necessary to suppose that the retraction of the palladium molecules takes place the moment the hydrogenium is first absorbed, instead of being deferred till the latter is expelled; for the righting of the particles of the palladium wire (which are in a state of excessive tension in the direction of the length of the wire) may as well take place in the act of the absorption of the hydrogenium as in the expulsion of that element. It may, indeed, appear most probable in the abstract that the mobility of the palladium particle is determined by the first entrance of the hydrogenium. The hydrogenium will then be assumed to occupy double the space previously allotted to it, and the density of the metal will be reduced to one-half of the former estimate. In the experiment referred to, the volume of hydrogenium in the alloy will rise from 4·68 per cent to 9·36 per cent, and the density of hydrogenium will fall from 1·708 to 0·854, according to the new calculation. In a series of four observations upon the same wire, previously recorded, the whole retractions rather exceeded the whole elongations, the first amounting to 23·99 m.m., and the last to 21·38 m.m. Their united amount would justify a still greater reduction in the density of hydrogenium, namely to 0·8051.

The first experiment, however, in hydrogenating any palladium wire appears to be the most uniform in its results. The expulsion of the hydrogen afterwards by heat always injures the structure of the wire more or less, and probable affects the regularity of the expansion afterwards in different directions. The equality of the expansion and the retraction in a first experiment appears, also, to be a matter of certainty. This is a curious molecular fact, of which we are unable as yet to see the full import. In illustration, another experiment upon a pure palladium wire may be detailed. This wire, which was new, took up a full charge of hydrogen, namely, 956·3 volumes, and increased in length from 609·585 to 619·354 m.m. The elongation was, therefore, 9·769 m.m. With the expulsion of the hydrogen afterwards, the wire was permanently shortened to 600·115 m.m. It thus fell 9·470 m.m. below its normal or first length. The elongation and retraction are here within 0·3 m.m. of equality. The two charges taken together amount to 19·239 m.m., and their sum represents the increase of the wire in length due to the addition of hydrogenium. It represents a linear expansion of 3·205 on 100, with a cubic expansion of 9·827 on 100. The composition of the wire comes to be represented as being—

	In volume.	
Palladium	100·000	or 90·895
Hydrogenium	9·827	or 9·105
	109·827	or 100·000

* Read before the Royal Society, June, 1869.

The specific gravity of the palladium was 12·3, the weight of the wire 1·554 grm., and its volume 0·126 cub. centim. The occluded hydrogen measured 120·5 cub. centims. The weight of the same would be 0·0108 grm., and the volume of the hydrogenium 0·012382 cub. centim. (100 : 9·827 : : 0·126 : 0·01238). The density of the hydrogenium is therefore

$$\frac{0{\cdot}0108}{0{\cdot}01238} = 0{\cdot}872.$$

This is a near approach to the preceding result, 0·854. Calculated on the old method, the last experiment would give a density of 1·758.

It was incidentally observed, on a former occasion, that palladium alloyed with silver continues to occlude hydrogen. This property is now found to belong generally to palladium alloys, when the second metal does not much exceed one-half of the mixture. These alloys are all enlarged in dimensions when they acquire hydrogenium. It was interesting to perceive that the expansion was greater than happens to pure palladium, about twice as much; and that, on afterwards expelling the hydrogen by heat, the fixed alloy returned to its original length *without any further shortening of the wire*. The embarrassing retraction of the palladium has, in fact, disappeared.

The fusion of the alloys employed was kindly effected for me by Messrs. Matthey and Sellon, when the proportion of palladium was considerable, by the instrumentality of M. Deville's gas furnace, in which coal gas is burned with pure oxygen; or by means of a coke furnace, when the metals yielded to a moderate temperature. The alloy was always drawn out into wire if possible, but if not sufficiently ductile, it was extended by rolling into a form of a thin ribbon. The elongation caused by the addition of hydrogenium was ascertained by measuring the wire or ribbon stretched over a graduated scale, as in the former experiments.

1. *Palladium, Platinum, and Hydrogenium.*—Palladium was fused with platinum, a metal of its own class, and gave an alloy consisting, according to analysis, of 76·03 parts of the former, and 23·97 parts of the latter. This alloy was very malleable and ductile. Its specific gravity was 12·64. Like pure palladium, it absorbed hydrogen, evolved on its surface in the acid fluid of the galvanometer, with great avidity.

A wire 601·845 m.m. in length (23·69 inches) was increased to 618·288 m.m., on occluding 701·9 volumes of hydrogen gas measured at 0° C. and 0·76 barom. This is a linear elongation of 16·443 m.m. (0·6472 inch), or 2·732 on a length of 100. It corresponds with a cubic expansion of 8·423 volumes on 100 volumes; and the product may be represented—

	In volume.
Fixed metals	100·000 or 92·225
Hydrogenium	8·423 or 7·775
	108·423 or 100·000

The elements for the calculation of the density of hydrogenium are the following, the assumption being made as formerly, that the metals are united without condensation:—

Original weight of the wire, 4·722 grms.
Original volume of the wire, 0·373 cub. centim.
Volume of the hydrogen extracted, 264·5 cub. centims.
Weight of the hydrogen extracted, by calculation, 0·0237 grm.

The volume of the hydrogenium will be to the volume of the wire (0·373 cub. centim.) as 100 is to 8·423; that is, 0·03141 cub. centim. Finally, dividing the weight of the hydrogenium by its bulk, 0·0237 by 0·03141, the density of hydrogenium is found to be 0·7545.

On expelling all hydrogen from the wire at a red heat, the latter returned to its first dimensions as exactly as could be measured. The platinum present appears to sustain the palladium, so that no retraction of that metal is allowed to take place. This alloy therefore displays the true increase of volume following the acquisition of hydrogenium, without the singular complication of the retraction of the fixed metal. It now appears clear that the retraction of pure palladium must occur on the first entrance of hydrogen into the metal. The elongation of the wire due to the hydrogenium is negatived thereby to the extent of about one-half, and the apparent bulk of the hydrogenium is reduced to the same extent. Hydrogenium came in consequence to be represented of double its true density.

The compound alloy returns to its original density (12·64) upon the expulsion of the hydrogen, showing that hydrogen leaves without producing porosity in the metal. No absorptive power for vapours, like that of charcoal, was acquired.

The same wire of palladium and platinum, charged a second time with hydrogen, underwent an increase in length from 601·845 to 618·2, or sensibly the same as before. The gas measured 258 c.c., or 619·6 times the volume of the wire. The product may be represented as consisting of—

	By volume.
Fixed metals	92·272
Hydrogenium	7·728
	100·000

The density of hydrogenium deducible from this experiment is 0·7401. The mean of the two experiments is 0·7473.

2. *Palladium, Gold, and Hydrogenium.*—Palladium fused with gold formed a malleable alloy, consisting of 75·21 parts of the former and 24·79 parts of the latter, of a white colour, which could be drawn into wire. Its specific gravity was 13·1. Of this wire 601·85 m.m. occluded 464·2 volumes of hydrogen, with an increase in length of 11·5 m.m. This is a linear elongation of 1·91 on 100, and a cubic expansion of 5·84 on 100. The resulting composition was therefore as follows:—

	In volume.
Alloy of palladium and gold ..	100·00 or 94·48
Hydrogenium	5·84 or 5·52
	105·84 100·00

The weight of the wire was 5·334 grms.
The volume of the wire was 0·4071 c.c.
The volume of hydrogen extracted, 189 c.c.
The weight of the hydrogen, 0·01693 grm.
The volume of the hydrogenium, 0·02378 c.c.
Consequently the density of the hydrogenium is 0·711.

The wire returned to its original length after the extraction of the hydrogen, and there was no retraction.

The results of a second experiment on the same wire were almost identical with the preceding.

The elongation on 601·85 m.m. of wire was 13·3 m.m., with the occlusion of 463·7 volumes of hydrogen. This is a linear expansion of 1·902 on 100, and a cubic expansion of 5·81 on 100. The volume of hydrogen gas extracted was 188·8 c.c., of which the weight is 0·016916 grm. The volume of the hydrogenium was 0·02365 c.c., that of the palladium gold alloy being 0·4071 c.c. Hence the density of the hydrogenium is 0·715.

In a third experiment, made on a shorter length of the same wire, viz., 241·2 m.m., the amount of gas occluded was very similar, viz., 468 volumes, and was not increased by protracting the exposure of the wire for the long period of 20 hours. There can be little doubt, then, of the uniformity of the hydrogenium combination, the volume of gas occluded in the three experiments being 464·2, 463·7, and 468 volumes. The linear expansion was 1·9 on 100 in the third experiment, and therefore similar also to the preceding experiments.

The hydrogenium may be supposed to be in direct combination with the palladium only, as gold by itself shows no attraction for the former element. In the first experi-

ment the hydrogenium is in the proportion of 0·3151 to 100 palladium and gold together. This gives 0·3939 hydrogenium to 100 palladium; while a whole equivalent of hydrogenium is 0·939 to 100 palladium.* The hydrogenium found is, by calculation, 0·4195 equivalent, or one equivalent hydrogenium to 2·383 equivalents palladium, which comes nearer to two equivalents of the former with five of the latter than to any other proportion.

To ascertain the smallest proportion of gold which prevents retraction, an alloy was made by fusing seven parts of that metal with 93 parts of palladium, which had a specific gravity of 13·05. The button was rolled into a thin strip and charged with hydrogen by the wet method. An occlusion of 585·44 volumes of gas took place, with a linear expansion of 1·7 on 100. A retraction followed to nearly the same extent on afterwards expelling the hydrogen by heat.

With another alloy, produced by fusing 10 of gold with 90 of palladium, the occlusion of gas was 475 volumes, the linear expansion 1·65 on 100. The retraction on expelling the gas afterwards was extremely slight. To nullify the retraction of the palladium, about 10 per cent of gold appears therefore to be required in the alloy.

Another alloy of palladium of sp. gr. 13·1, and containing 14·79 per cent of gold, underwent no retraction on losing hydrogen, as already stated.

The presence of so much gold in the alloy as half its weight did not materially reduce the occluding power of the palladium. Such an alloy was capable of holding 459·9 times its volume of hydrogen, with a linear expansion of 1·67 per cent.

3. *Palladium, Silver, and Hydrogenium.*—The occluding power of palladium appeared to be entirely lost when that metal was alloyed with much more than its own weight of any fixed metal. Palladium alloys containing 80, 75, and 70 per cent of silver, occluded no hydrogen whatever.

With about 50 per cent of silver, palladium rolled into a thin strip occluded 400·6 volumes of hydrogen. It expanded 1·64 part in 100 in length, and returned to its original dimensions without retraction upon the expulsion of the gas. The specific gravity of this silver-palladium alloy was 11·8; the density of the hydrogenium 0·727.

An alloy, which was formed of 66 parts of palladium and 34 parts of silver, had the specific gravity 11·45. It was drawn into wire, and found to absorb 511·37 volumes of hydrogen. The length of the wire increased from 609·601 to 619·532 m.m. This is a linear elongation of 1·629 on 100, or cubic expansion of 4·97 on 100. The weight of the wire was 3·483 grms.; its volume 0·3041 c.c. The absolute volume of occluded hydrogen was 125·1 c.c., of which the weight is 0·01120896. The volume of the hydrogenium was 0·015105 c.c. The resulting density of hydrogenium is 0·742.

In a repetition of the experiment upon another portion of the same wire, 407·7 volumes of hydrogen were occluded, and the wire increased in length from 609·601 m.m. to 619·44 m.m. This is a linear expansion of 1·614 part on 100, and a cubic expansion of 4·92 on 100. The absolute volume of hydrogen gas occluded was 124·0 c.c., and its calculated weight 0·01111 grm. The volume of the hydrogenium being 0·1496 c.c., the density of hydrogenium indicated is 0·741. The two experiments are, indeed, almost identical. The wire returned in both experiments to its original length exactly after the extraction of the gas.

4. *Palladium, Nickel, and Hydrogenium.*—The alloy, consisting of equal parts of palladium and nickel, was white, hard, and readily extensible. Its specific gravity was 11·22. This alloy occluded 69·76 volumes of hydrogen, with a linear expansion of 0·2 per cent. It suffered no retraction below its normal length on the expulsion of the gas by heat.

An alloy of equal parts of *bismuth* and palladium was a brittle mass that did not admit of being rolled. It occluded no hydrogen, after exposure to that gas as the negative electrode, in an acid fluid for a period of 18 hours. It seems probable that malleability and the colloid character, which are wanting in this bismuth alloy, are essential to the occlusion of hydrogen by a palladium alloy.

An alloy of one part of *copper* and six parts of palladium proved moderately extensible, but absorbed no sensible amount of hydrogen. The metallic laminæ which remain on digesting this alloy in hydrochloric acid, and which were found by M. Debray to be a definite alloy of palladium and copper (PdCu), exhibited no sensible occluding power.

The conclusions suggested as to the density of hydrogenium, by the compound with palladium alone and by the compounds with palladium alloys, are as follows:—

	Density of Hydrogenium observed.
When united with palladium	0·8540 to 0·8720
When united with palladium and platinum	0·7401 to 0·7545
When united with palladium and gold ..	0·7110 to 0·7150
When united with palladium and silver ..	0·7270 to 0·7420

The results, it will be observed, are most uniform with the compound alloys, in which retraction is avoided, and they lie between 0·711 and 0·7545. It may be argued that hydrogenium is likely to be condensed somewhat in combination, and that consequently the smallest number (0·711) is likely to be the nearest to the truth. But the mean of the two extreme numbers will probably be admitted as a more legitimate deduction from the experiments on the compounds alloys, and 0·733 be accepted provisionally as the approximate density of hydrogenium.

I have the pleasure to repeat my acknowledgments to Mr. W. C. Roberts for his valuable assistance in this inquiry.

* H = 1; Pd = 106·5.

ON CRYSTALS INCLOSED IN BLOWPIPE BEADS.

By H. C. SORBY, F.R.S., &c.

AT the *soirée* of the Royal Society on March 6, by the kind assistance of my friend Mr. Wm. Baker, I exhibited a number of blowpipe beads inclosing various crystals of such extreme beauty as mere microscopical objects, that probably some account of them may be interesting, independently of their connection with chemistry and mineralogy.

It has long deen known that blowpipe beads often become opaque on flaming; and Emerson* showed that, by proper manipulation, well-formed crystals can be produced in them, and recognised by their characteristic forms when magnified. Rose† described very interesting results thus obtained in the case of titanic acid; and Captain Ross has published several papers in the CHEMICAL NEWS,‡ in which he gives the results obtained by blowing out the beads into thin vesicles, exhibiting minute characteristic crystals. My method differs materially from those described by the above-named authors. I use borax as the solvent, and, if requisite, add various reagents to produce, as it were, precipitates of characteristic crystalline form. By keeping the supersaturated fused beads over the flame, crystals may be obtained in cases where, according to Emerson nothing satisfactory results from mere flaming: and the addition of various reagents adds greatly to our resources in the cases of earths variously mixed or combined with mineral acids. It is not my intention to enter now into the purely chemical part of the subject, or to show its application to mineralogy. I shall merely give a short account of some specimens thus prepared, which may be of interest as microscopical objects of remarkable character. Many are good illustrations of the manner in which crystals grow up from the simple nuclei to compli-

* *Proceedings of the American Academy*, 1866, vol. vi., p. 4[illegible].
† *Berlin Acad. Bericht*, 1867, pp. 129, 450.
‡ Vol. xvi., p. 370; vol. xvii., pp. 35, 63, 84, 87, and 107.

cated forms of extreme beauty; and it is very instructive to see how the definite secondary planes of the crystals, viewed as a whole, are produced by the regularly graduated growth of numerous small crystals symmetrically deposited. This is sometimes so striking as to lead me to hope that further study may throw important light on the cause of the production of secondary crystalline forms.

In preparing the specimens, so much of the substance must be added to the borax that it entirely dissolves at a high temperature, but is partially deposited when kept for some time at a heat below dull redness. The beads should be about ¼ inch in diameter, and one-third that thickness. The loop in the platinum wire can easily be made circular by bending it round a glass rod. I need scarcely say that no one ought to expect to obtain good specimens at first. Much depends on that sort of manipulation which is easier to learn by experience than explain by writing.

The most useful object-glass is a 4-10 inch, of small aperture, made to adjust for looking through thick glass, so that crystals may be distinctly seen in the interior of the beads. When no condenser is used, the double convex form of the beads prevents our seeing more than a small portion of the interior; but by using as a condenser a plano-convex lens, of about ¼ inch diameter and ½ inch focal length, nearly the whole bead is illuminated, without the definition being materially injured; and even this may be overcome by properly regulating the distance of the condenser, and the size of the aperture below it. The full beauty of the specimens can only be seen with a binocular microscope, and few objects are better fitted to show the advantage of that kind of instrument. The crystals then stand out in perfect relief, and are seen to be equally complicated in all directions. It must not be thought that in each case all the crystals are alike. Those formed on the surface differ much from those in the interior of the beads; and in both positions, though the type is constant, the forms vary very considerably.

After having obtained crystals of satisfactory character, if it be desirable to keep the specimen as a permanent object, the ring-shaped loop and inclosed bead should be cut off and mounted in a cell with Canada balsam. This is requisite, since the moisture of the atmosphere causes the borax to become hydrated and opaque; but, when properly mounted in balsam, it alters so slowly that I have not remarked any change for half a year. When thus mounted, the curved form of the beads almost ceases to be any impediment in examining crystals in the interior, and an ordinary achromatic condenser of long focal length may be used with advantage; but in some cases crystals on the surface are much less distinct than when the beads are not mounted.

Few objects of the kind are more easily prepared than the crystals of borate of magnesia deposited from borax saturated with magnesia. They first form as thin prisms, and smaller crystals are afterwards deposited, so as to give rise to objects very much like a handle with a brush at each end.

Zircon or zirconia fused with borax yields crystals of the borate. In their most rudimentary state they are small prisms with a simple cross at each end, which afterwards becomes complicated.

The crystals of molybdate of zirconia formed by fusing zirconia in borax with molybdic acid, are extremely elegant and beautiful objects. They are so delicate that their own weight would probably break them, if they were in an aqueous solution; but being supported in solid borax, like the insects inclosed in amber, they are secure from all injury.

Scheelite—native tunsgate of lime—fused in borax is deposited in crystals of great beauty, and is an object easily prepared.

The molybdate of strontia, produced by fusing strontia and molybdic acid in borax, crystallises in long spindle-shaped crystals, whereas the molybdate of lime yields very different crystals, of a form intermediate between that of molybdate of zirconia and scheelite.

Apatite—native phosphate of lime—fused with borax, deposits in crystals which vary much in shape. Six-sided stars are often formed on the surface, and needle-shaped crystals grow from their centres into the interior of the borax, so that they look like nails with highly-ornamental heads driven down into the bead. When formed with their axis parallel to the surface, the crystals are sometimes much like *diatomaceæ*. The addition of phosphate of soda to a borax bead containing lime in almost any state of combination gives rise to similar crystals.

On adding a certain amount of carbonate of soda to quartz or various silicates dissolved in borax, crystals are deposited, which vary much according to circumstances; but they all seem to be due to the variable growth of many small six-sided prisms with expanded ends. Sometimes they have a curious dice-box form, resulting from a bundle of such crystals. Probably such are some silicate of soda, modified by the presence of other bases.

Titanic acid gives hair-like prisms variously grouped. Molybdic acid is sometimes set free as liquid globules, which coalesce, rise to the surfuce, and afterwards solidify as small spheres.

These few examples will, at all events, serve to show that the crystals deposited in blowpipe beads are of considerable interest, merely as beautiful microscopical objects. I should, however, be very sorry if any one were to imagine that I considered this their chief merit. On another occasion my aim will be to prove that this method may be employed with great advantage in determining the nature of minerals and chemical precipipates, when so small a quantity can be procured that other methods would almost or entirely fail to give satisfactory results.—*Monthly Microscopical Journal.*

PROCEEDINGS OF SOCIETIES.

CHEMICAL SOCIETY.

July 1st, 1869.

Dr. A. W. WILLIAMSON, F.R.S., President, in the Chair.

The minutes of the preceding meeting were read and confirmed.

The PRESIDENT stated that, as the meeting was an extraordinary one, the routine business would be dispensed with.

A written communication from Dr. Mills, on the subject of "*The Atomic Theory*," was read. No discussion followed, but the President said he should feel honoured if, after seeing in print what he himself had put together on the subject, they thought it worth while to go into the question some evening.

A paper by Mr. H. Smith, F.C.S., "*On Ethyl Hyposulphurous Acid*," was then read.

The author prepared ethylic sulphide by placing protosulphide of potassium in a retort with ordinary alcohol, passing the vapour of ethylic chloride into the liquid, and then applying heat, when a distillate, containing ethylic sulphide, alcohol, and ethylic chloride, came over. Water was added, and the oil which separated re-distilled. After rectification with calcium chloride, it had a constant boiling point at 81° C.

Ethylic sulphide was treated with an equal bulk of strong sulphuric acid, a large quantity of water added, and the whole neutralised with pure barium carbonate, the resulting solution of barium ethy-hyposulphite evaporated to one-third of its bulk, and set aside to crystallise. The author has also prepared the copper, silver, and sodium salts.

The PRESIDENT remarked that, according to the formula given by Mr. Smith, half of the metal of ordinary hypo-

sulphites was replaced by ethyl, and it was merely analogous in its constitution to a sulphate. It did not, as far as he could see, bear in any direct way on the question of the constitution of the hyposulphites, which occupied their attention a few meetings since.

Mr. PERKIN wrote the following formula on the board:—Barium salt—$(C_2H_5)_2BaS_4O_6+2H_2O$. The sodium salt would, therefore, be:—$C_2H_5NaS_2O_3+H_2O$.

The PRESIDENT remarked that the constitutional water was still undisturbed.

A paper by Dr. Phipson, "*On the Absorption Spectra of Certain Organic Substances*," was then read. The author had found that cyanine gave an absorption spectra resembling that of mauve. He also found that the colours of certain flowers gave absorption bands in the spectrum.

Mr. MCLEOD then explained "*An Apparatus for the Determination of Gases Dissolved in Natural Waters.*" The water is measured in a graduated pipette into which it is introduced without coming in contact with air, mercury being drawn from the bottom of the pipette, while a narrow tube connected with the upper part of the measure is passed to the bottom of the bottle containing the water. The water is then allowed to flow into the lower of two globes connected by a narrow glass tube, and in which a Torricellian vacuum has been produced. The lower globe stands in a water-bath heated to 50°, and the water is allowed to remain at that temperature for about 30 minutes. During this time almost the whole quantities of the nitrogen and oxygen dissolved in the water are evolved together with some carbonic anhydride. Mercury is then allowed to rise from a reservoir into the bulbs, and the gas, which has been evolved, removed by means of a Sprengel's mercurial pump, through a stop-cock at the top of the upper globe. After this, the mercury is run out from the globes and the water-bath more strongly heated, a slow current of cold water being allowed to trickle over the upper bulb. By this means the water is distilled *in vacuo*, and the gases remaining, which consist almost exclusively of carbonic anhydride, are eliminated from the water. These gases are then removed, as before, from the apparatus, by means of the Sprengel and analysed.

It was found necessary to resort to the process of distillation in order to decompose the soluble acid calcic carbonate; as some of this compound remained unaltered, even when maintained for two hours at a temperature of 105°—109° in a salt water bath. The following results were obtained from 100 c.c. of a sample of tap water drawn from the cistern of the Royal College of Chemistry.

I.

	Gas evolved at 50°.	Gas evolved on distillation.	Total.

The mercurial pump employed in these experiments is slightly modified from that originally described by Dr. Sprengel, in the *Journal of the Chemical Society*, though in the three experiments which have been tried, the results have not nearly equalled those described in his paper. Dr. Sprengel obtained a residue of air in an exhausted receiver equal to 1·1,300,000th of the original quantity: the best result obtained in the above-mentioned experiments being only 1·516,666th. By means of this apparatus, however, Dr. Frankland and Mr. Lockyer have rarefied perfectly dry oxygen, nitrogen, and hydrogen to such an extent, that their resistance was equal to that of atmospheric air at the ordinary pressure. The quantity of carbonic anhydride in carbonates may be determined in the form of gas, as first suggested by Dr. Russell, the Sprengel being employed for removing the gas from the valve in which the carbonates are decomposed. For this purpose a weighed quantity of the carbonate is placed in a small glass tube, which is then introduced into a wide perpendicular tube about 900 m.m. in length, and provided with a stop-cock at the upper end. The lower orifice is placed under mercury, and the air removed by means of the Sprengel. Dilute sulphuric or hydrochloric acid is passed up the tube, and the carbonic anhydride which is evolved removed and measured. In two experiments, the quantities of carbonic anhydride evolved from white marble were 43·72 and 43·61 per cent.

"*A New Form of Apparatus for Gas Analysis.*"—This is a modification of the apparatus described some years ago by Dr. Frankland and Mr. Ward. It consists of two tubes, one about 5 and the other about 20 m.m. in diameter. These tubes are, respectively 1100 and 900 m.m. long. They are surrounded by a cylinder, through which a constant stream of water flows, and communicate with one another, just below the wide cylinder, by means of a caoutchouc joint surrounded by calico. The lower end of the narrow tube is also connected, in a similar manner, with a tube provided with a stop-cock, and which descends 900 m.m. below the joint, and communicates, by means of a long flexible tube surrounded with calico, to a reservoir containing mercury, which is so suspended that it can be raised above the level of the top of the apparatus. The narrower tube is graduated in millimetres from the bottom to the top, the upper end being closed by a glass stop-cock. The wide tube is marked with divisions at every 100 m.m., the contents of each division being determined. This tube is provided with wires, and closed at the upper end by a capillary tube and glass stop-cock, with a steel cap, by means of which it may be attached to a short and wide laboratory tube, such as is used in the apparatus described by Dr. Frankland in the *Journal of the Chemical Society*, 2nd series, vol. vi., p. 109. The analysis of gases is performed with this apparatus in the same manner as with the original one of Frankland and Ward, the measurements being made by determining the temperature and tension of fixed volumes of gas. The absorptions are performed in the laboratory tube, and explosions in the measuring tube. The whole apparatus may be easily worked with 900 c.c. of mercury, and the results obtained are very satisfactory.

Dr. RUSSELL read a paper entitled. "*Further Experiments on the Atomic Weights of Cobalt and Nickel.*"

In 1863, the author published an account of researches on the determination of the atomic weights of cobalt and nickel by the reduction of the oxide by hydrogen, when he found the atomic weights of cobalt and nickel to be 29·37. Since then, experiments had been made by two other chemists, Sommannga and Winkler, the former of whom gave 29·99 for the atomic weight of cobalt, and 29·01 for nickel, while Winkler's determinations showed cobalt to be 29·49, and nickel, 29·53. More recently, Dr. Schneider, in a paper to *Poggendorff's Annalen*, called attention to the fact that Sommannga's determination of the atomic weights almost coincided with the numbers he had previously obtained, and endeavoured to explain why Dr. Russell's numbers differed from his own. The author had lately experimented with the same cobalt and nickel used before, and determined the atomic weights from the volume of hydrogen evolved when a known weight of the metal was dissolved in hydrochloric acid, and the results fully confirmed the accuracy of his former experiments. The mean of four experiments by the reduction of the oxides determined the atomic weights of both nickel and cobalt

to be 29·37; the mean of four experiments from the volume of hydrogen evolved was 29·38 for each metal.

The PRESIDENT thought it a most admirable confirmation of the conclusion arrived at by different methods, that numbers so very nearly coincident with these should be obtained by this process, and it was satisfactory that the result was established by concurrent evidence of very different kinds.

Professor WANKLYN said that the experiments related by Dr. Russell were particularly interesting to him, as they confirmed the views expressed by himself and Mr. Chapman about the hydrogen process.

After a verbal communication "*On the Action of Phosphoric Chloride on Oil of Vitriol*," by the Rev. Mr. WILLIAMS, the meeting was adjourned till the next session.

CORRESPONDENCE.

GASEOUS SPECTRA.

To the Editor of the Chemical News.

SIR,—In the paper on "Researches on Gaseous Spectra in relation to the Physical Constitution of the Sun, Stars, and Nebulæ," by Dr. Frankland and Mr. Lockyer, as reported by you, the authors do not notice similar observations which I presented to the Royal Society in April, 1868. I send you the following extracts from that paper, which is printed in the *Phil. Trans.* for 1868.—I am, &c.,

WILLIAM HUGGINS.

"The following observations are suggestive in connexion with the point under consideration. Electrodes of platinum were placed before the object-glass in the direction of a diameter, so that the spark was as nearly as possible before the centre of the lens. The spark was taken in air. I expected to find the spectrum faint, for the reasons which have been stated in a previous paragraph (the diminution of the brightness of the spark from the distance at which it is placed from the slit), but I was surprised to find that only one line was visible in the large spectroscope when adapted to the eye-end of the telescope. This line was the one which agrees in position with the line in the nebula, so that under these circumstances the spectrum of nitrogen appeared precisely similar to the spectra of those nebulæ, of which the light is apparently monochromatic. This resemblance was made more complete by the faintness of the line; from which cause it appeared much narrower, and the separate existence of its two components could no longer be detected. When this line was observed simultaneously with that in the nebula, it was found to appear but a very little broader than that line. When the battery circuit was completed, the line from the spark coincided so accurately in position with the nebular line, that the effect to the eye was as if a sudden increase of brightness in the line of the nebula had taken place. In order to make this observation, and to compare the relative appearance of the lines, the telescope was moved so that the light from the nebula occupied the lower half only of the slit. The line of the spark was now seen to be a very little broader than the line of the nebula, and appeared as a continuation of it in an unbroken straight line. These observations were repeated many times on several nights."—(P. 542.)

"The double line in the nitrogen-spectrum does not consist of sharply defined lines, but each component is nebulous, and remains of a greater width than the image of the slit.* The breadth of these lines appears to be connected with the conditions of tension and of temperature of the gas. Plücker* states that when an induction-spark of great heating power is employed, the lines expand so as to unite and form an undivided band. Even when the duplicity exists, the eye ceases to have the power to distinguish the component lines, if the intensity of the light be greatly diminished.

"Though I have been unable to detect duplicity in the corresponding line in the nebula, it might possibly be found to be double if seen under more favourable conditions; I incline to the belief that it is not double.†

"In my tables of the lines of the air‡ I estimated the brightness of each of the components of the double line in the spectrum of nitrogen at 10, and the components of the double line next in brightness in the orange at 7 and 5, and those of a third double line on the less refrangible side of D at 6 and 4. It was with reference to these two double lines next in apparent brilliancy that I wrote,‖ in speaking of the line in the nebula, 'If, however, this line were due to nitrogen, we ought to see other lines as well; for there are specially two strong double lines in the spectrum of nitrogen, one at least of which, if they existed in the light of the nebulæ, would be easily visible.'

"As the disappearance of the whole spectrum of nitrogen, with the exception of the one double line, was unexpected, though, indeed, in accordance with my previous estimations, I examined the spectrum of nitrogen with a spectroscope furnished with one prism with a refracting angle of 60°, in which the whole of the spectrum from C to G is included in the field of view. I then moved between the eye and the little telescope of the spectroscope a wedge of neutral-tint glass corrected for refraction by an inverted similar wedge of crown glass, and which I had found to be sensibly equal in absorbing power on the different parts of the visible spectrum. As the darker part of the wedge was brought before the eye, the two groups in the orange were quite extinguished, while the lines in the green still remained of considerable brightness. The line which under these circumstances remained longest visible next to the brightest line, was one more refrangible at 2669 of the scale of my map. This observation was made with a narrow slit. When the induction spark was looked at from a distance of some feet with a direct-vision prism held close to the eye, I was surprised to observe that the double line in the orange appeared to me to be the brightest in the spectrum, and when the neutral-tint wedge was interposed, this line in the orange remained alone visible, all the other lines being extinguished.

"When, however, in place of the simple prism a small direct-vision spectroscope provided with a slit was employed, I found it to be possible, by receding from the spark, to find a position in which the double line in the green, with which the line in the nebula coincides, was alone visible, and the spectrum of the spark in nitrogen resembled that of a monochromatic nebula.

"It is obvious that if the spectrum of hydrogen were reduced in intensity, the line in the blue, which corresponds to that in the nebula, would remain visible after the line in the red and the lines more refrangible than F had become too feeble to affect the eye.

"It therefore becomes a question of much interest whether the one, two, three, or four lines seen in the spectra of these nebulæ represent the whole of the light emitted by these bodies, or whether these lines are the strongest lines only of their spectra which, by reason of their greater intensity, have succeeded in reaching the earth. Since these nebulæ are bodies which have a sensible diameter, and in all probability present a continuous luminous surface, or nearly so, we cannot suppose that any lines have been extinguished by the effect of the distance of these objects from us.

* Secchi states that with his direct spectroscope this line in the annular nebula in Lyra appears double. As the image of the nebula is viewed directly, after elongation by the cylindrical lens, and without a slit, it is probable that the two lines may correspond to the two sides of the elongated annulus of the nebula.

† "On the Spectra of the Chemical Elements," *Philosophical Transactions*, 1864, p. 141.

‡ Ibid.

‖ Ibid, p. 443

"If we had evidence that the other lines which present themselves in the spectra of nitrogen and hydrogen were quenched on their way to us we should have to consider their disappearance as an indication of a power of extinction residing in cosmical space, similar to that which was suggested from theoretical considerations by Cheseaux, and was afterwards supported on other grounds by Olbers and the elder Struve. Further, as the lines which we see in the nebulæ are precisely those which experiment shows would longest resist extinction, at least so far as respects their power of producing an impression on our visual organs, we might conclude that this absorptive property of space is not *elective* in its action on light, but is of the character of a *general* absorption acting equally, or nearly so, on light of every degree of refrangibility. Whatever may be the true state of the case, the result of this re-examination of the spectrum of this nebula appears to give increased probability to the suggestion that followed from my former observations, namely, that the substances hydrogen and nitrogen are the principle constituents of the nebulæ of the class under consideration."—(Pp. 543—544.)

MISCELLANEOUS.

Royal School of Mines.—At a meeting of the Council on Saturday, the 3rd inst., the results of the examinations for the past session were declared. The following gentlemen, having passed the requisite examinations, have obtained the title of "Associate of the Royal School of Mines" in the divisions mentioned:—Bell, Metallurgical; G. Broome, Mining and Metallurgical; L. Brown, Metallurgical; — Butler, Geological; R. J. Frecheville, Metallurgical; G. Green, Metallurgical and Geological; M. F. Maury, Mining and Metallurgical; F. J. M. Page, Mining and Metallurgical; — Tayler, Metallurgical. The following prizes and scholarships were awarded:—Two Royal Exhibitions of £15 for first year students—(1) J. J. Bowrey; (2) W. Gowland. H.R.H. The Duke of Cornwall's Scholarship, £30 for two years—W. J. Sollas. Royal Exhibition of £25 for second year students—W. Gowland. De la Beche Medal and Books, for Mining—G. Broome. The Director's (Sir Rod. I. Murchison's) prize for Geology—W. Gowland.

Inexhaustible Manures.—In the Atlantic Ocean, a little to the west of the Azores, there exists a space seven times larger than all Germany, according to the late A. von Humboldt, completely covered with a dense mass of vegetation, the so-called Sargasso Sea. M. J. Lavinière has proposed to the Société d'Agriculture to make these floating meadows, as they are called by Aviedo, subservient to the purposes of agriculture. His suggestion is that the ships occupied during the summer in cod-fishing should, in other seasons, be employed in conveying this abundant and excellent manure to the Azores, where an *entrepôt* could be established, the weeds pressed and dried, and the salts they contain extracted. Analysis has shown that these weeds possess the same fertilising properties as those employed as manure on the French coasts. M. Lavinière calculates that these floating meadows produce annually sufficient vegetable matter to manure 150,000,000 hectares, a hectare being about an acre and a half.—*Revista Industrial, &c.*

Pink Colour and Mineral Lake.—Under the name of pink colour there is met with in the trade, and manufactured by a process which is kept secret, a substance which is chiefly used in this country for painting faience and porcelain. According to M. Malaguti's analysis, this substance is composed, in 100 parts, of—Peroxide of tin, or stannic acid, 78·31; lime, 14·91; silica, 3·90; alumina, 0·05; oxide of chromium, 0·52; chromate of potassa, 0·20; potassa and loss, 0·48. The stannic acid, lime, and oxide of chromium are the essential elements; the silica and alumina are not indispensable; the richness and depth of the colour depends upon the larger quantity of lime and chromate applied in the manufacture. According to M. Gentele, this pink colour may be prepared in the following manner:—1 kilo. of granulated tin is oxidised with nitric acid, the meta-stannic acid thus obtained is mixed with 150 grms. of bichromate of potassa dissolved in 1 litre of water, and to this mixture there are added 2 kilos. of chalk and 1 kilo. of finely pulverised glass-sand; these materials are made into a paste, and strongly ignited, after having been placed in a crucible, to a bright red heat; the result of this calcination is ground to an impalpably fine powder, and again ignited, with the addition of carbonate of soda. When a mixture of 100 parts of stannic acid and 2 parts of oxide of chromium is ignited to a bright red heat a beautiful lilac-coloured material is obtained, which is neither injured by daylight nor atmospheric influences, resists the action of sulphuretted hydrogen, and is called by M. Malaguti "mineral lake."

CHEMICAL NOTICES FROM FOREIGN SOURCES.

In accordance with the generally expressed wishes of our friends and readers, we have effected arrangements to enable us to give, under the above heading, notices of EVERY CHEMICAL PAPER IN THE WORLD, *as soon as possible after publication. Whenever possible, these notices will appear in the form of carefully prepared, although necessarily brief, abstracts; as respects papers either too long or too abstruse to render condensation possible, their titles will be chronicled; and in all cases accurate reference will be made to the original publication. The two half-yearly volumes of the* CHEMICAL NEWS, *with their copious indices, will therefore be equivalent to an English edition of the "Jahresberichte," with the additional advantage of keeping the readers week by week on a level with the latest advances of science.*

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus des Séances de l'Académie des Sciences (No. 26), June 28, 1869.

We observe, in the first place, that Sir Roderick Murchison was present at this meeting of the illustrious scientific society of France, of which he has been elected a Foreign Member; being present for the first time after his election, he was most heartily received by the large number of *savants* present. The speech made by the celebrated British geologist was the signal for M. Dumas to say a few words, highly eulogising the excellent reception given to him while lately at London, and stating that, in the person of one of their perpetual secretaries, the British scientific world and renowned *savants* had honoured and feted the Academy. We notice the following papers:—

Mode of Condensing Magnetism Analogous to the Condensation of Electricity.—M. Jamin.—The author has caused M. Limet to make for him a horseshoe-shaped magnet, made up of ten bars of perfectly homogeneous steel, and fastened together by means of bolts. When this artificial magnet is properly magnetised, it is capable of bearing a weight of 300 kilos. at the armatures. When this armature is placed so as to be only in contact with one of the steel bars composing the horseshoe, it appears that the magnetism of the nine other bars is very perceptibly diminished. Under these conditions, and, notwithstanding the magnet was previously already saturated with magnetism, it is possible to saturate anew with magnetism, and make the horseshoe bear again 600 kilos. This experiment can be repeated: another armature may be put on, so as to bear only upon one of the component bars, and, again, more magnetism can be condensed. The learned author has already succeeded in making the horseshoe bear another 680 kilos. in this manner.

Researches on the Oxygenated Bases—Action of Chlorhydric Glycol on Toluidine.—M. Wurtz.—This is another instalment of the papers resulting from the author's labours on this subject. The paper here alluded to contains researches on the action of chlorhydric glycol upon aniline and toluidine. When a mixture of aniline and chlorhydric glycol are heated together on a water-bath, a thickish and coloured liquid is obtained, which yields, with a concentrated solution of chloride of platinum, a very unstable, readily-decomposable salt. When the mixture of substances just alluded to is heated in an air-bath to from 195° to 210°, and the fluid afterwards treated with water, and filtered, an abundant precipitate is formed with a concentrated solution of chloride of platinum. This salt, having been well purified, yields, on analysis, results leading to the formula—

$$(C_{14}H_{18}ON.Cl)_2,PtCl_4.$$

When toluidine is thus acted upon by chlorhydric glycol, the author obtains three bases—(*a*) vinyltoluidine—

$$C_9H_{11}N = \left.\begin{matrix} C_7H_7 \\ C_2H_3 \\ H \end{matrix}\right\} N;$$

(*b*) two other bases of complex composition, containing no longer toluyl, but the radical C_7H_8, toluenyl; while one of these bases contains, besides toluenyl, also two vinylic groups.

New Researches on Hydrogenium.—Mr. T. Graham.—From this paper we quote, in the first place, that the author finds the specific gravity of hydrogenium to be 0·872. The eminent *savant* records in this paper, consecutively, researches on—*palladium, platinum, and hydrogenium; palladium, gold, and hydrogenium; palladium, silver and hydrogenium; palladium, nickel, and hydrogenium.* We give these researches in a separate paper on another page.

Poisonous Effects of Coralline.—M. Landrin.—This paper, or report, rather, contains the results of the researches made at the request of the celebrated Dr. Tardieu, and the members of the Academy of Medicine. The result of carefully-made experiments, also by giving large doses of coralline to animals and applying it to their skin, is that coralline is no poison at all, whether internally or externally applied; and its use in dycing is quite harmless, provided it be not mixed with substances which are very decided poisons.

Certain Stellar Spectra.—M. Janssen, in a letter dated from Darjeeling, Sikim, British India, 22nd May last, says that the spectra of some stars, which are rather ruddy-coloured when not disclosing the presence of hydrogen, do positively disclose the presence of aqueous vapour.

Spectra which some Compound Substances Exhibit when Produced within Gaseous Mixtures which are in a state of Equilibrium.—Messrs. Berthelot and Richenau.—This paper is not suited for proper abstraction.

Presence of Peroxide of Hydrogen in the Atmosphere.—M. Struve.—The author, writing from Tiflis (a large town on the Caucasian side of Russia), calls attention to some interesting facts observed by him in reference to the quantity of nitrite of ammonia, ozone, and oxygenated water (peroxide of hydrogen) present in rain-water, and water obtained from melting snow and hail. The author applies oxide of lead as a test, which is converted into peroxide. M. Sainte-Claire Deville reminded the meeting that, while—in July and August, 1859—he was engaged in making some researches (he was, during that time, staying on the St. Bernard); on ascending two mountain tops, named Le Vélan and Le Combin, respectively 3762 and 4430 metres high, he collected there rain and snow water, which, on being analysed by M. Boussingault, was found to contain so much ammonia and nitric acid that, were it not that several bottles of the same sample were taken, it might have appeared as if bottles which were not well cleaned had been applied for collecting the fluids.

Heat of Combination of Hydrosulphuric and Hydroselenic Acids.—M. Hautefeuille.—This paper is too abstruse for condensation.

Theory of Etherification by means of Hydrochloric Acid.—M. Friedel.—When it is desired to obtain a compound ether, the mode of obtaining it often resorted to is, to mix the acid of which it is desired to have the ether with alcohol, and to pass through this mixture a current of hydrochloric acid gas. The author proves that, in that case, there is formed first a chloride of the acid radical, and that that chloride afterwards gives rise to the formation of the compound ether. The author describes at length a process whereby it is possible to obtain, by the action of hydrochloric acid gas upon benzoic acid, chloride of benzoyl.

Primitive Normal Butylic Alcohol.—Messrs. Lieben and Rossi.—This lengthy paper contains the results of experiments made by the authors to prove that a compound discovered and described by M. Wurtz as a butylic alcohol, in the year 1850, is only an isomer of the true and genuine butylic alcohol obtained in a peculiar manner, described at great length by the authors, and wherein an aldehyde plays an important part. We conclude these abstracts by simply quoting the titles of the following papers, which are either purely physical, or are not well suited for proper abstraction with due justice to their contents, and the labours bestowed thereupon by their authors:—

Compressibility of Liquids.—Messrs. Amaury and Descamps.

Measure for the Conductive Power for Electricity of such Fluids as are Generally Hitherto considered as Non-Conductors.—M. Said Effendi.

Alcoholic Fermentation Excited by the Microzymas of the Liver.—M. Béchamp.

Toluylen-Diamine.—M. G. Koch.—

Researches on Inuline and the Acetic Acid Derivatives therefrom.—Messrs. Ferrouillat and Savigny.

Deutsche Industrie Zeitung, May 24, 1869.

Detection of Arsenical Pigments.—M. C. Puscher states—That during the first five months of this year, no less than eight cases of accidental poisoning by these pigments have occurred at Nürenberg; he advises the use of liquid ammonia for the detection of these pigments, all of which, he says, are soluble therein, exhibiting a blue coloured solution, if copper is at the same time present; he further states that, on the evaporation of the ammonia, there remains a dirty greenish coloured precipitate of arsenite of oxide of copper; his advice is to paint some *white* paper with this solution in ammonia, which painting, when dry, if arsenic were present, will exhibit a dirty greenish colour, but if after drying a blue colour appears to have been imparted to the paper, the pigment is quite free from arsenic, and only consists of a compound of copper, of which latter metal there are several in use, as green and blue pigments, all soluble in ammonia, except such adulterations as do not essentially belong to the pigment itself.

The Journal of the Franklin Institute (No. 4), April, 1869.

We notice from this paper the following communications and papers:—

Spectrum Lines, a New Method of Illustrating them.—At a late meeting of the American Institute, Professor E. C. Pickering, of the Massachussetts Institute of Technology, employed the following method to illustrate his paper on spectrum analysis. A sheet of black lace, 1¼ ft. broad, and 3 ft. high, was suspended as a screen, and upon it was thrown a continuous spectrum from a magnesium light, arranged in the manner first developed for electric light by Professor Cooke, of Cambridge, U.S., except that only one bisulphide of carbon prism was used. The spectrum covered the entire lace screen, the curvature of its lines being corrected by an opposite curvature of the opening through which the light passed. Upon this black lace were attached a number of strips of white paper, so arranged as to occupy the places of the bright lines in seven different spectra, such as those of sodium, potassium, rubidium, cæsium, &c. These being illuminated by the variegated light of the continuous and broad spectrum, received and reflected each colour corresponding to its position, and, therefore (their adjustment being accurate), that which actually belonged to the band which it represented. The light falling between these paper bands was, of course, not reflected, and the appearance, therefore, was in each case (as in an actual spectrum) that of bright-coloured lines on a dark ground. When, however, as in the case of potassium, the nebula of Orion, &c., a faint continuous spectrum is, in fact, combined with that of the bright lines, this, also, was represented by attaching, in the required places, bands of white lace, which reflected enough of the coloured light to produce a hazy spectrum, admirably imitating that of the substances or bodies in question.

Acid-Proof Cement.—R. F. Fairthorne.—It frequently happens that the chemist requires some means for protecting cork from the destructive action of vapours such as arise from boiling nitric acid; the author found the following plan to meet this requirement:—Finding it necessary to connect a glass tube with a wide-mouthed flask, and, in so doing, to use a cork, which was exposed to the action of the fumes from boiling nitric acid for several hours, the author found the best preservative to consist of a coating of silicate of soda and powdered glass. The cork, having been bored to suit the size of the tube, was soaked for two or three hours in a solution of silicate of soda, consisting of one part of commercial concentrated solution to three parts of water. The tube was next inserted, and, when dry, the cork was covered with a paste, made by mixing the concentrated solution of the silicate with powdered glass, in such proportions as to form a mass of about the same consistence as that of putty. This is spread on the under surface, and then washed with a solution of chloride of calcium. It soon hardens; so that it is advisable to make the connection with the flask whilst the paste is in a plastic state, and to allow it to become solid before applying heat to the vessel containing the acid. Corks protected in this manner were but slightly acted upon after remaining over the boiling nitric acid more than four hours, and over hot acid for ten. The cement, the preparation and use of which is herein described, is very useful for general use as a luting for chemical apparatus.

Hot-Cast Porcelain.—Charles P. Williams.—This is the trade name of a peculiar tough, milk-white, translucent glass, not unlike French porcelain in appearance, and extensively made at Philadelphia and Pittsburg, U.S. It is intermediate in character between the glasses produced by the addition of phosphate of lime to the ordinary glass materials, on the one hand, and the white enamels, such as are produced by oxide of tin on the other, having more of the milkiness than the former and less opacity than the latter. The raw materials consumed in its production are sand, oxide of zinc, and cryolite, which are melted together in the ordinary clay pots of the glass maker. The following is the composition of an average sample of this glass, taken when the "metal" was in its best working condition:—Silica, 63·84; alumina, 7·86; peroxide of iron, 1·50; protoxide of manganese, 1·12; oxide of zinc, 6·99; lime, 1·86; magnesia, 0·25; soda, 10·51; fluorine, 8·05; [less oxygen (corresponding to the fluorine), 3·39] = 98·59 for 100 parts. The above is the mean of five analyses. The method pursued in the above analyses consisted in fusing the compound with carbonate of soda, extracting with water, and, after precipitating the silica and alumina in the aqueous solution by means of carbonate of ammonia, separating the fluorine as fluoride of calcium mixed with carbonate of lime, by the addition of chloride of calcium. The mixed salts were afterwards treated with acetic acid, and the separated fluoride of calcium, dried, burned, and weighed. The remainder of the analysis was conducted as is usual in the analysis of silicates, the alumina and oxide of iron being precipitated as basic acetates, and separated, after weighing, by means of tartaric acid and sulphide of ammonium. Admitting the fluorine to exist in the glass in the condition of silico-fluoride of sodium (NaF,SiF_4), the following formula will express the composition of the compound:—

$$2[R_2O_{8}3SiO_2+3(RO_3SiO_2)]+NaFSiF_3.$$

Zeitschrift für Chemie, von Beilstein, No. 9, 1869.

The original papers contained in this periodical are—

Monochlorocrotonic Acid and its Salts.—M. O. Froelich.—When two parts by bulk of perchloride of phosphorus act upon one part, by bulk, of ethyldiacetic acid, two new acids containing chlorine are formed; both are crystalline, and they are isomeric with each other; only one of these acids, the monochloroacetic acid,

$$C_4H_5ClO_2, (C = 12, O = 16),$$

has been further investigated; the pure acid is a solid substance, exhibiting crystalline structure, fusing at 59° C.; becoming solid again at 55° C.; boils at 194·8° C.; it is a rather volatile substance, prone even to sublime when kept in closed bottles at the ordinary temperature of the air. It is not very soluble in water; at 7° C. one part of the acid requires 70 parts of water for solution; readily soluble in ether and alcohol. It is a rather powerful acid, easily decomposing carbonates. The author has prepared a series of salts of this acid with alkaline, earthy, and metallic bases: the potassa salt, $C_4H_4ClO_2,K+H_2O$, is crystalline, like almost all of the salts this acid forms. Monochlorocrotonic acid-ethyl ether, $C_4H_4ClO_2(C_2H_5)$, is a colourless, oily fluid, possessing an aromatic odour and a cooling taste, boils at 161·4° C. Its specific gravity at 15° C. is 1·113. Slightly soluble in water, readily in alcohol and ether; does not affect the vegetable colours, as, for instance, litmus. The methyl-ether analogous with the preceding—

$$C_4H_4ClO_2(CH_3)$$

is an oily fluid boiling at 142°; its specific gravity at 15° is 1·143. Insoluble in water, less soluble in alcohol than the preceding.

Presence of Peroxide of Hydrogen in the Atmosphere.—M. H. Struve.—The author, writing from Tiflis, Central Russia, states that his observations and researches of the water of the river Kurr, after a heavy rain or snowstorm, led him to detect therein first, ozone, next peroxide of hydrogen, and afterwards nitrite of ammonia. In

order to detect peroxide of hydrogen in rain or snow-water, the author adds to 25 c.c. of water, 5 drops of a clear iodide of potassium and starch solution, and next a single drop of a solution of sulphate of protoxide of iron and ammonia. When only traces of HO_2 are present, a blue colouration soon ensues, but soon also disappears. The author has not made any quantitative researches, but he avers that, owing to the presence of HO_2 in the water obtained from snow and rain, at Tiflis at any rate, and in that portion of Europe, peroxide of hydrogen may be present.

On some Derivatives from Methylen.—M. Butlerow.—Chloride of methylen, CH_2Cl_2, was prepared from pure iodide of methylen, by passing a current of chlorine through it while placed in a distilling apparatus under water, and a long-continued purifying process; the chloride of methylen is a colourless, very mobile fluid, exhibiting a smell akin to that of chloroform, and like that endowed with a sweet, burning taste. Chloride of methylen is somewhat soluble in water; its specific gravity is at 0° C. 1·3604; it consists, in 100 parts, of—C, 14·12; H, 2·35; Cl, 83·53. Hexamethylenamin is the result of the action of oxymethylen and ammonia upon each other; this base yields with hydrochloric acid a crystalline compound, $C_6H_{12}N_4Cl$.

Bromated (Gebromtes) Toluidin.—When it is desired to prepare bromated aceto-toluidin, the latter substance is placed in a vessel and water is poured over it, and next bromine is added in small quantities at the time; the monobromated aceto-toluid, $C_7H_6BrN(C_2H_3O)H$, is a solid, crystalling in needle-shaped crystals, difficultly soluble in water, readily so in alcohol; fuses at 117·5° C.; bromated-toluidin is a colourless liquid, boiling at 220° C., insoluble in water; specific gravity 1·510 at 20° C. The nitrate of this last compound, $C_7H_6Br.NH_2.HNO_3$, is a beautifully crystalline substance, not readily soluble in water, fusible at 182° C., but at the same time becoming decomposed.

Action of Sulpho-Chloride upon the Bromide and the Iodide of Ethyl.—M. E. Wroblevsky.—SO_2HCl does not exert any action at all upon C_4H_9Br, until the heat of a water bath is applied; HBr and Br then escape. After dilution with water, neutralisation with $BaCO_3$, and a careful evaporation, the author obtained a salt, $(C_2H_5Br.SO_4)Ba$. SO_2HCl acts very energetically upon C_2H_5I, while, thereby, separation of HI and I takes place. When SO_3, anhydrous sulphuric acid, is made to act upon $C_2H_3Cl_3$, and the product was saturated with baryta, the barium salt was obtained of a very unstable chlorinated compound.

Series of Isomeric Derivatives from Toluol.—MM. Beilstein and Kuhlberg.—Paranitrotoluidin, $p.C_7H_6(NO_2)(NH_2)$, is prepared by the reduction of dinitrotoluol and hydrosulphide of ammonium; it exhibits a yellow-coloured crystalline mass, fuses at 77°, is soluble in hot, not so well in cold, water: the nitrate, hydrochlorate, and sulphate of this base are all crystalline substances. Nitrate of paradiazonitrotoluol, $p.C_7H_6(NO_2)N_2.NO_3$, is obtained by treating nitrate of paranitrotoluidin with nitrous acid. Of the long series of derivatives obtained, we only mention yet β nitrotoluol. $\beta C_7H_7(NO_2)$, is a liquid boiling at 222° C., having, at 25° C., a specific gravity of 1·163; is not acted upon by chromic acid.

Observations concerning the Essay of Frémy on Hydraulic Cement.—M. A. Schulatschenko.—The only matter of interest to our readers in this paper (which reviews all which has been stated and done from the year 1786, beginning with the celebrated Chaptal, up to the present day, as regards the hydraulic and other cements, especially in respect of the cause of the hardening under water as well as in air), is the analysis of a marl found on the borders of the river Wolchow, Russia, and applied to the manufacture of cement by careful burning. In 100 parts, this material contains—Carbonate of lime, 63·84; carbonate of magnesia, 5·78; peroxide of iron and alumina, 3·22; sulphate of lime, 0·32; water, 1·04; the remainder was insoluble in hydrochloric acid, and consisted of—Silica, 18·16; alumina, 2·02; peroxide of iron, 3·56; potassa and soda, 1·66; together, 99·60. This material yields, after burning, a product which, on being treated with water, becomes strongly heated, swells up and falls to powder, as does burnt limestone, but unlike it, the material alluded to hardens slowly under water; if, however, this marl happens to be more strongly burnt, exposed to more than a faint red heat, not visible in daytime, a product is obtained which does not, on coming into contact with water, act as just described, but which very rapidly sets and hardens under water. The author observes that we have to distinguish two kinds of cement—such as contain lime in a free state, the Roman cements of M. Winkler, and the hardening of which has been fully explained by Fuchs, and such cements which do not contain lime in a free state, the Portland cements of M. Winkler, the hardening of which is as yet not well explained. According to M. Rivot and others, the cause of the hardening is due to the binding of water by the silicates formed during the burning, while, according to Winkler and others, the effect of water and the cause of hardening is due to the splitting up of silicates into more simple silicates. It is a fact, however, that the action of lime upon Puzzolanes is not sufficiently great solely to explain the hardening of cements.

No. 10, June 8, 1869.

We learn from this number that a very flourishing Chemical Society has, with the permission of the Imperial Government, been established and recognised as one of the scientific institutions of the Russian Empire; the transactions of this society are to be published in the Russian language. The only original paper in the above-named periodical is the record of several researches made at St. Petersburg—

Isomeric Phenolsulpho-Acids and the Action of Chloride of Benzoyl on the Potassa Salt of that Acid.—M. Solomanoff.—according to the author's researches, there exist three isomeric phenolsulpho acids, all of which are simultaneously formed when sulphuric acid acts on phenol. The author distinguishes these acids by α, β, and γ, or by prefixing to the two first para and meta: the author prepared these acid in rather large quantities; the potassa salts of these acids are distinguished from each other by the following particulars: the α salt, $C_6H_5KSO_4$, crystallises in six-sided foliated crystals, is the most difficultly soluble of the three salts in water, fuses at 240° C; the β salt crystallises in needle-shaped crystals, and is capable of taking up variable quantities of water of crystallisation, varying from 1·01 per cent to nearly 15 per cent; it fuses at between 235° and 240° C, yielding a yellowish liquid; the γ salt contains from 16·28 to 17·51 per cent of water of crystallisation, does not, on being heated, melt until it just reaches 240° C. When α phenolsulpho-potassium is heated with chloride of benzoyl, hydrochloric acid is given off and benzoyl-phenolsulpho-potassium is obtained; this salt is soluble in water, and crystallises from its solutions therein in large needle-shaped crystals; the corresponding γ compound, after having been dried at 130° C, is composed according to the formula $C_6H_4(KSO_3)O(C_7H_5O)$; it is difficultly soluble in cold water, but readily in hot water; also soluble in warm alcohol.

Action of Chlorosulpho-Anhydride, $HClSO_3$, on Phenol and Phenolsulpho-Potassium.—MM. Engelhardt and Latschinoff.—The authors made some experiments in order to ascertain whether, when instead of sulphuric acid the compound SO_3HCl was made to act upon phenol, the result would be the formation of one acid only, or of three isomeric acids, as in the instance just previously alluded to; when to one equivalent of phenol, one equivalent of SO_3HCl is added, a very strong reaction takes place, the mixture becomes hot, hydrochloric acid is given off, a thickish red-coloured mass is obtained, from which, by gently heating, all hydrochloric acid was expelled; the mixture after having been formed into a potassium salt, this proved on analysis to be pure α or para phenolsulpho-potassium; the authors made experiments with divers proportions and quantities of SO_3HCl and phenol, and found as result chiefly the production of the acid of the salt just referred to.

Phenol Phosphosulpho-Acid.—M. Maikopar.—The author has studied the action of sulphuric anhydride upon phosphate of phenol, and also the action of phosphor oxychloride upon para phenolsulpho-potassium; the author describes at great length his researches: dry phenol phosphosulpho-barium, $(C_6H_4BaSO_3)_2PO_4$, gave in 100 parts—Baryta, 27·72; sulphuric acid, 29·84; and phosphorus, 4·03. When oxychloride of phosphorus was heated with dry para phenolsulpho-potassium a solid mass was obtained, on exhausting this with ether the latter left on evaporation an oil which was found to contain chlorine, phosphorus, and a substance belonging to the phenolsulpho-acid group; but the results of the analysis of this substance gave figures from which no definite formula could be deduced.

On Murrayin, a Newly-Discovered Glucoside.—Prof. Blas.—The author states that he received from Dr. de Vrij a quantity of murrayin, extracted by the latter gentleman from the *murraya exotica* during his sojourn in the East Indies; in pure state murrayin is a white coloured solid substance, exhibiting needle-shaped crystals, its taste is slightly bitter; it is difficultly soluble in cold water, and insoluble in ether, readily soluble in boiling water and in alcohol; these solutions are neutral to test paper. Murrayin fuses at 170° C.; is readily soluble in solutions of caustic and carbonated alkalies; these solutions exhibit a high degree of fluorescence, they appear yellow in direct light, greenish blue when the rays of sunlight are made to pass through the solutions; crystallised murrayin has the formula $C_{26}H_{44}O_{20}+H_2O$; when one part of murrayin is mixed with one part of strong sulphuric acid, and 25 parts of water, and this mixture heated in a sealed tube or in a flask, in an atmosphere of carbonic acid, the substance is split up, murrayetin and sugar being formed; this splitting up takes place according to the following formula:—

$$C_{26}H_{44}O_{20}+2H_2O = \underbrace{C_{24}H_{24}O_{10}}_{\text{Murrayetin.}}+2C_6H_{12}O_6.$$

Murrayetin is a solid substance, which readily crystallises; its concentrated solutions have a weak acid reaction; with perchloride of iron, it yields a beautiful blue colouration.

ON

HEAT TREATED AS A SCIENCE OF KINETICS.*

By G. F. RODWELL, F.C.S.

(Continued from p. 16).

II. (ABSTRACT).

IN this lecture, some of the effects of heat upon matter were discussed, commencing with expansion, and the experiments which illustrate this part of the subject were shown (such as the unequal of a compound bar, S'Gravesande's ball, and the various appliances by which liquids and gases can be shown to expand, as the alcohol and mercury thermometer, Galileo's air thermometer, Leslie's differential air thermometer, and so on). The intensity of the attractive force exerted by similar molecules acting through an insensible space (cohesion) was shown by the breaking of a bar of iron by the contraction of a metal bar during cooling.

The following definitions are taken for the most part from the lecture notes:—

"*Æstus est commotio . . . omnis commotio fervorem gignit.*" Heat having been defined in the last lecture as a motion of the small particles, or molecules, of matter, it is obvious that the addition of this motion to a congeries of molecules must cause them to occupy a greater space (*expansion*); while the subtraction of this motion must cause them to occupy a less space than before (*contraction*).

In virtue of this, heat determines the form which matter assumes. In solids, the attraction of the molecules for each other (sometimes called *cohesion*, *from cohæreo*, to stick together), greatly predominates over the molecular motion, and, by limiting the range of movement, keeps them comparatively close together. In liquids, there is a greater amount of molecular motion; hence the range of movement of the molecules is extended; the cohesive force is lessened by the distance, and the molecules have a less restrained motion. In gases, there is a still greater amount of molecular motion: the molecules move at such a distance from each other that their individual attraction becomes a vanishing force; hence they are absolutely unrestrained in their motion. Thus, in the passage from solidity to gaseity, there is a progressive decrease of cohesive force, arising from a progressive augmentation of the space between the attracting molecules, and a progressive increase of molecular motion, arising from direct addition; while in the passage from gaseity to solidity, there is a progressive increase of cohesive force, arising from the diminution of the space between the attracting molecules, and a progressive decrease of molecular motion; arising from direct transference.

An increase of external pressure will obviously tend to approximate the molecules of matter; and hence, *à priori*, will, to some extent, produce the same result as a subtraction of molecular motion; while a decrease of external pressure will afford the molecules a greater range of movement, and will hence produce the same result as an addition of molecular motion. Thus certain gases are liquefied by increasing the pressure (for example, chlorine and sulphurous anhydride), and certain liquids are gasified by the removal of the existing pressure (for example, ethers having low boiling points, and, *à priori*, the liquids of gases liquefied by pressure).

We do not know the nature of the motion which constitutes heat. According to an hypothesis, which is ably supported, the molecules of solids and liquids move circularly around a centre, while the molecules of gases move in right lines. Thus a solid becomes liquid, in the language of this hypothesis, when the amplitude of the oscillation of its molecules passes a certain limit; and a liquid becomes a gas when its molecules fly off at a tangent to the circles in which they previously moved. This hypothesis is eminently Cartesian in its tone and character. (Examples of the passage of circular into tangential motion may be frequently observed—notably in the water which is projected from a trundled mop, in the sparks which fly off from a Catherine wheel, in the mud projected from the periphery of a rapidly-moving carriage wheel, and in a stone hurled from a sling. This last example is frequently adduced by Descartes (see his *Principia Philosophiæ*, pars. 2, cap. 39, entitled, "Altera lex naturæ, quod omnis motus ex se ipso sit rectus, et ideo quæ circulariter moventur, tendere semper ut recedant a centro circuli quem describunt;" and again, pars. 3, cap. 57 and 58). As a lecture experiment, it may be shown by attaching a small wooden ball to a spring (a helix of brass wire answers the purpose well), and communicating circular motion by whirling it in a vertical plane, either by the hand, or by a whirling table. As the velocity of revolution increases, (analogous to the increased molecular motion induced by heating), the ball recedes from the centre of revolution (analogous to the act of expansion), until, at a certain maximum of rapidity, the ball may be released, or may be caused to break the spring, when it of course assumes a rectilinear motion (analogous to the passage of a liquid into the gaseous condition); or the helix of brass wire may be replaced by a piece of india-rubber tubing, to one end of which the ball may be fastened by a movable pin, worked by a string, which passes through the axis of the tube and is held by the hand. The revolution is commenced, and, when at its maximum, the string is pulled so as to dislodge the pin, and thus release the ball, which immediately changes its circular for tangential movement; or, again, rapid circular motion may be communicated to a very shallow bowl containing water, and the velocity augmented until the particles of water fly off tangentially.

Heat is usually measured by the expansion of a liquid or gas, it having been found that equal additions of molecular motion produce, (*α*) in the case of gases, equal alterations in bulk, irrespective of the nature of the gas; (*β*) in the case of liquids, nearly equal alterations in bulk in the same liquid, although different alterations in different liquids. (*Thermometry*, θερμος, heat; μετρον, a measure).

A *degree of heat* is an arbitrary quantity, and it may be defined as the amount of molecular motion which is competent to increase the bulk of a certain quantity of specified matter to a certain known extent. A *unit of heat* was defined in the last lecture.

The *co-efficient of expansion* of a substance is the increase in length, (*linear co-efficient*), or in bulk, (*cubical co-efficient*), produced by the assumption of a certain amount of molecular motion, by a substance whose length or bulk was known when it possessed a certain less amount of molecular motion, in both cases measured as described above. Thus, if the length of a brass rod at the freezing point of water (32° F.) be taken as 1·000000, its length at the temperature of boiling water (212° F.) will be found to be 1·001867, and the linear co-efficient of expansion of brass for 212° − 32° F. = 180° F. is hence 0·001867, and for $1° F. = \frac{0·001867}{180} = 0·00001038$.

Evaporation (*evaporo*, to disperse in vapour), is the conversion of a liquid into gas at its exposed surface. The molecules at the surface, unlike those in the mass of the liquid, are influenced and restrained by the proximity of other molecules, *in one direction only*; hence, in the language of the hypothesis mentioned above, they more readily assume the rectilinear motion appertaining to the molecules of a gas.

Ebullition, or boiling, (*ebullio*, to boil or bubble up), is the conversion of a liquid into gas by the assumption of

* A course of four lectures delivered at the London Institution

rectilinear motion by the molecules in the interior of the liquid mass. The liquid continues to receive molecular motion until the cohesion of its molecules (plus or minus any of the extraneous actions mentioned below) is overcome; the molecules thus freed from restraint, part company with the liquid in the form of bubbles of gas. The temperature at which this takes place, subject to the conditions which at that time prevail, is called the *boiling point* of the liquid under those conditions.

The boiling point of a liquid is influenced by the following extraneous causes:—(α), external pressure, which, by limiting the motion of the molecules, and thus assisting cohesion, raises the boiling point; (β), the substance of the containing vessel, between which and the liquid molecules a certain attraction, differing for different substances, exist, which consequently assists cohesion, and raises the boiling point; (γ), dissolved substances, which in the case of dissolved solids tend to raise the boiling point, and in the case of dissolved air, to lower it. Thus water boils—(α) at a lower temperature on the summit of a mountain than at its base; (β) at a higher temperature in a glass than in a metal vessel; (γ) at a higher temperature when it contains salt in solution, as in sea water, than when it is free from dissolved solids, as in rain water; and at a far higher temperature when it is freed from dissolved air than when it contains air in solution.

Evaporation in the spheroidal condition is the surface evaporation of a liquid spheroid, floating upon a layer of its own gas, which separates it from direct contact with a surface possessing a higher (usually, but not necessarily, a much higher) temperature.

The spheroid has been proved to be out of contact with the hot surface by various means; thus the light of a flame can be seen through the space intervening between the spheroid and the hot surface, and nitric acid in the spheroidal condition upon a hot plate of copper does not attack it; neither does dilute sulphuric acid act upon zinc under the same conditions. We have analogous actions in the reverse experiment, in which a hot metal is caused to float upon a liquid surface, buoyed up by the layer of gas beneath. Thus, if a light silver ball be heated to whiteness, it will readily float upon the surface of water; and when iron is burned in oxygen, the globules of molten oxide will frequently float for a second or two upon the surface of the water beneath, or sometimes they will fall through a layer of one or two inches of water, and yet be sufficiently hot when they reach the bottom to fuse themselves into the glass or earthenware tray. Again, the freezing of water and mercury in red-hot vessels is due to the same action: liquid sulphurous acid evaporates comparatively slowly upon a white-hot surface, and when a mixture of solid carbonic acid and ether is poured into a red-hot platinum crucible, it immediately assumes the spheroidal condition, evaporates comparatively slowly, and will readily freeze mercury.

ANALYSIS OF THE WATER OF THE "ROYAL SULPHUR SPRING," HARROGATE.

By SHERIDAN MUSPRATT, M.D. (Hon.), F.R.S.Ed., M.R.I.A., &c.

THE water of this new spring has recently been introduced into the Royal Pump Room at Harrogate Wells, and, as it may prove an efficient *intermediate* one (*i.e.*, not so *strong* as the "Old Sulphur Well," *vide* my analyses, CHEMICAL NEWS, vol. viii., p. 155, and *stronger* than the "Magnesia Water," vol. viii., p. 195), I forward the results for publication in your valuable journal. Its characteristics, on reaching me (it was in a large stone jar, well sealed), were the annexed:—

An opaque appearance, owing to a separation of sulphur; a strong smell (this it does not evolve when drawn from the pump) of sulphide of hydrogen, which, collaterally with the milky shade of the liquid, indicated oxidation and decomposition of the sodic sulphide (NaS). On immediately filtering the water, the filtrate was perfectly clear and bright. During the analysis, &c., I found that, on boiling the water by direct heat, and likewise by the agency of steam, 1·986 grains per gallon of the sulphur were eliminated as gas (sulphide of hydrogen), the remaining portion withstanding the effects of both kinds of caloric. The water was alkaline, due to the earthy carbonates. The sulphur calculated as gas (sulphide of hydrogen) constituted 11·80 cubic inches per gallon. By prolonged exposure to atmospheric influences, the *whole* of the sulphur in the water deposited. It gave no organic matter, and only mere indications of ammonia, &c. The occurrence of the salts of barium, strontium, lithium in all the spas of Harrogate is very remarkable, for these compounds did not, and could not, exist in them twelve years ago, when my distinguished collaborateur, Dr. Hofmann, investigated them. Sulphates have disappeared from all of them. I do not consider that the presence of the chlorides of barium and strontium in any way enhances their medicinal properties; for, as soon as the water is imbibed, the chlorides become sulphates.

There can be no question, I think, that the additional ingredients are derived from the strata in the vicinity of Pately Bridge, nine miles west of Harrogate. All the strong spas contain barium and strontium; the Dr. Muspratt Chalybeate "chloride of iron" (FeCl) also. A recent analysis of it gives 16 grains of this latter salt in the gallon; so the amount is just the same as it was when I discovered its presence in 1865. The efficacy of this ferruginous compound in a potable water is now beyond a doubt; it is more easily assimilated than any other ferrous salt: Dr. Myrtle remarks—"I could fill volumes with cases benefitted or cured by its use."

College of Chemistry, Liverpool,
July 1st, 1869.

ON THE EXAMINATION OF WATER FOR ORGANIC MATTER.*

By R. ANGUS SMITH, Ph.D., F.R.S., &c.

(Continued from vol. xix., p. 306.)

Use of Permanganate of Potash, or Chameleon.

IT must be remembered that the amount of organic matter obtained in the above way by weighing and burning may be equal to several grains in a gallon, and yet be quite innocent; for example, it may be a little peaty matter. One method of trying the quality is given above; another, of a very convenient kind, is by the use of permanganate of potash, or mineral chameleon. It will here be called chameleon, as the former term is very long. It is very highly coloured, and its decomposition is known by the disappearance of the colour.

Chameleon is decomposed by putrid organic matter, and by several unwholesome gases, rapidly or instantaneously. It is decomposed by fresh organic matter, and especially organised matter, less rapidly. The putrid portion may be estimated readily; the latter is more uncertain.

In using this test, it is well to take not less than 5000 grains of the water, or, still better, 1000 grammes, *i.e.*, one litre; but if a small specimen only can be obtained, then as little as 1000 grains may be used; but it is well always to give the figures for 1000 for uniformity, or (by multiplying by 70) to change them into the amount per gallon; one million, however, is still better, and I propose to use

* From vol. iv., 3rd series, of the *Memoirs of the Literary and Philosophical Society of Manchester*. (Communicated, with emendations and alterations, by the author).

it always for air and water. Grains or grammes may be used indifferently, the solution being made to contain simply so much in 1,000,000.

A convenient plan is to use 2 grains of the pure crystallised chameleon to 1000 of water. This, of course, is the same as 2 grammes to a litre of water.

The chameleon is poured conveniently from a Mohr's burette, or, better still, when the water is very pure, from a dropping-tube in which 1 c.c. is 6 to 8 inches long. Add a drop of the chameleon, and wait till the colour disappears; add another, and so on, till the colour remains permanent. The organic matter which decomposes the chameleon in a minute or two must be noted carefully; but generally there is a greater quantity which decomposes very slowly; the result obtained from the latter is, I believe, of less value. By decomposing in a minute or two, it is meant that when a few drops are added, producing a slight colour, this undergoes a change in a minute or two. But generally, considerable permanency is obtained in ten or fifteen minutes; then the slow decomposition begins of quite another quality of organic matter, requiring hours, or even days. This matter must be estimated either by the weighing process described, or by the further action of the chameleon, to be described. The amount decomposed instantly is a true measure of the putridity, it is believed. If there is very much organic matter, it is often very difficult to know when to stop, as the brown masks the red colour. But this must not bring discouragement, as experience will teach exactness; and, if it does not allow exactness, it then will be no great loss in such cases in a sanitary point of view, as in them there is decidedly too much organic matter, and the water may be condemned. From the same point of view, it is of less consequence whether the amount be a minute quantity more or less. It is well to make broad lines of distinction, and to condemn freely when there is rational hope of obtaining a purer water.

The amount of available oxygen in one of the solutions of chameleon described is 0·0005, which may be either grammes or grains, or almost exactly 1 of oxygen in 2000 of the solution. If we wish to know the amount of oxygen used, we simply divide the amount of chameleon by 2000. It is probable that the use of the oxygen column is the only exact method of recording the results; and it is probable that the amount of oxygen required is the only exact measure of the impurity of the substances. We obtain in this number the amount of oxygen which is required for purification.

Whilst looking over this plan in manuscript, I received Dr. Miller's paper, proposing also to use oxygen; he prefers a solution of chameleon containing 3·95 grains, equal to 1 grain of available oxygen to 10,000 of water, or 1 c.c. = 0·001 gramme, or, say, 1 milligramme of oxygen. This is a very convenient method; but it has been thought proper to keep the tables as given for various reasons, chiefly arising from this—that it has not been found so convenient to keep or to titre a very weak solution. In some cases, a very strong solution is required; we can easily dilute it, but we cannot concentrate it readily. After estimating its strength, we dilute it (if we require a weak solution) to any amount we think proper; and as the strength changes, the amount of water to be added will also change. If the amount of oxygen is given as the result of the analysis instead of the amount of chameleon solution, the strength of the latter does not require to be kept uniform. The analyst requires only to know its strength at the time of using it. For very bad water, the strong solution may be used; and, when greater delicacy is wanted, it may be diluted. The weak solution here used is made by adding nine of water to one of the strong solution.

To make the chameleon solution, very pure water must be employed, and very pure crystals, as well as very pure vessels; it is better kept in considerable quantities, such as a quart or two. It must be tried occasionally, say every month, in a cool climate: calculation must be made as allowance for any change which it may undergo. If calculation is not agreeable, a less quantity of solution may be made at a time, and that which is over may be thrown away, a fresh amount being made to the normal strength whenever the original weakens; or a certain amount of the crystals may be weighed and added to the solution; but this has been found less convenient.

The estimation of the value of the chameleon is sometimes made with a solution of chloride of iron, sometimes oxalic acid. For ready reference, a table is made showing the amount of a solution of iron which corresponds to a certain amount of chameleon. The sulphate of ammonia and iron has proved to be very valuable. The writer has not found oxalic acid equally sharp and quick; but eminent chemists use it—Mohr and Miller, for example.

Values of the Strong Solution.

Permanganate of Potash or Chameleon 2 grammes in 1000 c.c.	Oxygen.	Ferrum.	$FeO,SO_3+NH_4O,SO_3+6Aq.$	KO,Mn_2O_7.
c.c.	gr.	gr.	gr.	gr.
1	0·000500	0·0035	0·0247	0·002
2	0·001000	0·0070	0·0494	0·004
3	0·001500	0·0106	0·0742	0·006
4	0·002000	0·0141	0·0989	0·008
5	0·002500	0·0176	0·1237	0·010

In the oxygen column, 6 and 3 may be left out.

The first and under might be called the first quality of water; from 0·1 to 0·2, the second; 1 would be the tenth.

When it is considered better to acidify the water before adding the permanganate, this is done by adding 3 drops or water-grain measures of sulphuric acid to 1000 grains; some water will demand more; the object is to attain acidity equal to about 3 drops of sulphuric acid in 1000 grains of distilled water. I find Dr. Miller says 50 grains of diluted sulphuric acid (1 of acid to 3 of water) added to 8 ounces of water. Acid enables the oxygen to act on more matter, and more rapidly. Alkalies prevent the action, although they may prepare some of the matter to be more readily oxidised: when the colour has been diffi-

cult to see, the chameleon may have been used with alkali instead of acid, in which case a green colour is obtained, serving usefully as a corroboration.

As an illustration of the mode of examining water so as to obtain the first and the second conditions, if we may so call them, of organic matter, I will quote here a short paper, read to the Philosophical Society of Glasgow, on the water of the river Clyde. I think I there gave the proper use of the permanganate of potash.* There is a very sharp separation between those substances that decompose the permanganate at once and without acid and those which do so on the addition of acid, and after a short time. So decided is this, that I consider them as indicating two different conditions of organic matter.

"I thought it would be interesting to test the Clyde in this way, and for that purpose obtained specimens at various points from near Bothwell to the sea, afterwards continuing till the vessel came near Liverpool.

"The column to observe is number 1 of annexed table of either series. This gives the amount of oxygen consumed instantly, and corresponds, as I believe, to the amount of decomposed matter which has left in solution putrid gases, whatever these gases may be. We may suppose them to be sulphuretted hydrogen in minute quantities, or compounds of sulphur, or organic substances only, or all mixed. In the part of the Clyde near Glasgow, all these compounds will probably be found; as we go near the Firth, the sulphur will be fully oxidised, and the organic compounds only will be the active agents in taking up the oxygen, as they oxidise more slowly.

"The amount of oxygen is calculated from the amount of permanganate employed. The method is an extension of the original idea given out by the late Forchhammer many years ago; the amount of water used was 100 c.c., or 1544 grains. The permanganate required to give perfectly pure water perceptible colour was in every case subtracted from the number obtained.

"The examination of the Clyde is not perfect, but there is much to be seen that is interesting. Specimens ought to have been taken higher than any town on the river.

"The first was taken about 6¼ miles above the quay at Glasgow. We there find the oxygen required for the water to be 0·000045 per cent by weight, or equal to 3·15 grains per 100 gallons. When we come to the Broomielaw, at Glasgow, we find the amount of oxygen demanded had risen to 0·00022 per cent by weight, or 15·40 grains per 100 gallons.

"We then see it steadily diminishing; and when we arrive at Port Glasgow, 20 miles down, it has become equal to that at 6¼ miles above Glasgow. If we had taken the north side, below Dumbarton, instead of the south, on which the vessels sail, the difference would have been greater.

"Leaving Greenock, and turning the point, we have a rapid change; and when off the west of Gourock Bay, at the distance kept by the Liverpool vessels, the amount of oxygen demanded fell to 1·05. Off Wemyss Bay, the fall is remarkably low; but it is not always so, as it depends on tide and wind. The current seems to run down the centre, whilst the ocean water comes up the coast. The winds and floods may modify this.

"We have to observe a complete change about Gourock or the Cloch, if we keep to the south and east side; but, if we keep to the north, the greatest change is perceptible not far off Helensburgh.

"This wide space of water reduces the amount of oxygen required to 0·00001 per cent by weight, or 0·7 grain per 100 gallons.

"We are now led to ask if the purest state of the water is attained here. We may go further towards the open sea, and find that the amount required falls to 0·000005 per cent by weight, or 0·35 grain per 100 gallons. This is at Arran, where the sea is more extensive, and oxidation, even of the peaty matter from the hills, is nearly completed. We observe this to continue till the entrance of the North Atlantic is past; and, as we come south, to a narrower channel, the amount of oxidisable matter increases, and keeps up steadily till we arrive at Liverpool. No specimen was taken nearer than 17 miles from Liverpool. The point 0·00001 per cent oxygen by weight, or 0·7 grain per 100 gallons, is an important one to examine. We find that at Dunoon, Innellan, and Holy Loch, this amount may be called permanent. We may ask, Why does it not fall lower? and is it true that the sewage of Glasgow affects the Firth until we arrive at Lamlash, and obtain the number 0·000005 per cent oxygen by weight, or 0·35 grain per 100 gallons?

"We observe that the amount of purification is remarkably rapid whenever the Clyde widens, as at Greenock to Gourock; so that, even near Helensburgh, the number has fallen to 0·0000125 per cent oxygen by weight, or 0·875 grain per 100 gallons. This change, from 0·000045 or 3·15 grains per gallon has been effected in the space of about 2 or 3 miles. Is it possible, then, that the slight further change required demands all the wide distance between Gourock and Arran? I think not. The reason we do not find the number for oxygen falling below 0·00001 per cent by weight, or 0·7 grain per 100 gallons, at Holy Loch, Strone, Dunoon, and Cove, may be seen by examining the Lochs. We there find that they themselves send in water with the oxygen number 0·00001 per cent by weight, or 0·7 grain per 100 gallons.

"At this point we must remember that the oxygen may not all be required for putrid matter, and that the streams contain some peaty matter which may also instantly require oxygen. At any rate, we know this, that, for whatever they do require it, it can be for the destruction of no very unwholesome matter in the water, as the highland streams must be considered free from such taints. There is a little of the soil of cattle when the weather is wet, but perhaps none when the weather is so dry that the water must pass through the earth before reaching the bed of the stream.

"We cannot, then, expect the sea-water to demand less oxygen than the streams and lochs that affect it here. In other words, we discover the influence of the land on the drainage from the hills, even when all trace of the influence of Glasgow has gone. This is, I believe, the reason that, according to circumstances, such as currents and weather, we observe the water of the Firth sometimes as pure as the deep sea, and at other times less so. At Wemyss Bay, for example, the table does not show this very well. This will happen at other parts of the coast when the streams enter purer than the usual sea-water there, as, for example, at Dunoon and Innellan, where the water flows from streams equal, when not in flood, to the deep Firth water. We see the influence of the coast, also, as we go on towards Liverpool, and between the Isle of Man and Lancashire.

"I considered that 0·00001 per cent oxygen by weight, or 0·7 grain per 100 gallons, marked the limits of the Glasgow sewage. If the sewage were not all expended, the amount would be greater, because the lochs and their streams do not show a higher number. Whenever the water of the Firth falls down to that of the streams, we are, as I suppose, receiving the air at least as pure as the air above the streams on the hills, and may be contented.

"Some people will perhaps demand more than this number. I have not made examinations far enough towards the ocean to enable me to speak of it; but it seems to me that the numbers 0·00001 per cent by weight, or 0·7 grain per 100 gallons, of the streams, and 0·00005 or 0·35 grain per 100 gallons, mark two very important points. The first characterises air which is certainly most wholesome and agreeable; the second is that ocean air which some persons require, but which to others is

* We never understood the author of this paper to claim having first used permanganate of potash for water. He readily acknowledges being later than Dr. Miller and Dr. Woods, and still later than Mr. Condy, who seems first to have carried out Forchhammer's idea. He simply wishes to show his mode of analysis and the results, leaving the question of merit entirely aside. *Ed.* C. N.

said to be too strong. On the meaning of this expression "too strong," I will not attempt to speak; but it is very much used by a great public, and it must have a wide foundation. It is apparently certain that to some it is important not to have the extremely strong or perhaps purest air.

"These observations seem most curiously to coincide with general observation. The current of the Clyde keeps to the south; and we see that the water changes less rapidly there. At the north the direct current is not much observed, and the influence of the lochs or fiords is seen. The water from them presses against the Clyde current, and aids in keeping it to the south-east. This has influenced the building of the numerous residences on the Argyle side, lining all the coast. The population has not found it needful to make a chemical analysis, but has seen where the purest water was with the unaided eye. A mode of observation, apparently quite as good as chemical analysis, is the examination of the rocks on the coast, the dark and dirty aspects of these in impure water being very striking.

"I am not, however, inclined to look on my work here as useless, although common observation has done its part so well. I believe it to be of great importance to us to be able to apply tests so as to prove the truth of popular belief, which is formed by long and tedious processes. With these little chemical experiments we may do the work in an hour, which the instincts and expensive experience of whole generations were required to perform.

"I believe that in these results we have a method of examining the coasts which will be valuable to us as a sanitary police. It can be applied wherever there are sheets of water.

"I will not say that these numbers represent the relative wholesomeness of places on the land and on the sea; but I think it probable that they may fairly be used as comparisons of places on the sea only. When the land is in question, there are many sources of emanations to be considered.

"To be complete, the examination ought to be continued for several years. Last year was not an average one; there was much rain. (This regarding the Clyde and the sea was read in Dec. 1866.)

"There are floods in the Clyde which bear down so much water that the brown peaty matter is readily seen below Dunoon; but on these occasions there is no fear of putrid matter, as the water carried down is so abundant. At the same time there will be a certain degree of purity less at the sea-entrance, corresponding to the greater degree of purity caused by the flood at Glasgow. By this it is not meant that the water as low as Cloch or Dunoon is affected by more than an infinitesimally small amount of the sewage matter which is washed past Glasgow in floods, whilst at other times the effect has ceased, as before said, at least on the north, below Helensburgh. There is, however, a little muddiness observable for many miles, and this will be found even in places where the oxidation of all the readily transported matter has taken place.

"Even where total oxidation has occurred, a little muddy matter remains. It consists chiefly of earthy bodies, which may float until they obtain a suitable place for deposit.

"It would be interesting to find the time needful to perform this change on the organic matter of Glasgow. We see that the great bulk of the purification is performed in the fresh water. At Dumbarton it must be rare indeed that anything can be known to exist in the water from its smell. When the Clyde passes into the estuary, which may be said to begin at the Rock of Dumbarton, the change is effected by spreading the water over many square miles, and preparing it effectually for those who enter the sea- and Loch-regions below Helensburgh. Below this point it is not a river on which we are, but an arm of the sea, protected on all sides from oceanic waves.

"The water bears the qualities of coast-water in proportion to its excessive length of coast. This quality must exist more or less on all coasts which have fresh springs running into them. In cases where the rivers are large or numerous, the evil of the meeting of fresh and salt water is well known. On the Firth of Clyde no large bodies of fresh water are found after we leave the mouth of the river portion of the Clyde; and, as observed, these streams are remarkably pure, or, if coloured, it is only by peat-water. The absence of great rivers is therefore an advantage of an important kind to this coast.

"I was extremely glad to be able to speak thus favourably of the districts which are so agreeable to me; but I am certainly desirous of speaking still more favourably of some which are too much affected by Glasgow. They may be constantly deteriorating. This is a very serious matter, not merely for owners of property on the Firth, but for all the inhabitants of Glasgow, who are favoured more than those of any other large city in the kingdom by a ready access to this wonderful sanatorium.

In making these remarks, I take for granted that the air above the water will be pure in inverse proportion to the amount of volatile oxidisable matter.

"We must not, however, forget that, if the river is rendered impure, the town is proportionately purified. And we must also remember that the work done in the water is enormous. If the refuse matter were allowed to evaporate into the air, and so collect its oxygen, the act of purification would go on in the air we breathe; but now the water draws in oxygen, and, as soon as it is consumed, it draws in more. Even the air over the river is, at a distance of a few miles down, purer than the air of many towns; and when the spaces widen, the case is stronger still.

"I have sometimes inquired if we obtained in fish an equivalent of the manure sent out, and if it is not easier to gather the crop in boats than to put the manure laboriously on land. I find, however, that the loss by putrefaction, oxidation, and evaporation is so rapid that there was no hope of it being used profitably. In one current examined, a very deep one, and much stronger in sewer matter than the Clyde ever is, the whole nitrogen had disappeared in three days, the greater part in much less.

"Whilst the chief object of my paper is to show a new mode of examining climate as well as streams, I am glad to be able to say that Glasgow has failed to destroy the purity of the Firth beyond the points indicated, and that we may still rejoice in our summer dwellings. It is, however, not to be forgotten that the effects are found too far away, and that twenty-two miles of mischief is more than abundance. It is to be hoped that the cautious policy of the City in waiting for the best method to be adopted for using its refuse will enable it to carry out that future work, whatever it may be, with the greatest success.

"I have referred only to the 1st column: it indicates the amount of permanganate decomposed instantly; this represents the gases of decomposition, such as most readily pass into the atmosphere.

"It will not be supposed that this is the only offensive matter.

"The 2nd column represents the amount when acid is used to assist the oxidation. I suppose this to represent the amount easily decomposed.

"The 3rd column of the original paper, left out here, represents the amount of oxygen used by the organic matter in twenty-four hours. I do not at present see its use. I do not think this at all a fair mode of representing the impurity of water, unless we are sure that the quality does not change. We see this by the numbers above, and at Glasgow Bridge. The purer water has, by this mode of representing it, the appearance of being equal to the worst. The only column that gives the continuous increase and decrease exactly as the senses find the case to be is the column No. 1.

"It is not, however, meant that the gases of decomposition are the only evils to be apprehended from impure water; but, so far as I know, they are those that affect the air principally (from this source). The most dangerous bodies are probably in the water itself, and it is possible that they may not be affected by the process of column 1.

"I am not inclined to draw any important conclusion from the total organic matter without inquiring into its character. At present, I believe, we are quite safe in attending to the conclusions here given in column 1, with such precautions as I have elsewhere indicated—when, for example, nitrites, sulphites, &c., are present. By and by we shall learn the true mode of dealing with the other columns."

(To be continued.)

NOTICES OF BOOKS.

Sound: A Course of Eight Lectures delivered at the Royal Institution of Great Britain. By John Tyndall, F.R.S. Second Edition. London: Longmans, Green, and Co., 1869.

Dr. Tyndall has proposed to himself to publish a series of works on Natural Philosophy, suited not only to the requirements of the students, but, as far as is practicable, to the popular ear. They are to have as their bases, the lectures which he is in the habit of giving, year by year, at the Royal Institution, and already two such handbooks have appeared—the well-known treatise "On Heat Considered as a Mode of Motion," and the treatise "On Sound," the second edition of which we have before us. The value of these works is too well known to the scientific to need any mention here. They form the most complete separate works on the several subjects of which they treat to be found in this language, and Dr. Tyndall is careful to introduce the most recent researches of continental philosophers, many of which are not readily accessible to the English public.

In comparing our scientific works with those of France and Germany, there are, however, several most notable differences; differences which rest with the publisher rather than the author, and until these be overcome we cannot have any great diffusion of standard scientific works in this country. We allude chiefly to the great expense of our works on science, and the above are no exception to the rule. Let any of our readers look at the volumes of the admirable *Bibliothèque des Merveilles* at 2 francs the volume, and ask himself what would be their price in this country—certainly seven shillings and sixpence. They are by eminent men, are well printed, and well illustrated, and such a series would be a great boon to this country. As to woodcuts, they, for the most part, excel those of our best works on science, into which we rarely introduce copper or steel-plates, and coloured engravings less rarely still.

The second edition of Tyndall "On Sound" differs but slightly from the first; the main difference is the addition of an appendix of 9 pages, containing an account of the recent researches of M. Regnault on the propagation of sound, written by himself. Many of our readers have heard Dr. Tyndall's lectures on sound, and will remember how well they were illustrated, specially as regards the production of Lissajous' figures, drawings of many of which are given.

The first lecture treats of the production and propagation of sonorous waves through various media. The second distinguishes between noise and music, musical pitch is defined, and a good account of the admirable "double syren" of Helmholtz (from his "*Die Lehre von den Tonempfindungen*,") is given. In the third lecture is discussed the vibration of strings, the general nature of progressive and stationary waves, and the optical examination of the vibrations of a piano wire. Lecture 4.—The vibrations of rods, square plates, discs, and bells. Lecture 5.—The vibrations of columns of air in organ pipes, the human voice, and reed-pipes. Lecture 6.—Sounding flames which have of late engaged so much attention. Lecture 7.—The interference and coincidence of sonorous waves, and the theory of "beats." Lecture 8.—The conditions of musical consonance, the harmony of musical sounds, and the optical examination of musical intervals.

The work is well illustrated for an English scientific book, and the style is agreeable, yet the book is more for the student than for the general reader; nine out of ten well-educated persons unacquainted with science could not comprehend many of the subjects discussed without reference to other works bearing on the subject. As a handbook for the student of science it is a valuable contribution to our scientific literature.

Traité Eléméntaire de Physique. Par A. PRIVAT DESCHANEL, Ancien Professeur de Physique au Lycée Louis-le-Grand. Paris: Hachette et Cie. 1869.

DURING the last few years, there has issued from the French press (and notably from the press of Messrs. Hachette) a series of beautifully-illustrated works, having for their object the popularisation of science. We need not do more than refer to "Le Ciel," and "Les Phénomènes de la Physique" of M. Guillemin, with their beautifully-coloured plates, their copper-plates, and their innumerable woodcuts. The recently-translated "Vie Souterraine" of M. Simonin is another example. In fact, the world has shown its appreciation of these works by the rapidity with which translations have been made into numerous languages. We saw the other day an "edition de luxe" of Guillemin's "Le Ciel" in Greek; and we should suppose that, by this time, it is to be found in Hindoostanee, perhaps in Chinese. There is no denying that we have no books among our native scientific literature which can compare with these: somehow our drawings of apparatus are heavy and cold, there is nothing artistic about them, and they are too often repellent to the eye, rather than attractive.

The book before us, although not belonging to the class of "Le Ciel," boasts three coloured plates, and 719 woodcuts in its thousand and eight pages. It is rather a student's manual than a popular work on physics. The subject matter is arranged in the following order:—Mechanics; Hydrostatics; Pneumatics; Hydraulics; Heat; Electricity; Acoustics; Optics. "Le traité," says M. Deschanel, "que je publie aujourd'hui est destiné à faciliter le travail des jeunes gens qui veulent obtenir ces grades" (universitaires), and, coming as it does from a man who, for nearly twenty years, was Professor of Physics in the Lycée Louis-le-Grand, it is a valuable contribution to French educational works.

Although by no means overloaded with mathematics, we are glad to observe the introduction of mathematical formulæ, wherever it is possible, without adding a great complexity to the matter discussed.

In the "Pneumatics," we notice an account of M. Kravogl's mercury air-pump, also of that of Geissler, but we seek in vain for mention of the admirable Sprengel pump.

The chapters on Heat are good, and are clearly written, but we think an insufficient mention has been made of Tyndall's experiments on the absorption and radiation of heat by gases, while the space devoted to the mechanical theory of heat is undeniably too short.

A good account, accompanied by a capital drawing, of the "machine à gaz" of MM. Otto and Lungen will be found on p. 306, and of the electrical machine of M. Holtz on p. 357. The subject of static electricity has been discussed with perhaps more diffuseness than any other subject. In dynamic electricity, we notice a very clear exposition of the actions of solenoids.

A chapter is devoted to the "Effets calorifiques produits par les courants," in which will be found a charmingly artistic drawing of the magnified "image des charbons" of the electric lamp; and, while we are on the subject of the woodcuts, let us mention No. 576 ("Propagation du son dans un milieu indefini") as singularly felicitous and elegant.

Of the book as a whole, we may say that we cordially recommend it to the student of science; he will find it clear and concise, abounding in good woodcuts, and remarkably moderate in price.

CORRESPONDENCE.

EXPLOSION OF NITROGLYCERINE.

To the Editor of the Chemical News.

SIR,—The frightful explosion of three-quarters of a ton of nitroglycerine in Wales, last week, and the deplorable loss of life and injuries attending it, may probably lead to some consideration on the part of the authorities as to whether an explosive agent apparently so unsafe should be allowed to be imported, or even used, in this country, notwithstanding that it appears to be established, at least to the judgment of many competent authorities, that for blasting a certain class of rocks there is no other agent at once so cheap in proportion to power and so effectual as nitroglycerine. The explosion referred to does not appear to have been the result of any carelessness; the "oil" was packed in metal canisters, which were surrounded by sawdust, and no one who has experimented with nitroglycerine can well attribute the explosion to any concussion that could have been caused by the jolting of the waggon in which it was conveyed, over, even, a somewhat rough road. Must, then, this explosion be classed with that which took place in Australia when the oil was at rest in a cellar? It would seem so. But if so, no confidence can be felt in employing an agent which may go off at any time; and the risk to life and property incurred in using it, will overbalance any possible advantage to be derived from its economy and efficiency.

Yet it is stated that nitroglycerine is *safer* than gunpowder. It is certainly less liable to be exploded by fire, and to disrupt the slender link which retains its elements, subject to chemical force, and set its mechanical force at liberty, by concussion, needs that concussion be sudden and forcible. I believe that a bottle full of blasting oil may be dashed to the ground without much danger, yet a drop of it upon a stone may be exploded by a blow from a hammer. Now what can be the possible cause of such unexpected explosions as have taken place? I can see only two possible reasons—First, that the oil undergoes decomposition or chemical change under certain at present unknown conditions, of time, temperature, shaking, &c., which predispose it to undergo a complete and sudden decomposition from causes ordinarily inadequate; secondly, that the cases and bottles in which it is contained, being air-tight, are liable, from a very trifling escape of gas from the liquid, to arrive at a state of tension from which the passage to a sudden break is easy. But would the mere bursting open of a bottle or tin case produce concussion sufficient to determine an explosion of the oil, unless we suppose the latter to be altered in quality? I think it would. I have known a stout glass bottle, used in an ethyl experiment, to be shattered by slowly gathered internal pressure into *dust*, with a report like the firing of a pistol. In a close vessel, full, or very nearly full of the oil, not much gas relatively to the quantity of liquid need be evolved in order to induce such a degree of pressure as might cause explosive rupture of the vessel. If one vessel burst, the concussion would certainly explode also any that might be near.

If the true cause of these seemingly anomalous explosions is indicated above, the remedy is both simple and inexpensive. Let every vessel containing the oil have fitted to it a tube, with a capillary bore, such as a piece of thermometer tubing, one end of the tube entering the oil, the other exposed outside.

If the tube were enlarged below to make room for any expansion of the liquid by elevation of temperature, none could be forced out by that alone, and none could be spilt through the capillary orifice of the tube by inverting the vessel. With a little management in the arrangements, any overflow might be made certainly indicative of the formation of permanent gases, which would be a warning signal. This method might also be applied experimentally

to determine the probability or otherwise of the suggestion I have made as to the cause that may have led to these fearful explosions.

Certainly, the time is come when science should, in the cause of the public safety, investigate the "why" and the means of prevention of such horrors as that of the late catastrophe.—I am, &c.,

E. S.

Ramsay, Isle of Man,
July 7, 1869.

THE CHEMICAL SECTION OF THE BRITISH ASSOCIATION:

THE OFFICIAL REPORT.

To the Editor of the Chemical News.

SIR,—On comparing the official report of my paper entitled "Researches on the Ethers," with my paper as it appeared in the CHEMICAL NEWS some time ago, I was astonished to find striking differences between them.

In justice to you as well as to myself, I beg to state that the version which you have published is the authentic version, and that in the official one the alterations have been made without my knowledge. Possibly I may bring this matter before the Exeter meeting of the Association.—I am, &c.,

J. ALFRED WANKLYN.

London Institution.

MISCELLANEOUS.

Ashberrium, a New Alloy, consists of 80 parts of tin, 14 of antimony, 2 of copper, 2 of nickel, 1 of aluminium, and 1 of zinc.—*Polyt. Centr.*

New Alloy for Stereotyping.—M. Ed. Hofer-Grosjean recommends the use of an alloy, consisting of lead 50 parts, tin 36, cadmium 225; this alloy is readily fusible, and is harder than the alloy containing bismuth now applied for stereotyping purposes.—*Polyt. Centr.*

Mineral Lemonade.—When equal parts by weight of strong pure sulphuric acid and strong pure alcohol (85 to 90 per cent) are carefully mixed (the acid being poured into the alcohol and thoroughly mixed therewith), a liquid is obtained which has long been known and used by medical men under the older name of *Elixir acidum halleri*, more recently named *Mixtura sulphurica acida*. This fluid, which, if well prepared, contains essentially sulphovinic acid, is an excellent summer beverage when mixed with water in the proportion of one small teaspoonful to a tumbler of cold water, and sweetened with sugar, or, preferably, with some fruit syrup. Above the lemonades made with vegetable acids, this acid mixture has the advantage of not increasing the perspiration, as citric and other vegetable acids do, while, it is better borne by the stomach, and has a tonic action upon the vascular system. It is, indeed, a very pleasant drink, often given, at the *cafés* of Paris, Berlin, Vienna, and other places, along with some *syrop de groiselles* or *framboises*, and rather exorbitantly charged for. The proportions by bulk are—one of strong sulphuric acid and three of alcohol.—*Hamm's Agronomische Zeitung.*

Cellulose in Old Wood.—M. Payen has taken the trouble to analyse a piece of old woodwork, once belonging to the well-known Chaillot pumps, in order to ascertain what state the cellulose was in, after fully a century's exposure to wind and weather; he therefore treated the wood—first, for eight consecutive days, with a weak solution of caustic potassa (1 part in 10 of water), at a temperature of between 20° and 75° C.; secondly, he treated the residue with nitric acid, sp. gr. 1·2, without applying heat, and also for eight days; next with nitric acid, sp. gr. 1·05, taking care to wash out carefully all substances which, by each of these operations, could have become soluble, previous to proceeding with another operation; M. Payen obtained pure cellulose, as might have been expected, and was evidently also expected by Field-Marshal Vaillant, who happened to be present when the *savant* deposited, at a meeting of the Agricultural Society, a piece of pure cellulose obtained from the wood of the old pump, since the Marshal asked Payen, jocosely, whether he had not some old wood from the ruins of Carthage to operate upon; and M. Robinet, improving upon the occasion, offered to send Payen a piece of the wood of Noah's Ark, to continue his researches.

Fusibility and Volatility of Metals.—While engaged with experiments on the intrinsic composition and constitution of various pieces of silver money, made at the Royal Netherlands Mint, at Utrecht, Dr. A. von Riemsdyk carried on some experiments on the fusibility and volatility of metals, from the published record of which we abstract the following:—The metals tin, bismuth, cadmium, lead, and zinc, as chemically pure as they can be obtained, were molten, in order to prevent their oxidation, in a feeble, but constant, current of pure and dry hydrogen gas. The author found that—(1) the melting of these metals does not, either mechanically or by evaporation, give rise to any loss at all; (2) that *tin*, *lead*, and *bismuth*, when kept in a liquid state, are not volatile at temperatures greatly in excess of their melting points, and that, at a bright red heat, quantities of 2·3433 grms. of *bismuth*, and 4·5183 grms. of *lead*, did not lose, by being kept at that temperature for one hour, more than 1 and 0·5 m.m., respectively, by evaporation, while *tin* did not exhibit any volatility at all; (3) that *cadmium* and *zinc*, though completely fixed, non-volatile, at their melting point, begin perceptibly to volatilise at a few degrees above that point; (4) that there does not exist any relation at all between the fusibility and volatility of these metals, which may be arranged in the following manner, beginning from the most fusible and most readily volatile:—

Fusibility.		*Volatility.*
Tin	228·5° C.	Cadmium.
Bismuth	268·3° „	Zinc.
Cadmium.. ..	320·0° „	Bismuth.
Lead	326·0° „	Lead.
Zinc	420·0° „	Tin.

(5) that the so-called Rose's fusible metal, an alloy of tin, lead, and bismuth, the melting point of which is about 97·5°, and certainly not higher, is not perceptibly volatile when heated to a bright red heat in a current of pure hydrogen gas. Silver, unalloyed, melts at 1040° C., pure gold at 1240° C., while the author found that chemically-pure copper requires a temperature of 1330° C. to become liquid. Neither pure silver, nor pure copper, nor also the alloy of silver and copper containing 945-1000ths of the former metal (this alloy is the standard alloy of the Netherlands silver coins), loses anything at all by volatilisation when kept for a considerable time at temperatures higher than the melting points of both these metals, and in a feeble current of pure hydrogen to prevent their oxidation. The author has made some of these experiments on a very large scale, having at his disposal large quantities—several hundred kilos.—of these metals in pure and alloyed state; he also describes an ingenious pyrometer devised and invented by him, but space forbids us to enter into further details.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

In accordance with the generally expressed wishes of our friends and readers, we have effected arrangements to enable us to give, under the above heading, notices of EVERY CHEMICAL PAPER IN THE WORLD, *as soon as possible after publication. Whenever possible, these notices will appear in the form of carefully prepared, although necessarily brief, abstracts; as respects papers either too long or too abstruse to render condensation possible, their titles will be chronicled; and in all cases accurate reference will be made to the original publication. The two half-yearly volumes of the* CHEMICAL NEWS, *with their copious indices, will therefore be equivalent to an English edition of the "Jahresberichte," with the additional advantage of keeping the readers week by week on a level with the latest advances of science.*

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus des Séances de l'Académie des Sciences, vol. lxix., No. 1, July 5, 1869.

A very considerable portion of this number is filled with a lengthy discussion on some ancient letters and papers of historical interest. Incidentally with this subject, M. Balard stated that, having made use of M. Carré's plan to immerse written papers in dilute hydrochloric acid (one part, by bulk, of acid, to ten parts of pure water), he found very old writing to resist, even for fully twenty-four hours, the action of this acid, and that, although the figures become rather yellowish, they were perfectly and distinctly legible; yet, though this holds good for the documents operated upon, which were written between the years 1577 and 1770, it does not for documents tested in the same manner and written between the year 1793 and 1867. The observation was made that some ancient writing turned red in the acid; and, since this indicated the use of logwood in the ink, it was doubted whether this material had ever been applied at so remote a date as even the end of last century for ink making. M. Balard stated that he had found, in books printed and published more than 100 years ago, prescriptions to make black writing ink with logwood. M. Chevreul asked M. Balard whether he had tested the inks for oxide of manganese, since some prescriptions for the manufacture of black writing ink advise the addition of a salt of the protoxide of this metal, in order thereby to have a means of detecting any attempt to destroy the writing by means of chlorine. M. Chevreul pointed out the great difficulties in testing, by such methods, any writing, owing to the composition of the ink, the kind of paper, wherein it written, its sizing, and the very varying conditions wherein written documents may have been kept.

Researches on the Galvanic Battery, and the Origin of the Heat which is Produced in the Elements and is not Transmissible to the Conducting Wires.—M. Favre.—This is another portion of a lengthy memoir on this subject, and is full of allusions of

tabulated results, which cannot be left out without impairing the value of the research; we therefore only quote the title.

Poisonous Properties of Coralline, as used for Dyeing Purposes.—M. Tardieu.—This author, although not wishing directly to contradict M. Laudrin, insists upon the fact that silk stockings, dyed with coralline, and absolutely free from any such substances as arsenic, mercury, or lead, cause, to those who wear these on their feet, in many instances, grave inconvenience, certainly not due to the silk, and thus, inferentially, due to the dye.

Heat of Transformation of some Isomeric Bodies.—MM. Troost and Hautefeuille.—This memoir, a physico-chemical essay, treats of—1st, the heat of transformation of cyanic acid into cyamelide; 2nd, the heat of transformation of cyamelide into cyanuric acid; 3rd, on the relation which exists between the heat given off by the combustion of a substance and its specific gravity (under this head, sulphur and arsenious acid are treated).

Relations which Exist between Amido Acids, derived from Benzoic Acid, and the Alkaloids derived from Toluen.—M. Rosenstiehl.—The author says, there exist three acids, the composition of which is expressed by the formula $C_7H_5(NH_2)O_2$; they are—the *amido-benzoic*, *amido-dracylic*, and *anthranilic acids*; we are acquainted, moreover, with only two homologous alkaloids—to wit, *toluidine* and *pseudo-toluidine*. In order to elucidate the question, What relation there exists between these acids and the alkaloids, the author has acted upon these acids with hydriodic acid at a temperature of from 180° to 200°. The amido-benzoic acid yields pure toluidine, without any secondary product; amidodracylic acid yields pseudo-toluidine, but a secondary reaction takes place simultaneously, whereby carbonic acid, aniline, and hydride of methyl are formed; anthranilic acid behaves as amido-dracylic acid.

Solubility of Sulphur in Coal-Tar Oils.—M. Pelouze.—The author has operated with light benzines, sp. gr. 0·870 to 0·880, the former boiling between 80° and 100°, the latter between 85° and 120°; heavier benzines, sp. gr. 0·882 to 0·885, the former boiling at from 120° to 200°, the latter at from 150° to 200°; heavy oils, sp. gr. 1·010 to 1·020, the former boiling at from 210° to 300°, the latter at from 220° to 300°. The temperatures at which the solvent action upon sulphur was tried with these divers liquids, varied from 15° to 130°. The light benzines dissolve in the range of temperature up to their boiling point, from 2·5 per cent to 27 per cent of sulphur; the heavy benzines dissolve, for the same range of temperature, from 2·5 per cent to 38·7 per cent of sulphur; while the heavy oils dissolve in a range of temperature, from 15° to 110°, from 6 to 115 per cent of sulphur, and above 110° to 130°, indefinite quantities of that metalloid. At temperatures ranging from 200° to 300°, sulphur decomposes the heavy oils, sulphuretted hydrogen being set free.

Les Mondes, June 17, 1869.

We notice from this paper, in the first place, the few, but interesting words written by the Rev. Father Secchi, S.J., to M. F. Mazeo, at Turin—

On Electricity.—"I believe that the true theory of electricity will result from the principle that electricity is not a motion (*mouvement*), but a change of the quantitative and dynamic equilibrium of the ether which constitutes the atoms of the substances, and that the propagation of such a change is brought about by the moving of the ether from one atom to another; this motion shakes, disturbs the ether of the atoms, and thus produces heat."

Balances of Great Precision.—It appears that the celebrated physical instrument makers, Collot, Frères, Paris, have greatly improved the mode of making balances, by devising what is called a balance on two columns. Without reproducing the woodcut contained in the above-named periodical, it is not easy to describe this instrument so as to be clearly understood by our readers; the system is an entirely new one, and by its application only is it possible to place the point of support on the axis of the balance, and thereby to shorten the length of the arms which bear the weight. Among the particulars mentioned of balances made according to this new system, we quote a balance made to bear, in each pan, 35 kilos., and sensitive with that load for 5 milligrms., and possessing, at the same time, perfect stability. Several balances of this kind have been made for the Russian Government; and the University of Upsala, Sweden, has two balances, each to carry 1 kilo. in each pan, and sensitive for 1½ milligrm. The laboratory of the School of Mines, Paris, has received, from MM. Collot, a balance of precision which, the author says, excels anything hitherto made. Balances with aluminium beams have also been introduced by these makers.

Among the acknowledgements of books received, we notice brief reviews of two small pamphlets, written and published in Italian, by the Rev. Father Secchi, S.J. The first of these books is entitled "*The Prismatic Spectra of the Heavenly Bodies.*" Contents—1st, the prismatic spectra of the fixed stars; 2nd, the catalogue of the stars of which the luminous spectrum has been determined; 3rd, description of the instruments applied in this investigation. The work is illustrated with beautifully-executed engravings, and is, according to the opinion of the reviewer in *Les Mondes*, an almost herculean labour, executed with a care and precision which might, at first sight, appear to be beyond the powers of one man. The other work is on "*The Nebula of Orion*," and is rather an astronomical essay.

Researches on the Propagation of Sulphuretted Hydrogen Gas through other Gases.—Dr. Hillebrandson.—The author of this memoir, originally published in Swedish, has made a series of experiments with sulphuretted hydrogen gas, because it is very readily detected, and its presence shown among other gases; these experiments fully confirm what is already well known on this subject.

June 24, 1869.

This number contains more information on the subject of the—

Oxyhydrogen Illumination.—L'Abbé Moigno.—This paper is written with the express view of meeting the objections made in public prints against this mode of procuring artificial light, and answers each objection completely. The first objection, made and refuted, concerns the alleged difficulty which oxygen is supposed to have, of passing readily through pipes, and travelling therein with ease, on account of its high specific gravity; the author states that experience has proved that, under the same, and, in all respects, identical conditions, oxygen gas travels more rapidly than hydrogen. Another point is an objection concerning the comparative rare occurrence of peroxide of manganese, and the difficulty of obtaining it; to this the reply is, there is plenty of manganese, of excellent quality, readily accessible, and more than fifty times as much as any greatly-increased demand will ever absorb; moreover, the oxygen is made from permanganate of soda, which, it appears, is revived again after having yielded its oxygen. One ton of this permanganate yields in twenty-four hours 100 cubic metres of oxygen; and, from reliable data obtained, 300 tons of the salt will suffice to produce yearly about 10,000,000 cubic metres of oxygen gas (a cubic metre is equal to 35·316 cubic feet). These 300 tons of permanganate are composed of 150 tons of soda, and 150 tons of peroxide of manganese, an insignificantly small quantity, compared with the 60,000 tons which are consumed of this material annually. As to the too slow production of oxygen, the author says, at the oxygen gas-work, when in regular course of working, they have obtained, from each retort, 38 cubic metres of pure gas per day; as to the cost, he states that the gas-work intended to be established will cost, everything included (retorts, &c., gas-holders to hold 24,000 cubic metres of gas for twenty-four hours' supply, 32 kilometres' length of mains), 3,700,000 francs; as to the objection concerning the zirconia, or magnesia cones, these last for several days, and only cost one centime; at the same time, the glass chimneys and globes are dispensed with. As to the expense of this gas, it appears, from the statements of the author, that, taking into consideration the great quantity of light obtained, it is decidedly less expensive. The manufacture of hydrogen, by means of the patented process, from hydrate of lime, is, according to the author, very simple, and the pure hydrogen thus obtained costs less than two centimes per cubic metre, leaving even out of the question the sale of the by-products, which would not be trifling. Lastly, the author tells us that MM. J. Dumas (Senateur, &c.), Jamin, Balard, and H. Sainte-Claire Deville, all Members of the Institut; M. Debray, of the French Imperial Mint; and M. Alphand, Director of Public Roads and Promenades, have been appointed a committee, by M. Haussmann, Préfet du Département de la Seine, to inquire into, and minutely report upon, this subject in all its aspects and details.

July 1, 1869.

We learn from this number that M. Wurtz, of Paris, has been on an inspection journey to Germany, by order of the Minister of Public Instruction, to report upon the chemical laboratories of Germany, and to give his opinion as to the progress of chemistry made in that country. The lengthy report of the eminent Doyen de la Faculté de Médicine of Paris may be summed up in these few words—That the material aid given to chemistry in Germany, has developed that science there to a degree which it lacks in France, as well as in most other countries. It is not for want of zeal and industry, says the eminent *savant*, but for want of the material aid—good laboratories, plentifully supplied with all requisites—that we are behind, as compared with Germany.

Cyanide of Potassium in Blast Furnaces.—M. H. Pajot has made a series of experiments, on the large scale, at the blast furnaces of Randonnay, Département de l'Orne, and found that the fact announced now many years ago, by Messrs. Lyon Playfair and Bunsen, of the presence of cyanide of potassium in blast furnaces, is a reality, and that the salt is formed there in such large quantities that it might easily become a useful and plentiful by-product of ironworks.

Extension of Sulphuric Acid Manufacture.—M. Perret.—The enormous pyrites deposits of Chessy and St. Bel, France, are advantageously applied, by the owner of that mineral deposit, to manufacture, at five different sulphuric acid works, a quantity of no less than 100 tons of concentrated acid daily, exclusive of the simultaneous manufacture of a great many other chemicals, in the preparation of which sulphuric acid is used. The pyrites alluded to contains a sufficient amount of copper to make the extraction of that metal from the burnt pyrites a paying business. This mineral is largely exported from France into those places where it can be taken to at a remunerative price; the locality where the mineral is found is too far away from the sea or any readily navigable river thither to admit of its exportation being extended beyond the limits of localities on and near the Franco-Swiss and Italian frontiers.

The Journal of the Franklin Institute, May, 1869.

Among the Editorial Items and Novelties we meet with the following original communications:—

Invisible Light.—Prof. O. A. Rood.—Many years since, the author says, a photograph was made, at Berlin, of the well-known bronze statue of the Amazon; and it was observed that, in the negative, a

black streak occurred at the tip of the lance (held by the figure in an almost vertical position) while two other analogous marks appeared in other locations. This picture was sent to Prof. Dove (Berlin), whose investigations in connection with light are widely known, and he came to the conclusion that these markings might be due to electrical discharges going on from prominent points of the figure at the time the picture was taken, and which, though invisible to an observer, would, nevertheless, by reason of the high actinic power of electric light, produce an impression on the photographic plate. This conjecture has been fully confirmed by the author, who, in a series of ingenious experiments, proved that electric discharges, entirely invisible to the observer in the presence of daylight, might, nevertheless, produce images of themselves in a picture of the adjacent objects taken at the same time, the photographic plate being relatively more sensitive to these impressions than the human eye. The author describes at length his mode of experimenting; but, without a reproduction of the woodcuts illustrating this paper, it is not possible to enter into more details on this subject.

New Arrangement of the Holtz Machine.—Prof. Smith.—In the ordinary mode of excitation of the Holtz machine, the knobs of the dischargers are placed in contact, and afterwards separated; the excitation cannot be produced without contact. It follows, that, when the balls are separated beyond the striking distance, all action will suddenly cease, and, to renew it, the balls must again be brought together; and frequently, in addition to this, a new excitation of the sectors will be required. A large class of electrical experiments require, virtually, this separation of the balls beyond the striking distance—*e.g.*, the "electrical flyers," the "head of hair," and the insulating stool. The author fully explains his arrangement, so as to keep up an unlimited excitation, whatever be the number of points applied to the prime conductor, or whatever may be the distance of the balls of the dischargers; and, in order to excite the machine, it is not necessary that the balls should be in contact. We cannot, without woodcuts, give more details from this paper.

The greater part of the remaining papers of this number treat on matters of engineering, or are reproductions from papers found in European periodicals, among which the Chemical News occupies a prominent place.

Moniteur Scientifique, No. 300, June 15, 1869.

The greater part of this periodical is occupied with translations of papers taken from English and German periodicals already noticed by us. Among the original papers relating to natural sciences, excluding physiology, medicine, and natural history, we meet with a paper—

On the Rotatory Equivalent of Cane Sugar and Rock Crystal in their bearing upon Optical Saccharimetry.—M. Dubrunfaut.—The author states that the figure, 16·471 grms., which in the year 1850 was adopted as the correct unit for optico-saccharimetrical experiments, is wrong, and has been afterwards altered to 16·350 grms.; he next adduces, as proof of the necessity of a revision, also, of that last figure, some experiments of his, recently made with samples of sugar kept as standards at the French Ministry of Commerce. The author further alludes to the impurities of refined sugar as the cause of these errors, and finally states that, when a really well-made optical saccharimeter is used, and pure sugar, the figure 15·976 grms. represents truly the absolute rotatory equivalent of rock crystal as well as of pure cane sugar. The author quotes the results of an analysis of refined sugar, purified by him, by means of pure absolute alcohol, as follows, in 100 parts:—Ash, 0·00039; water, 0·00030; glucose, 0·00018; and traces of lactic acid. It appears, however, that M. Dubrunfaut is entirely unacquainted with the extensive series of experiments made on this subject in the Netherlands by Profs. G. J. Mulder, P. Harting, and F. C. Donders, and at Breslau by Dr. Duflos and M. Schloesser.

Among the subjects of *brevets d'invention*, we notice—

A Process of Preserving the Yolk of Eggs, patented by M. D'Andiran-Kœchlin, consisting in adding to the previously-broken-up yolks of eggs (the white being entirely separated and applied for the purposes of calico-printing), after having been dried, from 3 to 5 per cent of common salt, and one part per 1000 of arsenious acid. This yolk is not intended for food, but for the glove and wash-leather making factories; it is kept in air-tight vessels, filled without leaving any air whatever inside, and a couple of drops of pure carbolic acid are added to every litre of this homogeneous fluid.

To three gentlemen, has been granted a *brevet* for—

The Extraction of Benzine and its Homologues from Illuminating Gas obtained from Coals.—The precise process is not described; but, although it is certainly true that illuminating gas contains, by weight, ten times as large a quantity of benzine as does the coal-tar obtained at the same time, it is equally true that this benzine cannot be withdrawn from gas intended to serve the purposes of yielding good artificial light without greatly injuring its qualities in that aspect.

Improved Mode of Manufacturing Glucose from Starch.—M. Maubré.—The author states that, by the usual mode of proceeding, a portion of the starch is always left in the state of dextrine; he therefore operates under pressure and a higher temperature. For this purpose, he applies a strong cylindrically-shaped iron vessel, internally lined with lead; this boiler is charged with 28 kilos. of sulphuric acid, at 60° Beaumé, and 2800 litres of water, and this liquid is brought to the boiling point by means of high pressure steam. When boiling, there is gradually run into this fluid a mixture of 1180 kilos. of starch and 2500 litres of water, acidulated with 28 kilos. of sulphuric acid. When the whole of this quantity has been introduced into the aforesaid boiler, it is closed, and the temperature within it raised to 160°, by means of high pressure steam introduced into the boiler by leaden and perforated pipes. After about four hours, the action is complete, the fluid run off into tubs, and the acid saturated by means of 84 kilos. of finely-powdered good limestone. After separation of the sulphate of lime, the fluid is evaporated to 20° B., clarified with animal charcoal, and next evaporated in vacuum pans, yielding an excellent and beautiful glucose.

No. 301, July 1, 1869.

The only original paper contained in this number, is on the—

Platinising of Looking-Glasses.—M. Jouglet.—This paper, a very verbose and lengthy dissertation on a comparatively-speaking very trivial subject, appears to have been written with the view to bring forward a peculiar kind of manufacturing process, which, if it is attended with any improvement at all, will receive, no doubt, full justice at the hands of the public, who may be trusted to distinguish whether the covering the back of plate-glass with a thin layer of platinum is an advantage over the silvering, or amalgamating, generally applied for this purpose. The process itself does not seem to contain any novelty, and is described in this paper in a tediously-puffing style.

Cosmos, July 3, 1869.

New Dye from Madder.—Prof. Rochleder, at Prague, has found that, when madder is treated with dilute mineral acids, it yields, beside alizarine and purpurine, a small quantity of a third tinctorial substance, which, in alkaline solution, has a great similarity to chrysophanic acid dissolved in alkaline solution; acids precipitate it from this solution in the amorphous flocculent shape, the precipitate being of a pale yellow colour. This substance is soluble in alcohol and in acetic acid, and crystallises from these solutions, on the evaporation of the solvent, yielding orange-yellow coloured crystals; its aqueous solution mixed with acetic acid, and brought to boiling point, imparts to silk and wool immersed in that bath a beautiful and durable golden-yellow colour.

July 10, 1869.

This paper contains, as usual, a variety of information. The only note suitable for our readers is—

On the Seat of the Hygroscopic Properties of Silk.—M. Suida.—It is a well-known fact that crude silk is very hygroscopic; and some doubt has existed as to whether the exterior gum-like varnish of the raw silk, or the interior fibroine, was the chief seat of this great avidity for moisture. The author has taken a certain quantity of one and the same kind of silk (the avidity for moisture is by no means the same for all silks the produce even of one and the same country, and therefore it was necessary to operate upon one sample of known and the same origin), a portion of which had been deprived of its natural gum, while another portion was in its native state. The result of very carefully-instituted experiments is, that the fibroine—that is to say, the essential fibre of the silk itself, and not its tegumentary parts, gum chiefly, are the seat of the hygroscopic properties of raw non-dyed silk; the process of dyeing materially altering the fibre, also affects its hygroscopic properties. In 100 parts of silk, according to Mulder's analysis, the only extant, this substance consists of:—Fibroine, 53·37; gelatine, 20·66; albumen, 24·43; wax, 1·39; yellow colouring matter, 0·05; resinous and fatty matters, 0·10; this analysis refers to yellow (naturally coloured) silk from Naples. White native silk from the Levant was composed, in 100 parts, of—Fibroine, 54·04; gelatine, 19·08; albumen, 25·47; wax, 1·11; resinous and fatty matters, 0·30.

Bulletin de la Société Chimique de Paris, June, 1869.

From the *procès verbal* of the meeting of this society, held on the 16th of April last, we quote the following:—

M. Lefranc, a pharmaceutical chemist of the French army, presented to the Society a printed pamphlet—

On Atractylic Acid and Atractylates.—This acid is a naturally-existing compound sulpho-acid, met with in the *Atractylis gummifera* as a potassa salt; it is split up, by the action of acids, into sulphuric and valerianic acids, glucose, and a resin.

M. Tollens stated at the meeting that the well-known reaction of hypochlorite of lime and aniline is interfered with by the presence of ammonia, or any salt thereof, and that then the reaction only takes place when a large excess of chloride of lime is applied.

The following original papers are published in this number:—

Action of the Electric Spark upon Marsh Gas.

Direct Union of Free Nitrogen and Acetylene, and the Direct Formation of Hydrocyanic Acid.

Both these papers having been read by the author, M. Berthelot, also at meetings of the Academie des Sciences, have been already noticed by us; this remark equally applies to the next paper, by the same author—

Formation and Decomposition of Sulphide of Carbon.

Chemical Equilibrium, and the Influence of Pressure as Affecting the Action of Carbon and Hydrogen upon each other.—M. Berthelot.—The chief result arrived at by the author is that, when the pressure varies continuously, the equilibrium between carbon

and hydrogen changes by sudden shocks, thereby following rapports which are the multiples of the one and the other.

Essence of Sassafras.—Messers. Grimaux and Ruotte.—The essential oil of sassafras, obtained from the *Laurus sassafras*, is, when recently rectified, a colourless fluid, which, at 0° C. (32° F.), has a specific gravity of 1·0815. The oil is a mixture of a hydrocarbon and an inactive oxygen-containing principle; this latter consists, in 100 parts, of—Carbon, 74·43; hydrogen, 6·46; oxygen, 19·11. It is present in the natural oil in so small quantity that only just sufficient for a good elementary organic analysis was obtained. The hydrocarbon (safren) contains $C_{10}H_6$, and consists, in 100 parts, of—C, 88·23; H, 11·77. Its vapour density has been found equal to 4·84. Safren boils at about 156°. The oil further contains safrol, $C_{10}H_{10}O_2$, boiling at between 231° and 233°. Safrol is insoluble in water. Its specific gravity is 1·1141 at 0°; at −20° it is not frozen. The authors have studied the action of bromine, of hydriodic acid, of perchloride of phosphorus, and nitric acid upon safrol, but state that none of these reactions gave such results as they expected. With bromine, safrol yields a compound of the formula $C_{10}H_8Br_8O_2$.

Presence in the Air of Active Oxygen, or Ozone.—M. Houzeau.—The author demonstrates, at great length, in this paper that the air of the country is of a different character from that of towns; that the former is strongly disinfectant, has far greater bleaching power, and, especially after rainfall, affects bright and oxidisable metals far more than is the case in towns. This paper is not intended as a fully-demonstrative memoir, but in it the author calls attention to some facts readily observed, as, for instance, the rapid bleaching of all kinds of woven fabrics, be they made of linen, cotton, or woollen fibre; the rapid fading of very many dyed tissues; the far more active rusting of iron, steel, and even copper, in the country as compared with large towns. Curiously enough, the author does not mention the well-known fact of the effects of the air at sea, even at comparatively short distances from the shore, nor, also, the peculiar effects produced by the mountain air at no greater height than from 2000 to 6000 feet above sea-level.

Bromide and Iodide of Propionyl.—M. Sestini.—The specific gravity of the bromide of propionyl is, at 14°, equal to 1·465; its boiling point is about 97°; water decomposes it; formula, C_3H_5OBr. The iodide of propionyl boils at 127°: its specific gravity is far greater than that of water, in contact with which it is decomposed instantaneously; formula, C_3H_5OI.

Soluble Albumen which is not Coagulated by Heat.—Dr. Monnier.—We have already noticed this communication, but have to rectify the name of the author's place of residence, which is not *Lyons*, but *Nyon* (a town in the Département de Drôme); the *Deutsche Industrie Zeitung*, from which our abstract was made, had printed *Lyons*.

Use of Phosphate of Soda for Removing Manganese out of Solutions wherein Zinc has to be Estimated Volumetrically.—M. Renard.—The author states that he dissolved 1 grm. of zinc in hydrochloric acid, added thereto 0·6 grm. of chloride of manganese; next ammonia was added, and after that phosphate of soda; the result of his volumetrical estimation of zinc in this solution came to 0·998 grm. of zinc. When the addition of phosphate of soda to a solution of precisely the same composition as the one alluded to was omitted, the quantity of zinc was found to amount to 1·036 grm. The ferrocyanide of potassium process was used in these experiments.

The remaining pages of this periodical are filled with abstracts and translations from English, German, and American periodicals, and with abstracts from the *Comptes Rendus*. The large majority of these are taken from works published during the course of last year; most of them have been already noticed by us.

Journal für Praktische Chemie, No. 6, 1869.

This periodical opens with a very lengthy and exhaustive essay on the

Affinity between Solution of Acetate of Iron without Change of State of Aggregation.—Prof. A. Müller.—This memoir is subdivided into several chapters, and has a series of tabulated forms added: it is not well suited for abstraction.

Chemical Researches of the Eozoon Stone of Raspenau, in Bohemia.—Dr. R. Hofmann.—The stone here alluded to appears to be a serpentinoid mineral, embodied in a kind of dolomite, of which the composition, in 100 parts, is as follows:—Carbonate of lime, 58·815; carbonate of magnesia, 40·20; peroxide of iron, 4·291; insoluble in HCl, 1·261; water, 0·083; traces only of phosphoric acid. The shell of the eozoon stone consists, in 100 parts, of—Carbonate of lime, 97·711; carbonate of protoxide of iron, 1·660; carbonate of magnesia, a trace; alumina, 0·629; minute traces of phosphoric acid. The central portion of the inner part of the eozoon stone has a specific gravity of 2·687, and consists, in 100 parts, of—Water, 7·092; silica, 36·425; alumina, 32·944; protoxide of iron, 20·140; lime, 0·678; potassa, 2·721.

Dolomitic Limestone of Cheynov, near Tábor, in Bohemia.—Dr. R. Hofmann.—This limestone is deposited among and embedded in gneiss; it varies in composition as well as in specific gravity, the latter having been found as low as 2·711, and as high as 2·861; its extremes of composition, in 100 parts, are as follows:—Carbonate of lime, 98·418, and 57·809; carbonate of magnesia, 0·009, and 39·186; protoxide of iron, 0·346, and 0·628; peroxide of iron and alumina, none in either sample; insoluble in hydrochloric acid, 1·167, and 2·377.

Composition of Hauyn.—Prof. A. Kenngott.—This is a purely mineralogical paper.

Basic Salts of Zinc and Copper.—M. Franz Reindel.—The author says that, when a boiling solution of sulphate of zinc containing an excess of that salt is treated either with a solution of caustic or carbonated alkalies, precipitates are formed which, both in consequence of their composition and of their peculiar behaviour towards reagents, deserve the attention of chemists. It has often been stated that pure $CuOCO_2$ may be obtained by decomposing 1 equivalent of $CuOSO_3$ with 1 equivalent of $NaOCO_2$. The author has digested the mixture obtained as result of this reaction for one month with a concentrated solution of soda in the cold, and has not been able thus to obtain, even after very careful washing out, a product entirely free from sulphuric acid. The basic sulphate of zinc obtained by boiling a solution of sulphate of zinc in excess with ammonia constitutes a white powder, which, on being washed with water, is steadily but very slowly decomposed; the fluid running off from the filter has an acid reaction, and contains sulphuric acid as well as oxide of zinc. The author gives, in this lengthy and still unfinished paper, several analyses of basic salts, obtained under a variety of conditions, and dried at temperatures varying from 110° to 260°, whereby the quantity of water of these salts is reduced, but not eliminated, for some of these salts lose water up to a red heat.

Influence of Water upon some Siliceous Minerals.—M. A. Cossa.—The minerals submitted to experiment were two kinds of gneiss, ayenite, several kinds of trachyte, granite, and basalt. They were reduced to powder, and left for ten days in contact with twenty-five times their bulk of pure water, at a temperature of from 17° to 18°; the filtrates were evaporated to dryness, and, after having been moistened with hydrochloric acid, again evaporated, and the dry residue weighed as chlorides. The weight of these residues varied from 0·0567 per cent to 0·35 per cent of matter dissolved.

Annales de Chimie et de Physique, April, May, and June, 1869.

We do not separately notice each of them, for the reason that the last essay which concludes the number for May is continued through that of June, but not yet concluded.

The April number of this periodical opens with a portion of M. Friedel's essay on the Acetons and Aldehydes, which is concluded. Next we meet with a biographical notice of M. Sadi Carnot, by Le Comte Paul de Saint Robert. Next follows—

Researches on Resins.—M. Sacc.—The author observes that resins have been very little studied at all; and his researches recorded in this paper extend to copal, amber, dammar, colophony, lac (or shellac), elemi, sandarac, mastic, and carnauba wax (a resin). The author has studied the more or less degree of readiness wherewith resins are reduced to powder, the action thereupon of boiling water, of alcohol of 86 per cent strength, of ether, of ordinary acetic acid, of a hot solution of caustic soda of 1·074 specific gravity, of sulphide of carbon, of oil of turpentine, of boiled linseed oil, of benzine, of naphtha, of sulphuric acid of 1·83 specific gravity, of nitric acid of 1·329 specific gravity, and of caustic ammonia. All resins were applied in powdered state; and the solvents three times as large a bulk as that of the resins have acted for at least twenty-four hours, at temperatures varying between 15° and 22°. The general results arrived at are briefly as follows:—All resins submitted to experiments fuse quietly when heated, excepting amber, shellac, elemi, sandarac, and mastic, which swell up, and increase in bulk. Only the carnauba wax melts in boiling water; colophony becomes pasty therein, while dammar, shellac, elemi, and mastic agglutinate. Copal, amber, and sandarac do not change. Alcohol does not dissolve amber nor dammar; agglutinates copal, partly dissolves elemi and carnauba wax; while colophony, shellac, sandarac, and mastic are readily soluble therein. Ether does not dissolve amber and shellac; makes copal swell, and partly but slowly dissolves carnauba wax; dammar, colophony, elemi, sandarac, and mastic are readily dissolved therein. Acetic acid does not dissolve amber and shellac; causes copal to swell; somewhat acts upon carnauba wax, and does not at all act upon any other of the resins above named. Caustic soda solution readily dissolves shellac, difficultly colophony, and has no action upon the rest. In sulphide of carbon, amber and shellac are insoluble: copal swells therein; elemi, sandarac, mastic, and carnauba wax are difficultly dissolved therein, while dammar and colophony are readily so. Oil of turpentine has no action upon amber or shellac; causes copal to swell up; dissolves readily dammar, colophony, elemi, sandarac, carnauba, and very readily mastic. Sulphuric acid does not dissolve carnauba wax; all other resins are dissolved and coloured brown, excepting dammar, which becomes bright red. Nitric acid does not act upon the resins, but colours carnauba wax straw-yellow, elemi a dirty yellow, and mastic and sandarac bright brown. Ammonia does not dissolve some of these resins, but causes copal, sandarac, and mastic first to swell, afterwards dissolving them; colophony is easily soluble therein.

Researches on the Composition and Structure of Meteorites.—M. S. Meunier.—A very interesting and elaborate essay on this subject, but too long for proper abstraction.

On a Pump provided with a Free Plunger (*pompe à piston libre*).—M. le Marquis de Montrichard.—A physico-mechanical paper.

Pyro-Electric Properties of Crystals which are Good Conductors of Electricity.—M. C. Friedel.—The abstraction of this paper, without the re-production of the large number of woodcuts essentially belonging thereto, would be useless.

Nitriles of the Fatty Acids.—M. A. Gautier.

Neues Jahrbuch für Pharmacie, von Dr. F. Vorwerk, April, 1869.

We notice the following original papers:—

On Cytisin, an Alkaloid of the Genus Cytisus.—Dr. A. Husemann.—The seed, bark, and root of the well-known laburnum tree (originally from Switzerland, but now dispersed throughout Europe), *Cytisus laburnum*, L., contains, it appears, an alkaloid, which has been isolated by the author, and is described by him as a white crystalline solid substance, of bitter and somewhat caustic taste, soluble in water and alcohol, and hardly soluble at all in ether, chloroform, benzol, and sulphide of carbon. Cytisin is a strong basic substance, precipitating many metallic combinations from their solutions, and setting free ammonia from its compounds. Its composition, in 100 parts, is:—C, 73·84; H, 8·30; N, 12·92; O, 4·94; formula, $C_{20}H_{27}N_3O$. The nitrate of cytisin is a readily-crystallisable salt.

The other original paper is one belonging strictly to botany. Among the miscellaneous papers met with in this periodical, we meet with a communication—

On the Varieties of Tapioca and Sago Prepared in the Malaccas.—It appears that, at the request of the resident Governor of the Malacca Islands, researches have been instituted concerning this food, at the Laboratory, at Welte Vreden, Java. The authors of this paper, MM. Maier, Moens, and Scharlec, found that three varieties of sago, denominated white, red, and blue, contain, respectively—water, 16·14, 18·83, and 18·47 per cent; protein compounds, respectively—3·7, 2·5, and 2·4 per cent; starch, fat, &c., respectively—79·88, 78·06, and 78·15 per cent; ash, respectively—0·22, 0·62, and 0·94 per cent.

The remainder of the miscellaneous in this number are of no special interest to our readers.

Bibliothèque Universelle et Revue Suisse.—Archives des Sciences Physiques et Naturelles, No. 137, May 15, 1869.

The original papers of this number of this periodical are confined to—

A Note on the Aurora Borealis of the 15th of April, 1869.

On Berberis Vulgaris.—M. Schnetzler.

Experimental and Theoretical Researches on the Equilibrium Figures of a Liquid Mass not Possessed of any Weight.—M. Plateau.

No. 138, June 15, 1869.

This periodical contains an astronomical paper, unsuitable for abstraction here, and no other original papers: being filled with translations of memoirs taken from *Poggendorff's Annalen*, and other periodicals of that description, the papers having been alluded to and quoted by us already.

Chemisches Centralblatt, No. 20, May 19, 1869.

This number does not contain any original papers or communications.

Bayerisches Industrie und Gewerbeblatt, March and April, 1869.

The greater part of this double number is filled with "Dasr Berggesitz für das Königreich Bayern"—that is to say, a very lucidly and perfectly-made law (act of parliament) for the regulation of everything connected with mining, quarrying, and the extraction, from the earth, of minerals, including coal, limestone, and also building materials, &c., for the kingdom of Bavaria.

Boring of Wells, and the Water Supply to Large Towns.—M. Kieser.—This is a rather lengthy, but highly interesting, essay, on a subject of very great importance.

Experiments on the Bleaching of Wood Pulp for Paper Manufacture.—Dr. C. Winkler.—Neither chlorine, bromine, nor any substances the activity of which is due to oxidation, were found by the author to answer the purpose, the result always being the production of a decidedly yellow, and sometimes even brown, tinge. Sulphurous acid does not completely answer the purpose; the destruction of the natural colouring matters by means of fermentation did not lead, also, to any good result.

Effect of Temperature of the Air upon the Illuminating Power of Burning Coal Gas.—M. A. Vogel.—From this lengthy essay we only notice that, when the illuminating power of ordinarily good coal gas is equal to 100 at 18°, it is only 76 at 0° and 33 at −20°.

May, 1869.

This number chiefly contains officially-published matter, among which are very minute directions for the assay of gold and silver articles of *bijouterie* and the use of proof or touch needles in testing the quality of pure gold and silver contained in articles presented for assay to the parties appointed for this purpose; all such assayers have to pass a very strict examination in general and practical chemistry, and especially in the assay of gold and silver by the dry, and also the wet process, as far as the latter metal is concerned. The touch-needles alluded to are made at the Munich mint, uniformly for the seven assay districts into which the kingdom of Bavaria is divided. This number does not contain any original papers relating to chemistry, or sciences closely related thereto.

NOTES AND QUERIES.

Isinglass.—Can any of your correspondents inform me of any method of obtaining isinglass, by mixture or otherwise, in the form of a powder.—ICTHYOC.

Crystallisation of Supersaturated Solutions.—Will any of your courteous readers kindly furnish an enquirer, who is greatly interested in the subject, with a list of the bodies which are found to act as nuclei in determining the crystallisation of supersaturated solutions?—R. C. C.

Water Analysis.—I have just finished examining a spring well in the country, and found on evaporating one imperial gallon of the water to perfect dryness, the residue weighed 102 grains, and afterwards ignited and lost by ignition 40 grains. Besides, I found there exists 10 grains N_2O_5 in one gallon. Now I should like to know if it is the rule to deduct the whole, or only a part of this nitric acid, from the loss by ignition when drawing up a report, or how should I act?—J. WALLACE.

PATENTS.

Communicated by Mr. VAUGHAN, F.C.S., Patent Agent, 54, Chancery Lane, W.C.

THE CHEMICAL NEWS.

VOL. XX. No. 504.

RESEARCHES ON VANADIUM.*

By HENRY E. ROSCOE, B.A., Ph.D., F.R.S.

PART II.

On the Chlorides of Vanadium and Metallic Vanadium.

IN the first part of these researches ("Bakerian Lecture," *Phil. Trans.*, 1868, pt. i.) the author stated that the chlorides of vanadium, and probably also the metal itself, could be prepared from the mononitride, the only compound of vanadium not containing oxygen then known. The process for obtaining the mononitride described in the last communication was that adopted by Berzelius for preparing the substance which he conceived to be metal, but which, in reality, is mononitride. This method consists in the action of ammonia on the oxitic chloride; but it cannot be employed for the preparation of large quantities of nitride, owing to the violence of the action and consequent loss of material. The author, seeking for a more economical method, found that if the ammonium metavanadate (NH_4VO_3) be heated for a sufficiently long time at a white heat in a current of dry ammonia, pure vanadium mononitride remains behind. Analysis of a sample thus prepared gave 79·6 per cent of vanadium and 20·2 per cent of nitrogen, theory requiring 78·6 and 21·4 per cent respectively. The mononitride may likewise be directly prepared by igniting vanadium trioxide (V_2O_3) in a current of ammonia at a white heat in a platinum tube, and also by subjecting the dichloride to the same treatment.

The Chlorides of Vanadium.—Three chlorides of vanadium have been prepared, viz.:—

Vanadium tetrachloride ..	VCl_4
Vanadium trichloride ..	VCl_3
Vanadium dichloride.. ..	VCl_2

1. *Vanadium Tetrachloride*, VCl_4, molec. wt. = 193·3, V.D. = 96·6 (H = 1).—This chloride is formed as a dark reddish brown volatile liquid, when metallic vanadium or the mononitride is burnt in excess of chlorine. The first method adopted for the preparation of this chloride was to pass dry chlorine over the mononitride heated to redness; the whole of the nitride volatilises and a reddish brown liquid comes over. In one operation 44 grains of the crude tetrachloride was thus prepared; the liquid is purified by distillation, first in a current of chlorine and then in a stream of carbonic acid gas. On fractionating, the liquid was found to boil at 154° C. (corrected) under 760 m.m. of mercury. The second method depends upon a fact already noticed in the preceding communication, that the oxitrichloride ($VOCl_3$), prepared, according to the directions of Berzelius, by passing dry chlorine over a mixture of the trioxide and charcoal, possesses a port-wine colour instead of the canary-yellow tint of the pure substance. This dark colour is due to the formation of the tetrachloride of vanadium, and if the vapours of the oxytrichloride, together with excess of dry chlorine, be passed several times over a column of red-hot charcoal the whole of the oxygen of the oxychloride can be removed, and at last perfectly pure tetrachloride, boiling constantly at 154°, is obtained. This reaction, it will be remembered, served first to demonstrate the existence of oxygen in the oxytrichloride. In each distillation of the tetrachloride a peach-blossom coloured solid residue remained in the bulbs; this substance is vanadium trichloride, and it slowly burns away in excess of chlorine when heated, forming tetrachloride.

The composition of the tetrachloride was established by six well-agreeing analyses, made from several different preparations. The mean result is:—

	Calculated.	Found.
V = 51·3 ..	26·54 ..	26·87
Cl_4 = 142·0 ..	73·46 ..	73·02
193·3	100·00	99·89

Owing to the facility with which the tetrachloride splits up into trichloride and chlorine, a solid residue was left in the vapour-density bulb, and the density of the vapour (at 219°) was found by Dumas's method to be 99·06 (or 6·86) instead of 96·6 (or 6·69). By volatilising the liquid in a small bulb, and allowing the vapours to pass into a large bulb already heated above the boiling-point of the liquid, this deposition of trichloride was avoided, and the density was found to be 96·6 or 6·69 at 205°, and 93·3 or 6·48 at 215°, the last determination indicating that a partial decomposition into VCl_3 and Cl had occurred. The specific gravity of the liquid tetrachloride at 0° is 1·8584; it does not solidify at −18°, nor does it at this or any higher temperature undergo change of properties on treatment with chloride. It not only undergoes decomposition on boiling, but at the ordinary atmospheric temperatures it splits up into VCl_3 and Cl. Tubes in which the liquid chloride had been sealed up have burst by the pressure of the evolved chlorine. Thrown into water, the tetrachloride is at once decomposed, yielding a blue solution identical in colour with the liquid obtained by the action of sulphurous or sulphydric acids on vanadic acid in solution, and containing a vanadous salt, derived from the tetroxide V_2O_4. In order to prove that a vanadous salt is formed when the tetrachloride is thrown into water, the solution thus obtained was oxidised to vanadic acid by a standard permanganate solution. The calculated percentage of oxygen thus needed, according to the formula

$$2VCl_4 + O + 4H_2O = V_2O_5 + 8HCl$$

is 4·14; the percentage of oxygen found by experiment was 4·11.

The solution of the tetrachloride in water does not bleach; but if the vapour be led into water a liquid is obtained which bleaches litmus. Vanadium tetrachloride acts violently on dry alcohol and ether, forming deep-coloured liquids. The author is engaged upon the examination of this reaction.

Bromine and vanadium tetrachloride, sealed up and heated together, do not combine; on the contrary, trichloride is deposited. Hence it is clear that vanadium does not readily form a pentad compound with the chlorous elements.

2. *Vanadium Trichloride*, $VCl_3 = 157·8$.—The trichloride is a solid body, crystallising in splendid peach-blossom coloured shining tables, closely resembling in appearance the crystals of chromium sesquichloride. It is non-volatile in hydrogen, and, when heated in the air, it decomposes, glowing with absorption of oxygen, and forming the pent-oxide. Heated in hydrogen, the trichloride first loses one atom of chlorine, forming the dichloride (VCl_2), and afterwards, on exposure to a higher temperature, loses all its chlorine, leaving metallic vanadium as a grey lustrous powder. The trichloride is extremely hygroscopic, deliquescing on exposure to air to a brown liquid. The trichloride is best prepared by the quick decomposition of the tetrachloride at its boiling point, or by its slow decomposition at the ordinary temperature of the air. The crystalline powder obtained by either of these methods only requires freeing from adhering tetrachloride, by drying in carbon dioxide at 160°, in order to yield good analytical results.

* Abstract of a paper read before the Royal Society, June 17, 1869.

		Calculated.	Mean of 4 analyses.
V	= 51·3	.. 32·5	.. 32·57
Cl_3	= 106·5	.. 67·5	.. 67·42
	157·8	100·0	99·99

The trichloride thrown into water does not at once dissolve; but, as soon as the crystals get moistened, a brown solution is formed, which becomes green on addition of a drop of hydrochloric acid, and contains a hypovanadic salt in solution. This green tint is identical with that got by reducing a solution of vanadic acid in presence of magnesium. According to the equation—

$$2VCl_3 + O_2 + 3H_2O = V_2O_5 + 6HCl$$

the solution of the trichloride requires 10·14 per cent of oxygen to bring it up to vanadic acid, whilst analysis showed that 10·1 per cent was necessary. The specific gravity of the trichloride at 18° is 3·00.

3. *Vanadium Dichloride*, VCl_2 122·3.—The dichloride is a solid, crystallising in fine bright apple-green micacious plates. It is prepared by passing the vapour of vanadium tetrachloride mixed with hydrogen through a glass tube heated to dull redness. If the heat be pushed further, a blackish crystalline powder, consisting of a mixture of lower chloride and metal, is obtained. The dichloride, when strongly heated in hydrogen, loses all its chlorine, leaving vanadium in the metallic state in grey crystalline grains. Analysis gave:—

		Calculated.	Mean of 2 analyses.
V	= 51·3	.. 41·95	.. 42·16
Cl_2	= 71·0	.. 58·05	.. 57·88
	122·3	100·00	100·00

Vanadium dichloride is extremely hygroscopic; when thrown into water, a violet-coloured solution is formed, identical in tint with the liquid containing a hypovanadous salt obtained by reducing vanadic acid in solution in presence of zinc- or sodium-amalgam; and like this latter liquid, the solution of dichloride in water bleaches strongly by reduction.

Oxidised by permanganate, this liquid required 18·78 per cent oxygen (on the dichloride taken) to bring it up to vanadic acid, whereas the equation—

$$2VCl_2 + O_3 + 2H_2O = V_2O_5 + 4HCl$$

requires 19·6 per cent. The specific gravity of vanadium dichloride at 18° is 3·23.

Metallic Vanadium, V 51·3.—Although from what we know of the characters of vanadium, it appeared unlikely that any compound containing oxygen would yield the metal by direct reduction, the author has repeated the experiments of other chemists on this subject, but without success. There is no doubt that the metal cannot be obtained by any of the processes described in the books. The only methods which promised possible results were:—

1. The reduction of a vanadium chloride (free from oxygen) in hydrogen gas, either with or without sodium.
2. The reduction of the mononitride at a white heat in hydrogen.

The first of these methods has proved to be successful, whilst the second does not appear to yield metal, inasmuch as the nitride exposed for 3½ hours in a platinum tube to the action of hydrogen at a white heat, lost only 8 per cent, whereas it must lose 21·4 per cent on conversion into metal.

Notwithstanding the apparent simplicity of the method, the author has found it exceedingly difficult to obtain the metal perfectly free from oxygen. This arises from the fact that, whilst vanadium is quite stable at the ordinary temperature, it absorbs oxygen with the greatest avidity at a red heat, and that, therefore, every trace of air and moisture must be excluded during the reduction. Another difficulty consists in the preparation of the solid chlorides in large quantity and free from oxygen or moisture, as also in the length of time needed to reduce these chlorides in hydrogen, during which time unavoidable diffusion occurs, and traces of oxygen enter the tube. Again, the reduction can only be effected in platinum boats placed in a porcelain tube, as the metal acts violently on glass and porcelain, and tubes of platinum are porous at a red heat.

A description of the apparatus employed is then given, the main points being to guard against diffusion, and to introduce the powdered dichloride into the platinum boat in such a way that it shall not for an instant be exposed to moist air. After all precautions are taken, the tube is heated to redness, torrents of hydrochloric acid come off, and the evolution of this gas continues for from 40 to 80 hours, according to the quantity of dichloride taken. After every trace of hydrochloric acid has ceased to be perceptible, the tube is allowed to cool, and the boat is found to contain a light whitish grey-coloured powder, perfectly free from chlorine.

Metallic vanadium thus prepared, examined under the microscope, reflects light powerfully, and is seen to consist of brilliant shining crystalline metallic mass, possessing a bright silver-white lustre. Vanadium does not oxidise or even tarnish in the air at the ordinary temperature; nor does it absorb oxygen when heated in the air to 100°. It does not decompose water even at 100°, and may be moistened with water, and dried *in vacuo*, or at 100°, without gaining weight. The metal is not fusible or volatile at a bright red heat in hydrogen; the powdered metal thrown into a flame, burns with the most brilliant scintillations. Heated quickly in oxygen, it burns vividly, forming the pentoxide; but slowly ignited in air, it first glows to form a brown oxide (possibly V_2O), and then again absorbs oxygen, and glows with formation of the black trioxide and blue tetroxide, till it at last attains its maximum degree of oxidation. The specific gravity of metallic vanadium at 15° is 5·5. It is not soluble in either hot or cold hydrochloric acid; strong sulphuric acid dissolves it on heating, giving a yellow solution; hydrofluoric acid dissolves it slowly with evolution of hydrogen; nitric acid of all strengths acts violently on the metal, evolving red nitrous fumes, and yielding a blue solution: fused with sodium hydroxide, the metal dissolves with evolution of hydrogen, a vanadate being formed.

One sample yielded on oxidation a percentage increase of 77·94, whereas that calculated from metal to pentoxide is 77·98. Another preparation gave a percentage increase of 70·8, showing the presence of a small quantity of oxide. On treatment in a current of chlorine, metallic vanadium burns and forms the reddish black tetrachloride; heated in a current of pure nitrogen, the mononitride is formed.

The properties of the compounds of vanadium with silicon and platinum are then described in the memoir.

ON

COLOPHONINE AND COLOPHONIC HYDRATE,

NEW SUBSTANCES PROCURED FROM THE PRODUCTS OF THE DESTRUCTIVE DISTILLATION OF RESIN.*

By CHARLES R. C. TICHBORNE, M.R.I.A., F.C.S., &c.

When we submit to distillation (either with or without water) the natural exudations of the different pines, the first result is the extraction of volatile hydrocarbons, or oils of turpentine. These oils were, until very lately, considered as identical, but recent investigations have proved that there is a considerable disparity in the products from different species of the pines. If, after the extraction of the volatile oils, the distillation is pushed further, we get a second series of volatile compounds, which, however, differ materially from the first, inasmuch as they are de-

* Communicated by the author. Read before the Royal Irish Academy.

composition products, resulting from the splitting up of the colophony, or resinous part, into more simple molecules of different isomeric modifications.

All the resin oils obtained by myself gave the result I am now about to detail. I, however, believe that the discrepancies exhibited by the turpentines are perpetuated through the products obtainable upon the destructive distillation of the resins proper to such turpentines.

My attention was first directed to the substance which I have named colophine from an observation made preparatory to investigating the volatile oils procured on submitting resin to destructive distillation.

I took commercial resin, and, after drying for some time at a slightly elevated temperature, distilled it in an iron retort. I got, by this means, a thick distillate, which contained a considerable quantity of undecomposed resin. Gaseous products escaped which are said to contain ethylene, tetrylene, and marsh gas. The liquid products amounted to about 74 per cent of the resin employed, and a small coke was left in the retort. This thick oil, on rectification, gave about 5 to 6 per cent of a light yellow but mobile fluid, which is known under the names of "resin spirit," "vive essence," "Harzessenz."*

This lighter portion, or "resin spirit," is supposed to consist mainly of the hydrocarbons homologous of the series $C_n H_{2n-4}$ and $C_n H_{2n-6}$, and an oxygenated oil, which has been named colophonone.† It is these light oils that yield colophonic hydrate. They act energetically upon the fluid alloy of potassium and sodium, even when free from the last-named substance; therefore it is probable that colophonone, or other oxygenated oils, form a large ingredient.

It is given as a specific characteristic of colophonone, that, if it is treated with sulphuric or hydrochloric acid, a green oil separates on the addition of water. This is, however, only partially true; for I found that the "resin spirit"‡ procured in the above experiment, or old resin spirit that had been washed, only gave this reaction in a slight degree.

It was, therefore, evident that the colour-phenomenon was due to the presence of some other substance soluble in water, and not to a specific property of the colophonone. On treating old resin spirit with distilled water two or three times, and on evaporating these washings at a low temperature, a brown crystalline mass was procured, which gave the colour-reactions, hitherto attributed to the oil itself, in a most vivid manner. It therefore becomes evident that the whole subject of colophonone requires revision. It was probable that the substance analysed under that name was a mixture.

I subsequently obtained specimens of the new substance in which individual crystals had attained some considerable magnitude.

Some of them were 3 centimetres long, and over 2 grammes in weight. They were of an amber colour, from impurities, and were obtained by submitting a large volume (10 litres) of the spirit, in an imperfectly-closed vessel, to twelve months' slow evaporation and oxidation. I have procured as much as 281 grammes of the crude crystals from 4·5 litres of resin spirit by washing.

The following are the characteristics of this compound, which, when purified, is a truly beautiful substance:—

Colophonic hydrate is white, perfectly odourless, and has a sweetish taste; it is very soluble in water, alcohol, ether, chloroform, and tetrachloride of carbon; not quite so soluble in cold benzole and resin spirit, but slightly soluble in cold bisulphide of carbon.

Colophonic hydrate crystallises readily from water or alcohol, in beautiful acicular prisms, which sometimes attain some magnitude. Heated, it melts and sublimes, with a partial loss of the elements of water. The crystals which first sublime lose water, but nearly resemble those obtained from a solution, both as regards their appearance and composition. Those which afterwards rise or if the first are re-sublimed lose more water and form hexagonal plates, or fern like fronds, of great beauty. It was impossible to accurately measure the large crystals already mentioned, the twelve months immersion having rounded and worn the faces, from the rise and fall of temperature in the medium in which they are formed. They seem to belong to the dimetric system, and are the result of the combination of the two prisms of that system.

The hydrated crystals, when placed over sulphuric acid, or *in vacuo*, gradually lose water, and effloresce; but, as the substance is itself volatile, the loss could not be measured under such circumstances. When placed under a bell-glass over sulphuric acid, the surface of the acid becomes covered with a green film, produced, as will be afterwards explained, by the mutual action of the water, sulphuric acid, and colophonic hydrate. Some difficulty was experienced in procuring the anhydrous compound. From the above results, it was supposed that, on submitting the hydrate to sublimation, the water of hydration would be dissociated. Such, however, was not the case, and a combustion of the sublimed crystals pointed to no formula. The sublimate was, in fact, a mixture of the anhydrous and hydrated compounds.

The first of these substances I obtained in the following manner:—I gently fused, in a test-tube, for some time the crystals obtained from an aqueous solution, occasionally drying out the moisture which condensed at the top of the tube with bibulous paper. The sublimed crystals were repeatedly broken down, and mixed with the fused mass. This process was continued as long as moisture was given off. I retained the crystalline mass for analysis. It seemed to have suffered no decomposition, exclusive of dehydration, and formed a friable and nearly perfectly white substance.

On making a combustion of the above, 0·218 gramme gave 0·505 gramme CO_2, and 0·218 gramme H_2O.

In a second experiment, 0·307 gramme of the fused mass gave 0·7076 gramme of CO_2, and 0·324 gramme of H_2O.

These experiments point to the empirical formula $C_{10}H_{22}O_3$.

	I.	II.	Theory.	
Carbon	63·16	62·86	63·15	120
Hydrogen ..	11·10	11·72	11·58	22
Oxygen			25·27	48
			100·00	190

The crystals obtained from an aqueous solution gave, when burnt, the following results:—0·265 gramme of crystals produced 0·557 gramme of CO_2, and 0·270 gramme of H_2O.

		Theory.	
Carbon	57·35	57·70	120
Hydrogen ..	11·32	11·53	24
Oxygen ..		30·77	64
		100·00	208

Colophonic hydrate .. $C_{10}H_{22}O_3 : H_2O$.
Colophonine .. .. .. $C_{10}H_{20}O_2$.

Colophonine is, therefore, isomeric with terpine hydrate, or is, more properly, a homologue of terpine. It is another instalment towards filling up an interesting series. This compound is probably derived from terebene.

* Mr. J. Turner, a large distiller of resin, has kindly sent me the following notes regarding the statistics of the production of these oils on a manufacturing scale:—

	Percentage.
"Resin spirit" (boiling at 135° C.)	5·0
Heavy oils	64·0
Pitch	14·4
Gaseous products and H_2O	15·7

† Schiel.

‡ I shall use the term "resin spirit" throughout this paper, to designate the light oils got on rectifying resin oils.

Hydrocarbides.	Products formed therefrom by the occult molecule H_2O ("Turpentine Camphors.")	Hydrates.
$C_{10}H_{16}$, $C_{10}H_{16}$. ("Diterebene.")	$C_{10}H_{16}$, $C_{10}H_{16}$; H_2O.* ("Terpinole.")	
$C_{10}H_{16}$. (α) (Turpentine, or "terebenthene.")	$C_{10}H_{16}$; H_2O ("Liq. Turpentine Camphor.")	$C_{10}H_{16}$; H_2O : H_2O. Hypothetical hydrate, supposed transition products.
	$C_{10}H_{16}$; $2H_2O$. ("Terpine.")	$C_{10}H_{16}$; $2H_2O$: H_2O. (Terpine hydrate.)
$C_{10}H_{16}$. (β) ("Terebene.")	$C_{10}H_{16}$; $3H_2O$. (Colophonine.)	$C_{10}H_{16}$; $3H_2O$: H_2O. (Colophonic hydrate.)

In the above table, I have endeavoured to convey, by the punctuation, the accretion of the series, and the different degrees of molecular integration.

It will be observed that each hydrate would be isomeric with the next higher homologue in the camphor series. The hydrates to the first two in the series are wanting, but it is probable that they exist, as the compound called liquid turpentine camphor is, in the presence of water, converted into terpine, the isomer of its hydrate. If we do not suppose that the hydrate is first formed, we could hardly account for the formation of terpine.

Colophonic hydrate was violently acted on by bromine, accompanied by a copious separation of carbon and hydrobromic acid. In water, the action was more manageable, and the ultimate product was a brominated oil, which, after washing, first with a diluted solution of carbonate of sodium and then with water, was dried over sulphuric acid. 0·471 gramme of this oil, after being decomposed in a sealed tube with pure soda, was treated with an excess of nitric acid, and nitrate of silver. It gave 0·766 gramme of bromide of silver, agreeing very nearly with the formula of a tetrabrominated compound.

Professor Jellett, who kindly examined this substance for me as regards its optical properties, finds that it is perfectly inert when in solution, and possesses neither right nor left-handed rotation.†

As previously stated, the light oils from resin when treated with sulphuric acid, and then with water, produce a green substance. This colouration is, however, due to the presence of colophonic hydrate. On treating that compound with acids, a series of striking phenomena is exhibited, conjugated acids being formed, which exhibit a fine display of colours. The generality of these are green. Sulphuric, phosphoric (monobasic and tribasic), arsenious, citric, and tartaric acids give these reactions.

On treating the crystals with an excess of the acid, and then adding spirit, the colour is developed. It is necessary to use heat in most cases. The sulphuric acid reaction is capable of rendering evident a milligramme of the new substance, if properly applied. It is not necessary to use heat in this case. Under certain circumstances, hydrochloric acid is capable of producing this green reaction; but when colophonic hydrate is treated with an excess of strong hydrochloric acid, after the expiration of half-an-hour, a brilliant rose colour is developed on pouring it into alcohol. If the experiment is pushed further, different shades of violets are produced, until the ultimate result of the maceration is a magnificent indigo blue.

Terpine hydrates do not give any of these reactions. The coloured solutions give absorption spectra, represented by the accompanying diagram. The longitudinal lines *A*, *a*, *B*, *C*, &c., represent the position of the solar lines. The thickness of the dark bands represent intensity of absorption, in a similar manner to Bunsen's graphic method used for metal spectra. Fig. 1 is the spectrum seen on viewing an alcoholic solution of the sulphuric compound. Dr. Reynolds, to whom I showed this spectrum, noticed that, when the acid is first mixed, the spectrum shows an absorption between the lines *D* and *E*, β, Fig. 1; this, however, after a little time, begins to fade from its more refrangible end, the centre of the spectrum gradually clearing, until the band is lost, and the spectrum, Fig. 2, obtained, the band *a*, *a'*, being intensified. Hydrochloric acid spectra behave in a somewhat similar manner, the ultimate result, either from age or boiling, being a spectrum similar to Fig. 3, the bands *a*, *a'*, slowly fading. These results would lead to the inference that the normal colour is purple, which is afterwards converted into the green compound.

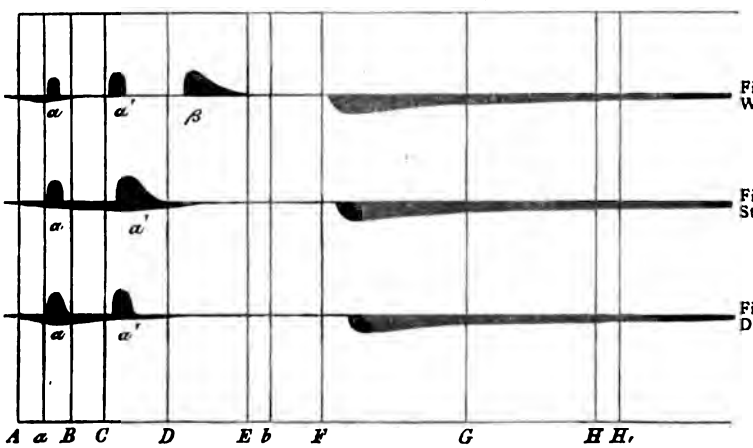

Fig. 1. H_2SO_4, or HCl. When first mixed.

Fig. 2. H_2SO_4. Strong alcoholic solution.

Fig. 3. H_2SO_4. Diluted alcoholic solution.

As regards the origin of colophonic hydrate, it is probably formed under similar circumstances to the terpine camphors, *i.e.*, by oxidation, or the assimilation of the elements of water. I have failed, however, in forming this substance artificially by oxidising the resin spirit with nitric acid.*

It is not present in newly-prepared resin spirit, as I have already explained; and, as my supply of colophonic hydrate was expended, my researches upon this substance were, I am sorry to say, brought to a close. It is, however, my intention to renew them at a future period.

* Formed by the action of dibromhydrate of citrene on acetate of silver—

$$2(C_{10}H_{16}Br_2)+4(C_2H_3AgO_2)-4(AgBr)-2(C_2H_4O_2)-\left.\begin{matrix}C_2H_3O\\C_2H_3O\end{matrix}\right\}O=$$
$$=C_{20}H_{34}O.$$
(Terpinole.)

Vide "Naquet's Principles," p. 396.

† It does not differ in this respect from its congeners the terpine hydrates, and similar products, in which, although the hydrocarbide preserves its integrity, its gyratory power is suspended.

* Mr. Turner forwarded me from England a bottle containing resin spirit, in which he had observed crystals. They proved, on examination, to be colophonic hydrate. The bottle originally contained about 8 ounces, but, from evaporation, only ½ an ounce remained; it consisted of about 25 per cent of colophonic hydrate. It had been exposed to sunlight for about eight years—light, however, is not essential to the formation of this compound.

CONTRIBUTIONS TO OUR KNOWLEDGE OF

NATURAL WATERS USED FOR DRINKING AND OTHER DOMESTIC PURPOSES.

WHATEVER can serve for the purpose just named cannot but be highly acceptable at a time when the question of water supply, purity of water, and the origin therein of substances deemed by some injurious, and indicating its contamination with the products of the decomposition of animal matter, is daily discussed. It is not our intention to enter upon speculative ground, but we will simply place before our readers a few facts, relating to the natural history of various kinds of water investigated by the Royal Committee appointed for the purpose of making a thorough inquiry into all matters relating to potable waters, and those used for domestic purposes, in the kingdom of the Netherlands, which facts, including chemical analysis, microscopic investigation of sediments, engineering, and geological matters, have been embodied in a printed report. We have selected those samples of water which, for their peculiarities in some respect or other, are best fit to bear especially also upon the question *how* and *whence* ammonia and nitrates, as met with in natural waters, are derived.

We have to call attention first to some facts which are, especially in this country, rather overlooked; to wit – (1) that, although the larger portion of the Netherlands territory in Europe is of comparatively very recent geological formation and consists of strata of very great permeability for water, that permeability exists in almost all kinds of geological formations, and, therefore, in all countries, hence the water of rivers, lakes, sea and other water-courses penetrates, to greater or less extent and depth, into the soil and contributes with the water fallen as rain and snow to fill the springs and more or less deep wells.

The second observation relates to an essential difference in the primitive source of the water of the British rivers as compared with, for instance, that of the Rhine; for the sake of illustrating what we mean, we will just briefly quote a few facts and figures, first about the Rhine, and next about the Thames. The Rhine has its sources in that portion of the Swiss Alps called the St. Gothard group, at an elevation above sea level of 9,967 feet; it is fed by the constantly melting ice and snow of the higher peaks of the Alps, and its three main constituent rivulets flow into one at Reichenau, at a height of 2021 feet above sea level; thence to the lake of Constanz or Bodensee the river takes its course over a hard, rocky bed; it traverses the lake just named, which, by-the-by, is exceedingly deep, and contains water of great purity. The direct course of the Rhine has a length of 415 miles, its basin has an area of 65,280 square miles, and its tributaries, large and small, number fully 12,000.

The Thames, although not the largest of British rivers, is, undoubtedly, the most important in many aspects beside commercial; it takes its origin from some rather insignificant brooks and rivulets near Cirencester; at Thames Head Bridge its level is 376 feet above that of the sea; its direct course to the Nore is 124 miles, and the area of its basin is 6,160 square miles. What is, however, of far more importance in this comparison of these rivers for our purpose, is the fact that, throughout its entire course, and especially previous to the point of bifurcation, the waters of the Rhine essentially retain that purity which gave rise to its being named in Switzerland, "*Reiner*" (purity). Dr. Von Planta Reichenau, an eminent Swiss *savant*, and the owner of large estates on and near the sources of the Rhine, has analysed its waters, taken at different seasons of the year and at different places of the course of this river, from Reichenau downwards to Emmerich, and has found that, what is in a very high degree the case with these waters at their primitive source, is retained in a very marked measure over this entire length of the river's course, viz., that the water always contains, dissolved, a large and abundant quantity of oxygen: this, coupled with the fact that the large bulk of the water of this river is not, to any great extent, modified by the water of its tributaries, some of which are large streams also taking their origin in ice and snow, may have some bearing upon the very small quantity of organic matter and the infinitesimal small quantity of ammonia met with in the water of the Rhine.

Sufficient has been said to point out that there exists a primitive and essential difference between the sources of the supply of water of the Thames and Rhine to account for more impurity in the latter, while, moreover, the value of manure of all kinds is too greatly esteemed along the major portion of the course of the Rhine to allow fæcal matters and other refuse and offal to find its way into a river, the police of which, or, rather, *administration de la sureté publique*, about which is under the control, not of one state, but of that of France, Baden, Bavaria, Hesse-Darmstadt, Prussia, and the Netherlands, jointly, whereby proper care is also taken as regards the fouling of the river and the pollution of its waters. Except in the Netherlands, and excepting also the men who, while navigating the Rhine or its tributaries, drink of its waters, that water is not used for drinking purposes by the great bulk of the large population dwelling on the banks of that river, since excellent water of easier access than that of the river is readily to be had. The writer of this article had, last year, while in Germany, an opportunity of obtaining some information about the supply of water, quantity, and quality, in use by the large numbers of soldiers at Coblentz, Cologne, Wiesbaden, and other places; great care has been taken to insure a constantly plentiful supply, and, above all, of good quality, by boring deep wells. Notwithstanding, the river water is excellent to the taste, rather less saline, however, and is certainly better for washing purposes, neither the military nor civil population of the places just named, and others situated along the Rhine, Moselle, Lahn, Maine, &c., ever think of using the water of these rivers, which, in many instances, indeed, they would have to fetch at a comparatively great distance from their dwellings. The writer was also informed that the water obtained from the public pumps, pants, and fountains, was regularly submitted to analysis, and that the authorities took great care to keep wells, and tubing, and all works in proper repair, so as to insure good and wholesome water.

Turning now to our chief subject, we quote, in the first place, the results of analysis, and other particulars of the water of a canal at Zwolle. This canal is so connected with the Züyder Zee and tidal rivers that its level, by the effect of the flood and ebb, varies about 13 inches daily; the water was clear, pale yellow coloured, its taste somewhat similar to rain-water; on standing, it deposited a sediment, which, on being submitted to microscopic research, proved to contain not only minutely divided mineral matter, but also various infusoria, remnants of partially peatised vegetables, and small molluscs.

The result of the chemical analysis in this, as in every following instance, refers to *one* litre of the water, and the quantities are expressed in grammes—Total solid residue, 0·181; organic matter, 0·020; sulphate of lime, 0·0087; carbonate of lime, 0·0008; alkalies, 0·066, consisting chiefly of chlorides without any sulphates; ammonia, 0·00023; nitrates or nitrites, none; colour of dry residue, yellow before ignition, grey after. This water is not liked for drinking or domestic purposes, but occasionally used.

Water from a Pump at Groningen.—The well supplying this water is in very permeable soil; from the surface to a depth of 2·7 metres, layers of peaty soil are found; next follow sand and gravel. At 3·5 metres distance from the pump, an open sewer—a dirty ditch—runs. The water of the well is undoubtedly partly surface-water. Its physical properties are—Dark yellow colour; somewhat milky turbidity; taste not disagreeable, but very vapid. The microscopical examination of the sediment led to no other result than that structureless membranes were seen, which

disappeared when a single drop of dilute hydrochloric acid was added, causing, at the same time, effervescence. Analysis yielded the following results:—Total solid residue, 1·386; organic matter, 0·225; sulphate of lime, 0·1094; carbonate of lime, 0·6556; alkalies, 0·396, consisting chiefly of chlorides without any sulphates; ammonia, 0·00700: nitrates or nitrites, none; colour of dry residue before ignition, brown; after, black. Almost all who reside in the neighbourhood where this pump is placed detest the water: it is only used after having been left quietly standing for at least twenty-four hours, and then only after having been boiled and cooled again. At the time the water was taken for analysis, much rain had fallen. The city of Groningen is situated at a considerable height above sea-level, as compared with many other places of the kingdom.

Water taken from a Brook situated near Leeuwarden, in the Alluvial Soil of the Sea formerly existing there.—The bottom of this brook consists, for about 2 metres depth, of a layer of partly-decayed fresh-water plants. At about 150 metres distance from the brook, a large dung-heap is permanently placed. Physical properties of this water—Nearly colourless; quite limpid; tastes like rain-water. After long standing, a very slight sediment is deposited, which, on microscopic investigation, was found to consist of very small molecules, and flocculent vegetable matter, containing the very lowest order of infusoria. Result of chemical analysis—Total solid residue, 0·5135 gramme per litre; organic matter, 0·0675; sulphate of lime, 0·0583; carbonate of lime, 0·2617; alkalies, 0·126, chiefly chlorides without any sulphates; no ammonia, and only very faint traces of nitrates; colour of residue before ignition, yellow; after, greyish black. This water is largely used by the inhabitants, and very well liked. At the time the water was taken for analysis, not much rain had fallen. The level of the water in this brook is 47 centimetres below A. P.,* which is about sea-level.

Water from a Pump at Dokkum.—This pump is placed on a now disused cemetery. The water is collected in an underground vault made of masonry. The level of the water is 2·45 metres below the surface of the pavement, and is evidently also fed by a canal which is situated at about 100 metres distance from the vault. No sewers are anywhere in the neighbourhood; but close to the pump is a building used as a school-house, and this place being unprovided with an urinal, the boys (200 in number) are in the habit of making their water outside the school, against the wall, in consequence whereof the soil in the immediate vicinity of the pump is saturated with urine. The water is about colourless, clear, and limpid, and not at all disagreeable to the taste. A sediment subsides after some time; and this, on being investigated with the microscope, was found to contain molecules of clay, very small vegetable seeds, and pieces of threads of white wool and blue cotton. Total solid residue, 1·6935; organic matter, 0·1550; sulphate of lime, 0·4669; carbonate of lime, 0·2831; alkalies, 0·7885, chiefly chlorides without any sulphates; no ammonia; no nitrates or nitrites; residue yellow before ignition, grey after. This water is not much used, except by the schoolboys. At the time the sample was taken for analysis, there had been a good deal of rainfall.

Water from a Canal called the Dedemsvaart, Province of Overijssel.—This water is derived from the extensive peat bogs, to which the canal gives ready access. Its colour is as dark as sherry, but it is limpid and clear; taste vapid and disagreeable. The sediment which subsides exhibits, when viewed under the microscope, a multitude of peatified vegetable substances and infusoria. Total solid residue, 0·131; organic matter, 0·080; sulphate of lime, 0·0146; carbonate of lime, 0·02854; alkalies, 0·021; no sulphates; ammonia, 0·00041; of nitrates rather a large quantity; residue brown, black after ignition. While burning, it gives off an odour resembling that of smouldering nitrogenised organic matter. No rain had fallen for several days when the sample of water for analysis was taken. This water is not used for drinking or domestic purposes.

Water from a Pump surnamed the "Staten Pomp," at the Hague.—This pump is placed close to one of the most ancient buildings in the said town, and stands on a comparatively high level. The level of the water in the well is about 3 metres below the pavement. A thin brick wall only separates this pump and well from an extremely foul and dirty canal, a rather large open sewer, which winds its course to a large canal named the "Spui." The water is rather turbid; does not become clear on standing; exhibits a yellowish colour; taste saline; no microscopic investigation. Total solid residue, 0·750; organic matter, 0·060; sulphate of lime, 0·0639; carbonate of lime, 0·1831; alkalies, 0·443; no sulphates of alkalies; ammonia, 0·01181; large quantity of nitrates; colour of residue before ignition yellow, after ignition grey. This water is largely used, and relished, by those who reside near enough to make it worth their while to fetch it.

Water from a Pump situated in the Cité Ouvrière belonging to M. Régout, at Maestricht.—This pump is of comparatively recent construction, is in good working order, and the well is built in by means of brickwork laid in strong hydraulic cement; a canal is at 159 metres distance. No infiltration of surface water, nor of the contents of a large underground sewage cistern, has been found to exist. The water is of excellent quality, quite clear, colourless, and pleasant to the taste. Total solid residue, 0·650; organic matter, 0·020; sulphate of lime, 0·043; carbonate of lime, 0·342; alkalies, chiefly as chlorides, 0·245; no sulphates of alkalies; no ammonia; no nitrates nor nitrites. The soil in and about Maestricht is full of fossils, and noted for having been the place where very interesting animal remains have been found, while, moreover, the town, in consequence of having been since at least three centuries a fortress, and having frequently been besieged for months together, is, in a sense, a vast cemetery, full of the human remains of soldiers killed during such sieges and interred within the town, which, however, is of large extent of surface. Colour of solid residue of water before ignition, pale brown; after ignition, greyish black. The water is largely used, and very much praised and relished.

Rain-water Collected at St. Annaland, Province of Zeeland, at no great distance from the Sea.—The water was taken from a large, well-made, underground cistern, used for storing the water, built of bricks and strong cement; the water, on falling on a tiled roof, is led by means of wooden spouts to the cistern, which is surrounded by sand and clay soil; the water was slightly coloured, somewhat turbid, but does not deposit a sediment; taste, the same as is usually experienced from rain-water. Total solid residue, 0·4775; organic matter, 0·055; sulphate of lime, 0·136; alkaline chlorides, 0·2085; alkaline sulphates, 0·004; no ammonia; a very faint trace only of nitrates; colour of residue, before ignition, pale yellow; after ignition, pale grey. The water is much used, since there is no other but brackish water, quite unfit for any use.

Water taken in the Middle of the River Merwede (a local name given to a portion of the Rhine after the river Maas has joined it near Woudrichem).—Off the town of Dordt, the river is at this point about 1200 metres wide, and rather deep. The water was taken about the middle of the month of March last year. The water was very turbid, did not become clear on standing, and its taste was disagreeable. Total solid residue, 0·160; organic matter, 0·040; sulphate of lime, 0·0355; carbonate of lime, 0·420; alkalies, chiefly chlorides, 0·0425; sulphates of alkalies, none; ammonia, none; of nitrates, a faint trace; colour of solid residue, before ignition, pale yellow; after, pale greyish. This water is largely used, but in many households it is filtered previously.

* A. P. stands for *Amsterdamsch Peil*, which is the starting point, or zero, from which all levels below or above are measured in Holland. This true and very accurately-determined point was first adopted at Amsterdam about the year 1680; and, after having been verified over and over again, has been, since 1818, adopted as the general zero of all levels in the country.

Water from a Well bored, in 1866, at the Hague, for the private use of a Manufactory.—Total depth of boring, 5·65 metres, passing through 1·05 metre of sand; 0·40 metre of blackish peaty soil; 1·0 metre pure peat bog; 0·70 metre sand and peaty veins; 1·50 metre bluish coloured sand; 1 metre white-coloured sand mixed with shells of molluscs; the water leaves 0·704 gramme to the litre of solid residue dried at 120° C.; organic matter, 0·198; carbonates of lime and magnesia, 0·192; chloride of sodium, 0·247; sulphuric acid, 0·006 gramme to the litre; no ammonia, and no nitrates nor nitrites have been detected in this water although diligently sought for in a large quantity of water carefully evaporated to small bulk; the water is not colourless, but excellent to the taste, and the supply very abundant.

Results of the Analysis of Three Varieties of Water, obtained at Rotterdam by means of Norton's Well Tube, driven into a Layer of Whitish coloured Sand.—No. 1 well is 23 metres deep below sea level; No. 2 well has the same depth; No. 3 is about 14 metres below sea level. The physical qualities of these waters are good; the water has risen within the tube to about 1 metre below the surface of the mouth of the tube, which is level with the soil wherein it is driven.

The analyses of the few samples of water selected for quotation from upwards of 300 analyses published in the report, represent the varieties of water used for domestic purposes in the Netherlands; to wit, rain-water, river-water, water from brooks and canals, water taken from more or less deep wells, sunk or bored, into the ground to more or less depth, but never reaching to layers of very solid, and never to what should be properly called rocky, material. The localities selected are situated many miles distant from each other. As regards the alkalies, potassa and soda, it should be observed, that while generally no sulphates of the same are met with, a portion of these substances is very frequently combined in the waters analysed with humic, ulmic, crenic, and apocrenic acids and other organic substances. The composition of the water of the great rivers, passing through the country, does not materially differ at any point of their course as long as that water remains potable, from not being within sea reach, when the samples are taken at the same period of the year.

SPECTROSCOPIC OBSERVATIONS OF THE SUN.*

By Lieut. J. HERSCHEL.

THIS letter, written from Bangalore, states that the author discovered a new line in the spectrum of the sun's rays, in the neighbourhood of G; the author determined its position without difficulty, with reference to the rest of that crowded group of solar lines, and found it identical with the thick line at 2796 of Kirchhoff's chart; while studying this newly-discovered line, the writer succeeded in distinctly seeing a fainter red flash, already described by Mr. Lockyer, and he also noticed another line (the 6th) between F and G. These lines are defined by the figures of the Greek alphabet, and their number and position indicated according to Kirchhoff's chart. The letter then enters into details of mode of observation, and proceeds to discuss an article by Mr. Huggins in the *Quarterly Journal of Science*. This part of the letter, however, is not suitable for abstraction.

* Abstract of a letter addressed by the Author to W. Huggins, F.R.S., and communicated by him to the Royal Society.

NOTICES OF BOOKS.

Laboratory Teaching; or Progressive Exercises in Practical Chemistry. By C. L. BLOXAM. John Churchill and Sons. 1869.

WE can scarcely imagine a man more competent to treat of laboratory teaching than Mr. Bloxam. Commencing his studies at the College of Chemistry, he soon became the first assistant there, and the work which he then brought out in conjunction with Mr. Abel has long been familiar to the student of practical chemistry; altogether, for no less than twenty-three years has Mr. Bloxam been a teacher of laboratory practice; hence we have before us no imaginative system, elaborated in the mind but unpractised in the laboratory, but a system of instruction based on—nay, entirely made up of—experience. And it is not alone the most efficacious mode of teaching practical chemistry which must result from lengthy experience, but an exact and elegant manipulative skill; and an ingenuity in devising processes and experiments are alone attainable by this means.

The work before us is quite devoid of any theory; there is not a formula or a symbol in the whole book; it is essentially a treatise on *practical* chemistry. It contains, in the words of the author—

(1). "A series of simple tables for the analysis of unknown substances of all kinds (not excepting organic bodies) which are known to be single substances, and not mixtures.

(2). "A brief description of all the practically important single substances likely to be met with in ordinary analysis, by which the learner may satisfy himself that his results are correct, and may, at the same time, become acquainted with the leading properties of the most important chemicals, and with the foreign substances which they are liable to contain.

(3). "Simple directions and illustrations relating to chemical manipulation, not collected into a separate chapter, but given just where the learner requires them in the course of analysis.

(4). "A system of tables for the detection of unknown substances with the aid of the blowpipe.

(5). "Short instructions upon the purchase and preparation of the tests, intended for those who have not access to a laboratory."

Mr. Bloxam describes the various processes of chemical manipulation with an extreme minuteness of detail, and always effects his object by the simplest means; thus he says, "When a mortar is not at hand, substances of moderate hardness may be powdered on a hard surface by rolling a bottle over them;" a piece of broken porcelain may be often substituted for platinum foil; and Bunsen's burners may be improvised by placing a funnel over and a little distance above an ordinary gas-burner. We think, however, that a crudity of operation, although safe in the hands of a careful and accomplished chemist like Mr. Bloxam, may lead to carelessness and a want of delicacy and cleanliness in the student; it may lead him to regard processes which require the utmost skill as more or less rough operations, in which a large margin may be left for error of action. To our mind, we cannot have too elaborate or perfect apparatus for our infinitely delicate chemica

operations; we cannot warn the student too often against inattention to minute points of cleanliness in his operations; we cannot too often impress upon him the necessity of rendering assurance doubly sure—the double rinsing of his cleaned (and nominally clean) test-tubes, and other vessels, the examination of the purity of his tests, the infinite solicitude which he must give to his boiling liquid, or his filtering solution, lest one small drop—be it but so much as makes "the twentieth part of one poor scruple"—be lost; and, although in qualitative analysis the need for extreme caution is to some extent removed, we must remember that a careless habit once acquired is not relinquished when the student passes to quantitative analysis. We were in a laboratory the other day which, for neatness and cleanliness, not to say primness, might vie with a quaker's drawing-room; not a speck of dust was visible, not a bottle had dirty streaks of its contents coursing down its sides to deposit themselves on the shelf beneath; there was no confusion, and the air was as fresh as it ever can be in London; the usual dirty benches were replaced by clean slabs of plate-glass, whitened beneath, and everything was trim and smart. Yet this was not one of the laboratories of the *dilettanti*; there was plenty of good hard work going on in it; and, with a little management, all laboratories might be equally clean.

Mr. Bloxam has introduced a number of extremely useful tables into his work, to indicate the mode of detecting various elements and compounds; these tables are explained in the text, and constant back-reference is given to them and to individual paragraphs, which latter are distinguished by thick-letter numbers. Not only do we find the modes of detecting the simpler substances, but a large number of organic bodies are also introduced, together with the means of their identification; thus we find picric acid, cholesterine, acetone, naphthaline, aniline, and many other organic bodies described. Altogether, the work is most comprehensive; a great deal could be done with it; a chemist cast upon a desert island with it, and a box of reagents, could examine with ease all the principal products of the place, both mineral and vegetable. To the mining chemist, the work will be of much service; indeed, its usefulness is by no means confined to the student: we venture to assert that the book will be found useful in every laboratory as a work of quick reference and concise direction.

Mr. Bloxam is a thorough conservative; we imagine he is the General Peel of his party—a thoroughly conscientious, sound, true old tory, just a thought obstinate, but with the firmest convictions. It will be remembered that, in his "Chemistry Inorganic and Organic," he has not adopted the new nomenclature or the new equivalents; and we observe here that he has introduced such words as "white vitriol," zinc-white," "Glauber's salt," and "Scheele's green." An air of conservatism pervades the whole work, yet we do not intend to deprecate this, but are rather of opinion that it may help to check the rapidly-advancing tide of chemical radicalism.

MISCELLANEOUS.

Alkaloid Formed during Alcoholic Fermentation.—M. Oser has instituted researches with pure sugar brought into fermentation, and, after a series of operations, has succeeded in obtaining an alkaloid composed according to the following formula:—$C_{18}H_{20}N_4$. The hydrochloric acid combination has the formula—$C_{18}H_{20}N_4HCl$; the combination with chloride of gold is expressed by $C_{18}H_{20}N_4AuCl_4$. The author states that this alkaloid is positively the result of fermentation; but he also intimates that, since older wines contain, according to Ludwig's researches, trimethylamine, it is probable that the alkaloid here alluded to is either decomposed in older wines, or is only met with therein in very minute quantities.—*Polyt. Centr.*

Estimation of the Goodness of Soap.—Prof. Schültze, of Rostock, starting from the view that, the better the soap, the less thereof will be required for the entire unhardening of water, employs the reverse of Clark's process, in the following manner:—He applies a solution of lime in water containing excess of carbonic acid, so that litre of water contains exactly 1·6 grm. of lime. Of this fluid he takes 3 c.c. (containing, accordingly, 4·8 milligrms. of lime), and adds 20 c.c. of water, and a small quantity of soda solution; he further applies an aqueous solution of 5 grms. of soft soap in 100 c.c., or of the same quantity of solid soap in 200 c.c., of water, and adds of these solutions from a burette to the aforesaid lime solution until a lather is fully and completely formed. The smaller the quantity of soap solution required for this purpose, the better, of course, the soap is; and it is easy to calculate how much of the soap solution has been required for one part, by weight, of lime; a perfectly pure soap, however, will be required, for comparison's sake.

Nitroglycerine.—The only safe and proper mode of permitting the use of this substance is, undoubtedly, that adopted in France, Southern Germany, Belgium, and the United States, that is, to allow its use only on the absolute condition that it be made on the very spot where it is wanted, and be only made in quantities sufficient for, at most, three days' sufficient supply. In an article which appeared in the CHEMICAL NEWS, No. 422, vol. xvii., p. 11 (January 3, 1868), on this subject this point was briefly alluded to; and the experience since obtained in the countries above-named, the United States being foremost in this matter, has fully proved the utility of this rule. Nitroglycerine making is readily taught to workmen, and, with some care, succeeds exceedingly well. There is no sound reason why this plan should not be adopted in this country too.

Hygrometer.—Naudet and Co., Paris, Rue et Place Thorigny, 2 and 4, have constructed a portable hygrometer, shaped like a watch. The measuring of degree of moisture is effected by means of a peculiarly-prepared human hair, 0·35 metres long. The mechanism is graduated by placing the instrument under a bell-jar, wherein the air is kept dry by means of recently burnt quick-lime and fused chloride of calcium; and next it is placed under a bell-jar, wherein the air is kept saturated with moisture by means of a wet sponge. The distance between these two extremes, indicated by a properly-constructed mechanism, is divided into 100 parts. The price of this instrument, which is highly spoken of, is 25 francs (£1). It is intended for use in spinning and other establishments, and for observations. —*Deutsche Ind. Zeitung.*

Indelible Ink.—Two solutions are required—No. 1 consisting of—Crystallised chloride of copper, 8·52 parts; chlorate of soda, 10·65 parts; and chloride of ammonium (sal ammoniac), 5·35 parts, to be together dissolved in 60 parts of distilled water. No. 2 solution consisting of 20 parts of hydrochlorate of aniline, to be dissolved in 30 parts of water, to which has to be added 20 parts of a solution of gum (made by dissolving one part, by weight, of gum in two parts of water), and, lastly, 10 parts of glycerine. These solutions are kept in separate bottles. When it is required to write anything with these fluids, one part, by bulk, of solution No. 1 is mixed with four parts, by bulk, of No. 2. The ink must be applied to paper, linen, cotton, wool, or silk, with a quill pen, or small hair brush; at first the writing appears greenish, but it soon becomes black, especially if it is exposed to a higher temperature. This writing is perfectly indelible, and can only be destroyed by destroying the fabric it is placed on.—*Dr. Artus's Vierteljahreschrift.*

Production of Oxygen for Industrial Uses.—The works, in running order, although not yet quite finished, are located at the foot of Forty-first Street, in this (New York) city, a malodorous neighbourhood, where some means, artificial or otherwise, would not be out of place in substituting oxygen for the foul emanations of butchers' shops and dirty gutters. The essential or characteristic portions of the process are carried on by the aid of brick furnaces, of which only one was in operation at the time of our visit, several others being, however, rapidly put up and fitted for use. Each furnace has its fire-box so arranged as not only to heat the retort which holds the manganate of soda (the vehicle through which the process is carried on), but also one or more chambers through which an air-blast passes to the retort. The retort, furthermore, communicates, by a pipe furnished with stop-cocks, with a suitable steam-boiler. The process is carried on as follows:—About 600 pounds of manganate of soda are placed in the retort, heated to the requisite degree in the furnace; superheated steam from the boiler is then admitted for about ten minutes. Two equivalents of the manganate of soda and two of water react upon each other, as indicated by the formula—

$$2(MnO_3,NaO)+2(HO)=2(NaO,HO)+Mn_2O_3+O_2.$$

In other words, the water combines with the soda of the manganate to form a hydrate of soda. The manganic acid is changed to sesquioxide of manganese, containing only half the proportion of oxygen, and the other half of the latter passes off in a free condition. At the conclusion of this part of the process, the steam is shut off, and the superheated air is admitted for about fifteen minutes, whereupon the sesquioxide combines with more oxygen from the air, and is converted back into its original form of manganic acid, which, of course, resumes its former relation to the soda, reconstituting manganate of soda, ready for a repetition of the process. In forcing the air to the apparatus, a steam-pumping engine is used, noticeable for the manner in which friction gearing is applied to transmit power from the engine to the air-forcing pumps, without the jar incident to the use of cogged wheels. The air-blast passes first through cylindrical vessels containing caustic soda, by which its carbonic acid is removed, and thence through the superheating chamber previously mentioned, to the retort. The retort is never opened, as the material shows no signs of deterioration by use. That in the retort at the time of our visit was tested continuously for six months before being brought to this country, and has been in constant use for six weeks past, the period during which the works have been in constant operation. As the oxygen leaves the retort it passes through a suitable meter, which registers the quantity, and thence to the gasometer, which, at the present time, contains 25,000 feet of oxygen gas, much purer than is required for most of the purposes for which it is to be employed.—*American Artisan.*

CHEMICAL NOTICES FROM FOREIGN SOURCES.

In accordance with the generally expressed wishes of our friends and readers, we have effected arrangements to enable us to give, under the above heading, notices of EVERY CHEMICAL PAPER IN THE WORLD, *as soon as possible after publication. Whenever possible, these notices will appear in the form of carefully prepared, although necessarily brief, abstracts; as respects papers either too long or too abstruse to render condensation possible, their titles will be chronicled; and in all cases accurate reference will be made to the original publication. The two half-yearly volumes of the* CHEMICAL NEWS, *with their copious indices, will therefore be equivalent to an English edition of the "Jahresberichte," with the additional advantage of keeping the readers week by week on a level with the latest advances of science.*

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Monatsberichte der Königlich Preussischen Akademie der Wissenschaften zu Berlin, March, 1869.

This number of this periodical, which is always rather behind-hand as regards its time of being published, does not contain any memoirs or papers which bear upon chemistry, or sciences closely allied thereto.

Annales des Mines, vol. xv., 1st part for 1869.

This periodical contains—

A Biography of the Chemist, P. Berthier.—A concise review of his arduously-accomplished and incessant labours. This lengthy paper is concluded by an enumeration of the titles of the memoirs, papers, and books published by this *savant*, which catalogue occupies no less than fourteen octavo pages, printed in small type.

Although not belonging to the subjects usually treated by us, we cannot refrain from calling attention here to an excellent report on a steam boiler explosion, which took place at Moulins-Lille.

The rest of the papers in this number of this periodical bear upon practical mining, and are not of general importance.

Revue Universelle des Mines, de la Métallurgie, des Travaux Publics des Sciences et des Arts Appliqués a l'Industrie, Nos. 1 and 2 for 1869.

This very useful periodical is published in Belgium, and its editors are Belgians of high scientific as well as practical attainments. The first paper we meet with in this number is an excellent monograph on the—

Mineralogical Character and the Mineral Value of the Iron Ores of the Province of Luijk (Liege).—M. Franquoy.—From among the large number of analyses which accompany this very lengthy paper, we quote the analysis of a couple of samples of *fer-carbonaté lithoide des houillères*. The first sample contains, in 100 parts:—Carbonate of iron, 73·66; carbonate of lime, 2·98; carbonate of magnesia, 2·06; carbonate of manganese, 3·31; clay, 12·17; water and carbonaceous matter, 5·53; phosphoric acid, 0·29; yield of metallic iron, 34·76 per cent; specific gravity of this sample of ore, 3·15. The other sample contains, in 100 parts:—Carbonate of iron, 56·23; carbonate of lime, 4·84; carbonate of magnesia, 2·93; carbonate of manganese, 0·58; clay, 26·20; water and carbonaceous matter, 9·22; phosphoric acid, a trace; yield of metallic iron, 26·96 per cent; specific gravity of this sample of the mineral, 3·123.

On Saccharimetry.—This paper is a magnificent monograph on this subject, being the result of researches instituted in consequence of the International Convention agreed to by France, the United Kingdom, the Netherlands, and Belgium, on the 8th of November, 1864, in reference to the rules which shall apply to the amount, and mode of payment, of the duties on sugar in these four countries. The paper here alluded to is chiefly the work of Prof. Landolt, of Bonn, and is published by the kind permission of His Excellency the Belgian Minister of Commerce; we regret that it is too full of interesting matter, too concisely written, and, moreover, by far too lengthy for any useful abstraction. As a curiosity rather, and as proving the correctness of the figures adopted by the Netherlands Society of Commerce—whereby raw sugars are designated by the cypher-figures 1, 2, 3, and so on up to 21, according to the degree of purity, and the higher percentage of crystallisable sugar contained in the various samples so designated—we quote the following analysis:—No. 9, in 100 parts—Pure cane sugar, 89·6; organic salts, 4·3; water, 3·8; undetermined substances, 2·3. No. 12, in 100 parts—Pure cane sugar, 93·0; organic salts, 3·7; water, 3·1; undetermined substances, 0·2. No. 15, in 100 parts—Pure cane sugar, 95·0; organic salts, 1·6; water, 2·0; undetermined substances, 1·4. The composition of treacle, in 100 parts, varies between the following limits:—Best sample contained—Cane sugar, 61·8; sucrose (*sucre interverti*), 1·9; salts, 18·9; water, 14·2; undetermined substances, 3·2. Worst sample contained—Cane sugar, 54·4; sucrose, 1·6; salts, 19·9; water, 21·0; undetermined substances, 3·1. All the experiments were made on samples taken from quantities several thousand kilogrammes in weight, and they were performed at Cologne, in the establishment of the Rheinischen Actions Verein für Zuckerfabrikation, one of the largest and best-conducted sugar refineries in the world.

Observations on M. Margueritte's Process of the Volumetrical Estimation of Iron.—M. Léon Moyaux.—This paper ends with the following concisely-stated conclusions, arrived at by the author as result of his experiments:—1st. The normalisation of the permanganate solution can only be properly made by means of metallic iron, and, when the latter metal, in sufficiently pure state for this purpose, does not happen to be at hand, by means of oxalic acid (indirect titration). 2nd. The use of ammonio-sulphate of iron should be rejected; unless, indeed, the precise composition of this salt is repeatedly ascertained, it is not to be relied on, and this testing is a loss of time. 3rd. Repeatedly-continued research is required to ascertain that the solutions of *proto*-salts of iron really keep and continue to be so. 4th. The evaporation of solutions of iron containing hydrochloric or other volatile acids, after the addition of sulphuric acid, always impairs the result of the titration. 5th. The reduction of solutions of *per*-salts of iron to *proto*-salts, after driving off excess of hydrochloric acid, is best effected by means of zinc, better yet by means of amalgamated zinc; but this last metal is to be rejected when a solution of iron happens to contain, at the same time, a proto- and a per-salt. 6th. When 0·3 grm. of ore is taken for assay, in case the ore should contain more than 40 per cent of metallic iron (or, when less than that quantity, 0·5 grm. is taken for assay), the quantity of fluid best suited to yield accurate results should not, in either of these cases, respectively exceed ½ or ¼ a litre.

The other papers of this periodical relate chiefly to mechanical engineering and machinery.

Chemisches Centralblatt, No. 21, May 26, 1869.

The larger part of this paper is occupied with a treatise on the—

Chemical Constitution of the Organic Hydrocarbons.—M. Kolbe.—The author of this lengthy treatise begins by stating that, however ingenious M. Kékulé's theory may be, that theory is, after all, a failure, and in every respect erroneous. The author next states that, according to his opinion, a solid basis for speculation, on the true constitution of the organic hydrocarbons, is to be deducted from our experience with organic ammonias. The comparison of these two kinds of compounds has made clearly understood to him the nature of di- and tri-carbon acids, in reference to mono-carbon acids; and the organic ammonias, wherein nitrogen and phosphorus equivalently act, are the counterpart and example for the mode of constitution of the carbo-sulpho-acids. Ammonia, H_3N, and marsh gas, H_4C, are, in this sense, comparable, and may be placed side by side, just as, from ammonia, by substitution of the hydrogen atoms for the alcoholic radicals, organic ammonias are produced, which possess basic properties, so, from marsh gas, *carboles* are formed. Ammonia, therefore, agrees (*entspricht*) with the carbol, H_4C; the methylamine, the methyl-carbol, and di- and tri-methylamine agree with the di- and tri-methyl-carbol.

$\left.\begin{matrix}H\\H\\H\end{matrix}\right\}N$	$\left.\begin{matrix}CH_3\\H\\H\end{matrix}\right\}N$	$\left.\begin{matrix}CH_3\\CH_3\\H\end{matrix}\right\}N$	$\left.\begin{matrix}CH_3\\CH_3\\CH_3\end{matrix}\right\}N$
Ammonia.	Methylamine.	Dimethylamine.	Trimethylamine.
$\left.\begin{matrix}H\\H\\H\\H\end{matrix}\right\}C$	$\left.\begin{matrix}CH_3\\H\\H\\H\end{matrix}\right\}C$	$\left.\begin{matrix}CH_3\\CH_3\\H\\H\end{matrix}\right\}C$	$\left.\begin{matrix}CH_3\\CH_3\\CH_3\\H\end{matrix}\right\}C$
Carbol.	Methylcarbol.	Dimethylcarbol.	Trimethylcarbol.

The learned author proceeds, in this manner, with his essay, proving, by a great variety of instances, the truth of his statement; his paper is, however, not well suited for abstraction, and the less so from the fact that, in the above-named periodical, a condensed abstract only is published.

Reduction of Carbonic Acid to Oxalic Acid.—M. E. Drechsel.—Pure and clean sodium, exhibiting a metallic surface, is placed, along with some freshly-ignited quartz-sand, into a clean flask, and a rapid stream of carbonic acid gas is passed into the flask, which, at the same time, should be heated to the temperature of boiling mercury, 662° F. The sodium molten at this temperature yields, on being stirred up with a glass rod, a silvery semi-fluid paste. As soon as the reaction sets in, the metal assumes a purple colour, and, after a few hours, is converted into a dark pulverulent mass. Too much heat should not be applied; and, especially towards the end of the operation, great care is required in managing it, since a too high degree of temperature may cause the combustion of the newly-formed product. After having cooled in the flask, the substances therein contained are withdrawn from it, and, having been spread out in a thin layer, so as to effect the oxidation of any small particle of sodium not yet acted upon, the mass is exhausted with water, the aqueous solution saturated with an excess of acetic acid, and, after having been filtered, precipitated with chloride of calcium; the precipitate thus formed is almost always rather brownish coloured. It is dissolved in hydrochloric acid, filtered while yet hot, and precipitated with ammonia, whereby the salt, oxalate of lime, is obtained perfectly snow-white; 60 grms. of sodium yield, by this process, 6 grms. of pure oxalate of lime. Instead of sodium, a potassium-amalgam, containing 2 per cent of the alkali metal, and otherwise treated in the manner just described, yields a fair percentage of oxalate of potassa.

Nos. 22 and 23, June 2 and 9, 1869.

These two numbers do not contain any original memoirs, papers, or communications.

Bulletin de l'Academie Royale des Sciences, des Lettres et des Beaux Arts de Belgique, No. 4, 1869.

The only treatise contained in this number relating to chemistry is the first portion of an essay on the—

Isomerism of the Salicylic Series.—M. L. Henry.—The first section is headed—*Chlorinated Derivatives from Salicylic Aldehyde.* The derivatives of the *mono-substitués* of toluen and benzoic acid are pretty well known, and ought, according to this author, to be separated into three distinct groups, designated respectively—*ortho, para*, and *meta* series, each of these embracing a peculiarly characteristic monochlorinated benzoic acid, $C_7H_5ClO_2$, and a diatomic acid $C_7H_6O_3$. The author also proposes to name each of the three groups already alluded to the *ortho*, or *oxy*, the *para*, or *oxybenzoic*, and the *meta*, or *salicylic* series. Of each of these series a large number of very complex formulæ are given by the paper, however interesting in a purely scientific point of view, is, on account of its length, and on account of the large space which the quotation of the formulæ would require, not quite suitable for further abstraction.

Berichte der Deutschen Chemischen Gesellschaft zu Berlin, No. 9, May 23, 1869.

We notice the following original papers from this periodical:—

Contribution to our Knowledge of the Doubly-Coupled (Gepaarte) Compounds of Inorganic Chemistry.—M. C. W. Blomstrand.—In the introduction to this paper, the author refers to a published work of his, to which the title "Die Chemie der Jetztzeit" (the chemistry of the present day) is given. Next, he states that, when explaining and settling the question about coupling, he mentioned some experiments of his on the behaviour of iodine towards yellow prussiate of potassa, which were not quite successful. The author next proceeds to review the ammonia compounds of platinum, and says that he considers the so-called platino-cyanide of chloride of potassium, $2KCl + PtCy_2$, to be the perfect analogue of Grosses's base, which manner of viewing may be made evident by giving to the respective formulæ of these substances the following form:—Grosses's base—

$$(Cl—NH_3—NH_3)_2Pt_1Cl_4;$$

platino-cyanide of chloride of potassium—

$$(K—Cy—Cy)_2Pt_4Cl_4.$$

The author next proceeds to describe a lengthy series of researches on this subject, but his paper, an abstract of an abstract and *viva voce* communication by Dr. H. L. Buff, at the meeting of the Society, is too full of formulæ to be suitable for further abstraction.

On Binitro-Cresol.—MM. Martius and Wichelhaus.—There is met with in commerce, under the name of Victoria yellow, or aniline orange, a reddish powder, which yields highly yellow-coloured solutions, and bears, in general, great likeness to the binitro-naphthol compounds. The authors have instituted some researches on this material, and have made found it to be a nearly pure binitro-cresol salt. The binitro-cresol they separated from it is readily soluble in alcohol, ether, chloroform, and boiling water; it may be obtained in crystalline shape; the dry substance fuses at about 110° C.; the silver-salt is rather difficultly soluble, and may be obtained in crystals. The authors have tried in vain to obtain, by the experimental method, a clue to the mode of manufacture and origin of this material. The solutions of binitro-cresol become gradually deep-red coloured on exposure to air, and also when chloride of iron is added to the same.

Some Derivatives from Phenylacetic Acid (α Toluylic Acid. M. B. Radsiszewski.—The author first describes the method whereby he prepared this acid; we need not repeat this, as the author says it is well known, and is that used by Cannizzaro. The methyl ether of this acid is a colourless liquid of 1·044 sp. gr. at 16°; it boils at 220°, without decomposition. The ethyl ether of the above-named acid is a liquid, having a sp. gr. of 1·031; it boils at 226°. The author next proceeds to describe the action of bromine upon the α toluylic acid; then the action of bichromate of potassa and dilute sulphuric acid; next, the action of chlorine, of nitric acid, and other chemicals; and winds up with saying—"The result of my researches is, that the α toluyl acid behaves with the haloids, and with nitric acid, as does toluol, giving rise, chiefly, to the formation of para products."

On the Pyromucic Acid Group.—M. Limpricht.—This paper could not be understood without the reproduction of the woodcut annexed to it.

Action of Sulphuric Acid upon Polychlorated Hydrocarbons.—M. A. Oppenheim.—When ethylen-chloride is acted upon by sulphuric acid, at the ordinary temperature of the air, and at 100°, in sealed tubes, no action whatever ensues; at 130°, however, decomposition takes place, carbon is separated, sulphurous acid formed, and, hydrochloric acid generated. When chlorobenzol, $C_6H_5.CHCl_2$, is mixed, at the ordinary temperature, with sulphuric acid, hydrochloric acid is given off without causing a colouration of the liquid; but, at 100°, complete decomposition sets in, and carbonaceous matter is deposited. A syrupy product of this decomposition may be obtained, exhibiting a fluid having a constant boiling point at 175°; its smell is akin to that of the essential oil of bitter almonds.

Constitution of Epichlorhydrin.—M. L. Darmstädter.—The author states that, according to his opinion, the formula of epichlorhydrin has to be written—

$$O\begin{matrix}CH_2Cl\\CH\\CH_2\end{matrix}.$$

Next, he mentions some experiments, in order to prove that the oxygen of epichlorhydrin is combined, by double affinity, to carbon, and is not present therein as hydroxyl. To prove this, he states, at length, what action bromine and chloride of phosphorus exert upon substances containing hydroxyl; and then he gives an account of the action of these two chemicals upon epichlorhydrin. One of the results of this reaction is a liquid, which, in 100 parts, contains:—C, 15·22; H, 2·11; Cl, 15·01; Br, 67·65.

Constitution of the Native Combinations of Tantalum and Niobium.—M. C. Rammelsberg.—This paper is more of mineralogical than chemical interest; and, being an abstract from a large essay on this subject is not well suited for further condensation.

On Dinitronaphthalin.—M. A. de Aguiar. The author states that when dinitronaphthalin is prepared from naphthalin, an isomer thereof is formed at the same time which, being readily soluble in alcohol may by that means be separated from the not soluble variety. The variety soluble in alcohol the author calls α dinitronaphthalin; it is a crystaline solid substance, containing, in 100 parts: C, 55·04; H, 2·75; formula, $C_{10}H_6(NO_4)_2$. The solutions of this substance become red on exposure to the atmosphere, and also on being treated with ammonia; treated with nitric acid, trinitronaphthalin is formed.

Annalen der Physik und Chemie, von Poggendorff, No. 4, June 1, 1869.

This periodical contains, as usual, a large number of original essays, for, in reality, the labours of the authors are rather essays than papers. The first we meet with is—

A Contribution to our Knowledge about Thunderstorms.—M. W. Bezold.—Although this is a meteorological subject, we call attention to this paper, in compiling which the author has made use of the records of insurance companies in Bavaria and Austria, and also of some local statistics collected in the towns and districts, and has applied these materials for the purpose of making a valuable essay on a subject which, as he rightly remarks, cannot be so well elucidated by the observations made at the meteorological observatories, these being too few in number and too far distant from each other. Between the years 1844 and 1865, no less than 1143 buildings, among the large number of those insured against accidents by fire, in Bavaria, were struck by lightning; this is in the proportion of forty-four buildings struck by lightning each year, upon 1,000,000 of buildings insured. The essay, from which we cannot abstract more, on account of its subject matter being foreign to the subjects treated of in our paper, deserves the attention of those whom it may concern in many aspects.

On Leucitstone, as it occurs in a Peculiar Ore-Bearing Rock.—M. F. Zirkel.—This communication is a purely mineralogical essay, the subject of which is, beside, of local importance, only referring, as it does, to a single locality.

Certain Phenomenon of Refraction of Light first Observed by Quincke, and Changes of the Rays of Light during Total and Metallic Reflection.—M. E. Jochmann.—This, being an entirely mathematico-physical essay, is not suitable for abstraction.

Meteorites Deposited and Kept in Museums.—Dr. Buchner.—This is the fourth and concluding portion of a lengthy essay on this subject, compiled, in great measure, from previously-published papers dispersed through a series of periodicals.

A Hitherto-Unobserved Electric Powder Figure.—M. Kundt.—The author, referring to the well-known Lichtenberg figures, caused by electricity when very finely-powdered substances, such as Lycopodium, are applied to an isolator, states that he has discovered a new kind of these figures, formed on a conducting surface, and less dependent than the Lichtenberg figures upon the peculiar kind of electric developer to be used. The author describes, at length, the various means by which he obtained these figures.

Determination of the Specific Heat of a Constant Bulk of Air by means of the Metallic Barometer.—M. Kohlrausch.—A mathematico-physical essay.

Trigonal Pyramid ξ on the Quartz from Baveno.—Dr. Becker.—A mathematico-crystallographic essay.

Composition of Hydrofluocerite.—M. Nordenskjold.—The author says this mineral, which contains fluoride and cerium, was discovered in the year 1838, at the Bastnäs quarry, near Riddarhyttan, Sweden, and then analysed by M. Hissinger. The author further states that, when he resumed the researches of this mineral, he found that its earlier investigators had made a mistake as to its containing water, of which it contains a mere trace; and, next, he records the mode of his researches of the mineral now named by him *hamartite*, from the Greek ἁμαρτω, to err. The result of his analysis is, that this mineral contains, in 100 parts:—Oxide of lanthanum, 45·77; oxide of cerium, 28·49; carbonic acid, 19·50; water, 1·01; fluorine, 5·23. Formula, $CeFl + 2(LaO,CeO)CO_2$.

Grain Test for Bin-Axial Mica.—M. E. Reusch.—A crystallographical essay.

Discovery of Large Crystals of Quartz in a Very Difficultly-Accessible Portion of the Swiss Alps.—This paper is a reproduction from a newspaper published at Berne, and describes the cavern wherein these crystals were found; one of these weighs 267 lbs., is 69 centimetres in height, and has a circumference of 122 centimetres. This may suffice for this subject.

The editor of the *Annalen* very properly calls attention to a most useful work, now in regular course of publication under the auspices of the Prussian government—viz., the *Repertorium der Technischen, Mathematischen und Naturwissenschaftlichen Journal-Literatur*. This most useful work, to which we may add the index of foreign scientific periodicals, will, as justly observed by the editor of *Poggendorff's Annalen*, keep the place of a permanent and periodically-pub-

lished supplement to the catalogue of scientific papers published by the Royal Society. The repertorium records the titles of the papers of some 150 periodicals, in all languages, and published over the whole world. It may be inspected at the Library of the Commissioners of Patents, where it is regularly taken in.

Annalen der Chemie und Pharmacie, June, 1869.

Contents :—

Action of Boiling Liquids containing Acids and Alkalies upon Glass and Porcelain Vessels.—Dr. A. Emmerling.—This essay, or rather monograph, contains the record of a series of most minutely-executed experiments, whereby to determine the influence of various fluids, containing acids, salts, and alkalies, upon vessels made of different qualities of glass and porcelain, in order to determine the amount of substance dissolved by such chemicals, and also by pure distilled water, and to ascertain what influence is thus exercised upon the accuracy of analysis and chemical researches in general. This monograph is full of interesting details, including analyses of glass. *En résumé*, its leading features are the following:—The action of boiling liquids, as specified above, upon glass vessels is proportionate to the duration of time of boiling; the action is proportionate to the surface which is in contact with the boiling fluid; the action is independent of the quantity of fluid which evaporates during a given time; the action decreases with the decrease of temperature of the solution; alkalies, even in dilute solutions, attack glass very strongly; acids generally act less than pure water, excepting sulphuric acid; among the salts, those act most energetically whose acids produce insoluble salts with lime—*e.g.*, sulphate and phosphate of soda, carbonate of soda, and oxalate of ammonia, the action of each of which increases with the degree of concentration of the solution; such salts as form, in water, readily-soluble lime-salts—for instance, the chlorides of ammonium, potassium, calcium, and nitrate of potassa less strongly than pure water alone, and, with the greater degree of concentration of these salts, the action decreases. Bohemian glass stands acids better than the kinds of glass containing soda; the Berlin porcelain ware is only perceptibly acted upon by alkalies.

Researches on the Isomers of the Benzoic Series (ninth monograph, containing "The Chlorinated Derivatives of Toluol").—MM. Beilstein and Kuhlberg.—This essay is too lengthy for abstraction; the subject, moreover, has been already abstracted from another German publication.

On Oxylohydroxamic Acid. Dr. H. Lossen. This acid is a solid substance, difficultly soluble in cold water; submitted to a higher temperature it is slowly decomposed; when suddenly heated to 105°, it detonates; boiling for a length of time with water does not decompose it; on being boiled with caustic potassa solution it is converted into oxalic acid: nitric acid decomposes it completely and very rapidly. This acid consists, in 100 parts, of:—C, 20·00; H, 3·33; N, 23·33; O, 53·34. Formula, $C_2H_4N_2O_3$. The author describes, at great length, a series of salts of the oxylohydroxamic acid.

Researches on Mesitylen (sixth series).—Some Newly-Discovered Derivatives of Mesitylen.—MM. Fittig and Hoogewerf.—This essay has been noticed by us already, since an abbreviated account of the subject herein refered to was published in another German periodical published previous to this number of the *Annalen*, and noticed by us.

Chemical Constitution of Glycerine and its Derivatives.—M. Kolbe.—The learned author of this monograph starts from the hypothesis that glycerine should be equal to—

$$\left.\begin{matrix} CH_2 \\ CH_2.HO_{II} \\ HO \\ HO \end{matrix}\right\} C;$$

and next states that glycerine contains the elements of two groups of methyl, constituted in the following manner:—

$$\left.\begin{matrix} CH_2.HO \\ CH_2.HO \\ H \\ HO \end{matrix}\right\} C, \quad \text{and} \quad \left.\begin{matrix} CH.(HO)_2 \\ CH_2 \\ H \\ HO. \end{matrix}\right\} C.$$

The author then reviews such a lengthy series of compounds, and takes such extensive excursions over the immense field of organic chemistry, that it is impossible to compress into a small space even a minute fraction of this monograph, to which, therefore, we will not allude any further, especially as it is more a philosophico-chemical dissertation on an abstruse subject than of direct practical application.

Journal für Praktische Chemie, No. 7, June 15, 1869.

The following original papers are found in this periodical:—

On Sanguinarin, its Properties and Composition.—M. Naschold.—Sanguinarin is so named because it is prepared from the *Sanguinaria canadensis*, but it also occurs in the *Chelidonium majus*, and *Glaucium luteum*: it is an alkaloid which, in pure state, is a crystalline, white-coloured solid; formula, $C_{17}H_{19}NO_4$. As a peculiarity, the author observes that the estimation of the nitrogen contained in this substance cannot be satisfactorily executed with the well-known soda-lime process, but has to be performed by Dumas's method. The author describes, at length, several combinations of sanguinarin with the chlorides and cyanides of platinum, its behaviour towards reagents, and its products of decomposition, but none of these are so precisely characteristic as thereby to render it easy to distinguish and detect sanguinarin from all other alkaloids.

Brandy obtained from Reindeer Moss.—M. Stenberg.—This paper contains, translated from a pamphlet published in Swedish, a more extensive account of a subject to which, some time since, we referred in our columns, and, since it is of no importance, except where the *Cladonia rangiferæ* is found, we make no further abstract of this paper.

Estimation of Sulphur. Dr. G. J. Mulder.—The author speaks of the estimation of sulphur in such substances which contain carbon and sulphur together, and are not very volatile, and are, at the same time, free from any ash or incombustible matter. A certain quantity of the substance wherein the sulphur has to be estimated is weighed off in a porcelain capsule; there is next added a weighed quantity of finely-powdered nitrate, or acetate of lead; next, some nitric acid, the strength of which depends upon the nature of the substance to be assayed; and, lastly, a few crystals of pure nitrate of ammonia are added. The contents of the porcelain vessel are now carefully evaporated to dryness, ignited, and weighed. Since the weight of the oxide of lead derived from the acetate or nitrate employed is known, the increase of weight of the capsule and contents is due to the sulphate of lead which has been formed from the sulphur originally contained in the substance submitted to experiment. This method also yields accurate results when, besides sulphur, there may be iodine and bromine present, and also lead; the method may be used, also, for the estimation of phosphorus, when, in substances containing both that element and carbon, it is desired to estimate the former quantitatively, provided, of course, sulphur be absent.

Products of Decomposition of Legumin when Boiled with Dilute Sulphuric Acid.—M. Ritthausen.—The author states that, while he was engaged studying the products of decomposition of legumin and conglutin, he discovered a nitrogenous acid, which contained, in 100 parts:—C, 39·46; H, 6·14; N, 12·04; O, 42·36. This acid was called, by the author, leguminic acid. On resuming his investigations on this subject, he finds, as explained in this paper, that the acid just alluded to is a mixture of two amine acids—to wit, asparaginic acid, $C_4H_7NO_4$, and glutaminic acid, $C_5H_9NO_4$; both these acids are homologous—both are solid crystallisable substances, yielding, among their products of decomposition, by the action of nitric acid, malic and glutanic acids.

Gewerbsblätter fur das Königreich Würtemberg, Nos. 5 and 6, 1869.

This periodical rarely contains anything but matters relating to applied mechanics and agriculture; in this number, however, we meet with a paper—

On Cyanine.—M. Morat.—The author says that the colouring matter of flowers consists—1st, of cyanine, or a blue pigment; 2nd, a rose, or pink-coloured matter, in reality identical with the first, and only altered by an acidity of the juice; 3rd, two yellow-coloured matters—xanthine, insoluble in water, and xanthéine, soluble in that liquid. Cyanine is best prepared from the petals of violets or iris flowers; by exhausting these with boiling alcohol, a blue solution is obtained, which solution, however, soon turns brown, but is restored to its primitive colour by being shaken up in contact with air. In order to obtain the colouring matter in a pure state, the alcoholic solution is evaporated to dryness on a water-bath, and the residue taken up with water, wherein the blue pigment is soluble, while fatty matter and resins are left behind; the aqueous solution is precipitated by acetate of lead; the ensuing green-coloured precipitate is decomposed by sulphuretted hydrogen, filtered, and washed, and the filtrate next evaporated to dryness upon a water-bath; the residue is exhausted with absolute alcohol, and the cyanine precipitate from its solution therein by ether. Cyanine does not crystallise, is soluble in water and alcohol, and insoluble in ether; acids turn it red, and alkalies green—it is a very highly sensitive reagent for both. Reducing agents decolourise cyanine; oxygen restores the colour. The red colouring matter of flowers is extracted in a similar manner, and, once isolated, exhibits characters identical with cyanine.

On Oenoline.—M. Morat.—Oenoline is the colouring matter met with in genuine red wines obtained from grapes; it is obtainable by treating the wine with basic acetate of lead; the ensuing precipitate is collected on a filter, washed, dried at 100°, and placed in a displacing apparatus, and while therein there is poured over the dry precipitate anhydrous ether, previously saturated with dry hydrochloric acid gas. There runs off a brown-coloured liquid; the precipitate is washed with anhydrous ether until what runs off ceases to have an acid reaction. The residue in the displacing apparatus, which now exhibits a bright red colour, is treated with alcohol of 36° Beaumé, which thereby assumes the same bright red colour. The alcoholic solution is concentrated, by evaporation, to a small bulk, and water is next added; this causes the colouring matter to precipitate as a red-coloured flocculent substance, insoluble in ether, very difficultly soluble in water, soluble in alcohol, and insoluble in benzol. By a long-continued boiling in water, this colouring matter is changed, becomes brown, and loses its solubility in alcohol. The solution of the unaltered red pigment in dilute alcohol exhibits the following reactions:—Chlorine water and chlorine gas destroy the colour, producing thereby a yellow substance soluble in water; caustic potassa causes, first a blue, and next a brown colouration; lime-water yields a yellowish precipitate; bicarbonate of soda in aqueous solution, and aqueous solution of chloride of calcium, cause a blue colouration; solution of alum causes a brighter red colouration; hydrochloric acid effects no change; with nitric acid, a yellowish flocculent matter is thrown down; acetate of lead causes a blue precipitate; nitrate of lead produces a violetish red precipitate; acetate of copper yields a chestnut-brown coloured precipitate. This red colouring matter is composed according to the following formula: $C_{10}H_{10}O_5$. Young red wines contain, moreover, a pigment, soluble in acetic and butyric ethers.

with a bluish violet colour, becoming green by ammonia, and finally turning brown. Some chemists consider that this material is identical with cyanine; it is not a very stable compound, and is only met with in young wines. The colouring matter of wine is of some interest, as affording a means for detecting adulterations and artificial substitutes of wine.

Polytechnisches Journal von Dingler, second number for May, 1869.

Among the original papers, other than those relating to mechanical art and purely practical engineering, we meet here with a lengthy essay on the—

Conditions which are required for the Formation of Hypochlorite of Lime.—MM. Tschigianjanz, Fricke, and Reimer.—The authors, who have most thoroughly investigated this subject, begin their essay with the statement that, in practice, as well as in theory, a real influence has been ascribed to the moisture and state of hydration of the slacked lime which is submitted to the action of the chlorine gas; next, they review the opinions and labours on this subject of MM. Weisz, Morin, and Houton-Labillardière, Dr. Ure, Dr. Muspratt, Prof. T. Graham, and, lastly, Dr. Bolley. Curiously enough, the opinions of these learned gentlemen vary, and even to such an extreme that, whereas some of them assert that dry hydrate of lime (slacked lime) is capable of taking up 40, or even 50 per cent of chlorine gas, some of them declare that hydrate of lime, dried at 100°, does not take up any chlorine gas at all. The authors of this essay, fully convinced that men of eminently high standing in scientific matters, and especially Prof. T. Graham, were not likely to err in their observations, were led by an observation, made by the last-named *savant*, that lime dried over sulphuric acid in the vacuum made by an air-pump behaved differently towards chlorine gas from that dried at 100°. To investigate this subject fully, the authors of this essay commenced by procuring good pure caustic lime, a matter of far more difficulty than one would imagine at first. They succeeded in obtaining this material by taking the caustic quick-lime of commerce, made from pure mountain limestone, soaking that material with oil, and burning or igniting it a second time, after having placed it in a crucible heated in a furnace with coke and charcoal, and a strong blast produced by a pair of blacksmith's bellows. Quick-lime, thus prepared, when placed in water, is instantaneously converted into hydrate of lime, while there is produced, at the moment of contact of the quick-lime and water, a hissing noise, as if of a piece of red-hot iron quenched with water. The authors also prepared a quick-lime from pure white marble, soluble in very dilute hydrochloric acid, without residue; they took care that, whenever they dried the hydrate of lime intended for their experiments, to exclude the access of carbonic acid gas from that hydrate. They next repeated Prof. T. Graham's experiment, working comparatively drying weighed quantities of slacked lime over sulphuric acid, as well as by means of heat, passed chlorine over these quantities for 1½ hours, and expelled excess of that gas, left uncombined by means of a current of dry air free from carbonic acid. The results of their extensive labours are:—1st. Slacked lime, retaining even as small a quantity as 0·4 per cent of water (as is the case with that dried over sulphuric acid *in vacuo*), and any larger quantity of water retained is sufficient to effect the formation of hypochlorite of lime at any temperature. 2nd. Hydrate of lime, dried at 100°, or even at 130°, is converted into hypochlorite of lime, even at 0° (32° F.), provided the lime is freely allowed to become heated by the absorption of chlorine gas; but, if by means of keeping the temperature at 0°, or even lower, the lime is prevented becoming heated, no action at all, or only a very slight one, took place. The authors call attention to the often-overlooked fact that it is very difficult to obtain a chlorine gas quite free from hydrochloric acid gas, against which they have taken peculiar precautions in the course of the experiments just alluded to.

Behaviour of Chlorine, Iodine, and Bromine towards a Solution of Permanganate of Potassa.—M. W. Lindner.—The author says, when, to any solution containing a compound of iodine, a drop of a dilute solution of permanganate of potassa is added, the peculiarly characteristic colour of the latter substance is changed into brown—that is to say, that iodine is set free and the permanganate reduced. It does not matter whether the original solution of the iodide has an acid or an alkaline reaction, for, in the former case, the fluid will be clear and transparent, in the latter turbid. A neutral solution of a bromide is not affected by the permanganate, neither is an alkaline solution; but if the solution of the bromide is acidified with nitric acid, the reaction, on addition of the permanganate, takes place in the same manner as for the iodide solution. A solution of a chloride is never, under any conditions, acted upon by the permanganate. The author states that, even when solutions of iodides or bromides are so dilute as hardly to be detected by nitrate of silver, the permanganate never fails to detect the presence of them, but does not, at the same time, distinguish between iodine and bromine, for which purpose the specially-distinguishing reagents for these two halogens have to be applied.

Les Mondes, July 8, 1869.

We find in this paper the following original communications:—

Agronomical Map of France.—M. Delesse has received, from every canton the empire is subdivided into, two average samples of the arable soil of each of these small districts, taken at a depth of 15 centimetres below the surface. The author has thus in hand 6000 samples, and proposes, after chemically and mineralogically testing and classifying them, to employ the information thus obtained in constructing an agronomical map of France, whereupon the nature of the soils of the divers localities will be clearly indicated.

Electrical Phosphoroscope.—M. Laborde.—This instrument is based upon the same principle as that of M. Becquerel; its essential parts are a Ruhmkorff induction apparatus, the spark of which throws light on the phosphorescent object, and of a sliding frame, one of the ends of which hides the object during the brief moment it is illuminated by the electric spark. This sliding frame is 40 centimetres in length by 10 centimetres in breadth; it is fixed at its centre on an axis, which may be made to move rapidly by means of a pedal. The arrangement of this apparatus, which is rather confusedly described in the original, and could not be well understood without a diagram, is such as to render it serviceable for studying the phosphorescence excited by a blow, as well as by friction. The phenomena of phosphorescence of substances which, like nitrate of uranium, is only of very short duration, can be observed by means of this instrument equally well as the long-continued and strong phosphorescence induced by friction in pieces of porcelain or glass.

Bulletin de la Société d'Encouragement pour l'Industrie Nationale, No. 197, May, 1869.

The greater part of this periodical is devoted to mechanical science. The only paper of interest to chemists is a lengthy report on the—

Manufacture and Use of Animal Phosphated Chlorinated Manure.—Dr. Boucherie.—All farmers know that now and then it happens that horses, cattle, or sheep die; and it is chiefly the disposal of their carcases which the report here alluded to treats of. The skin is taken off, and, after having been disinfected, is sold; the intestines are mixed with quick-lime, and buried in a spot to be always kept for such a purpose; the remainder of the carcase is cut into pieces weighing from 5 to 6 kilos., and placed in a wooden tank lined inside with lead, and of about 120 cubic feet capacity. Water is added to the remains of the dead beast, bones included, and about 400 kilos. of crude commercial hydrochloric acid; ebullition is effected by means of the introduction of steam, obtained from the portable steam boiler; after boiling for about six hours, the entire mass is disintegrated. In order to destroy the very unpleasant smell resulting from this ebullition, some lumps of peroxide of manganese are added, whereby a slow but constant disengagement of chlorine gas, is obtained, and all disagreeable smell avoided. When the liquid and contents of the tank are thoroughly cold, the solidified fat which floats on the top is taken away, and fit for the soap or candle maker; the clear liquid is run off and mixed with 200 kilos. of coprolite powder, or bone-ash, and thus converted into a useful manure. At the bottom of the tank will be found a brownish-coloured pulpy mass, which has lost all traces of organised structure, and this materia., after having been mixed with some mineral phosphate, is also applied as manure. The following is the composition, in 100 parts, of the liquid manure here alluded to, previous to its being mixed with mineral phosphate:—Water, 79·60; organic matter (containing 1·28 per cent of nitrogen), 10·65; ash (containing 2·38 per cent of phosphoric acid), 9·45. The browniah pulpy mass contains, in 100 parts:—Water, 16·75; organic matter (containing 3·90 per cent of nitrogen), 31·17; ash (containing 8·20 per cent of phosphoric acid), 52·08. The quantity of materials obtained at each operation is stated to amount to about 70 kilos. of fat, 1500 litres of liquid, and 700 kilos. of brownish pulpy animal matter; these quantities, however, will vary according to the size, weight, and nature of the animals so disposed of. This process is recommended above the burial of dead animals; and in some communes of France, it is already ordered to be adopted in all cases, since it is a useful addition to the sanitary regulations of the country.

NOTES AND QUERIES.

Powdering Isinglass.—Isinglass, owing to its toughness, is a substance which it is almost impossible to reduce to powder by means of pestle and mortar; but, akin to horn, to cork, and such-like substances, it may be obtained in pulverulent shape by means of a sharp, well-hardened, but not too coarse file. Lump isinglass answers best for this purpose.

Pattinson's Method for Extracting Magnesia from Limestone Rocks.—Would any correspondent obligingly give me the process of extracting magnesia from the limestone rocks containing that earth, by Pattinson's method; it appears to be accomplished by carbonic acid.—W. R.

THE CHEMICAL NEWS.

VOL. XX. No. 505.

ON SOME GENERIC REACTIONS IN ORGANIC CHEMISTRY.

By S. E. PHILLIPS.

ORGANIC chemistry has been variously defined: I would represent it as essentially "the chemistry of generic reactions."

It is mooted that a fuller recognition, and a more systematic study of a few widely-generic reactions, may do much to bring about a more simple outline classification of the vast wonders of organic combinations.

These reactions have been recognised in their simplest expressions; but it has not been so clearly shown that they extend into regions of great intricacy, where the guidance of law is so much needed in the discrimination of complex types of combination.

Astronomy and geology have aspects of immensity which engage and entrance the noblest powers of human intellect, nor is chemistry in any way inferior as another receding horizon of infinity.

These aspects are, indeed, the inverse of dissolving views, for it is the reward of genius, of labour, and sacrifice, to decipher, out of the dim chaos, minarets and pinnacles of architectural beauty, which entrance the mind and afford a pleasure that never satiates: and every line traced adds a new lustre, and a richer meaning, to those already drawn.

Moral and physical truth have a distinction only in a human or circumferential sense. All aspects of divinity coalesce and commingle towards an effulgent centre of infinite harmony; hence poets have been co-labourers with our profoundest philosophers and physicists in promoting the conviction that—

> "Discord is harmony ill-understood;
> All partial evil, universal good."

In offering these thoughts as an amateur, in presence of men whose abilities and means of investigation are greatly superior, some apology or explanation may be desirable.

The sincere desire is to write in a humble spirit of enquiry, rather than of dictation.

It is true that most English chemists have adopted the new notations; but, seeing that in the continental journals fully one-half the articles are written in old style, and that so great an authority as Dumas does not hesitate to express entire inabillty to read modern chemical memoirs, owing to their complex types and "barbarous" nomenclature, surely it may be forgiven in an unpretending student to express long-pent-up thoughts in what appears to him as the clearest and simplest language, the more so as his object is purely to ventilate principles (which are independent of modes of representation), and also to challenge students of the modern ways, to see if they can penetrate deeper or see further into the wonderful labyrinth.

The pretentious methods of modern notation are certainly curious in their way; and it is refreshing to see the tone of sober-minded reaction which has been evinced at the recent discussions of the Chemical Society.

One of the most prominent facts of general chemistry is that hydrides are "indifferent bodies"—they do not combine without decomposition—yet Professors Hofmann and Wanklyn see in these prolific sources of substitution, and even of direct dedoublement; they are prominent in the diamines and triamines of the former, and to the latter they are leading types to which other definite chemical combining bodies may be referred:—

Ethylene. $C_4\begin{cases}H\\H\\H\\H\end{cases}$ Hydride of ethyl. $C_4\begin{cases}H\\H\\H\\H\\H\\H\end{cases}$

Rosaniline. $C_4\begin{cases}NHC_{12}H_5\\NHC_{12}H_5\\NHC_{12}H_5\\H\end{cases}$ Leucaniline. $C_4\begin{cases}NHC_{12}H_5\\NHC_{12}H_5\\NHC_{12}H_5\\H\\H\\H\end{cases}$

M. L. Henry holds that salicylic alcohol is an *aldehyde* as well as a *phenol*, and that by chloro-variation it gives the following series:—

Salicylic alcohol, $C_6H_4<^{HO}_{CHO}$

Doubly-chloruretted cresol, $C_6H_4<^{HO}_{CHCl_2}$

Triply-chloruretted toluol, $C_6H_4<^{Cl}_{CHCl_2}$

Chloruretted aldehyde of salicyl, $C_6H_4<^{Cl}_{CHO}$

Whether the first really be an alcohol, or the last an aldehyde, is by no means certain, or even apparent, so random are these type-building speculations. And it seems strangely overlooked that the old radical theory is, peradventure, adequate to explain all these substitutions without any such paradoxical nomenclature.

The first pair, as *hydrides*, would be—

$(C_{14}H_5O_4),H$ and $(C_{14}H_5O_2),H$;

the second pair are evidently chlorides—

$(C_{14}H_5Cl_2);Cl$ and $(C_{14}H_5Cl_2O_2),Cl$;

as *alcohols*, the first pair would be—

$(C_{14}H_5O_2)O+HO$ and $(C_{14}H_5Cl_2)O+HO$

Another authority, speaking of an acid derivative of mesitylen, $C_{18}H_{11}H$, says $C_9H_6O_6-3CO_2=C_6H_6$, therefore it is a benzol with 3(COHO), substituting 3H!

In order to parallel the cogency of this logic, I would say of the thousands or millions of organic bodies which similarly break up into oxalic acid, that, therefore they are oxalic acids with the infinity of residues replacing, &c., &c.

M. Schorlemmer, before the Royal Society (CHEMICAL NEWS, vol. xix., p. 196), similarly says, the oxidation products of propylic glycol are carbon dioxide, and acetic acid, which proves that the structure of the glycol is expressed by the formula $CH_3—CH(OH)—CH_2OH$.

Another authority, with like wonderful prevision, says that hydrocinnamic acid is $C_6H_6+CH_2-CH_2-COHO$, and the saltic type is $(C_9H_9O_2)_2Ca+1\frac{1}{2}H_2O$.

Another insists that the acid, with 2H less than cinnamic acid, $C_{18}H_7O_2+HO$, and therefore $C_{18}H_5O_3+HO$, coumaric acid, is phenyl-propiolic acid—

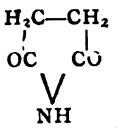
$$C_6H_5C$$
$$\|$$
$$C$$
$$|$$
$$CO_2H$$

Professor A. Matthiessen thinks that all the reactions of narcotine may be accounted for by the following rational (?) formula:—

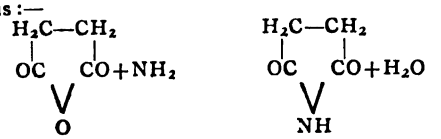
$$\left.\begin{matrix}CH_3\\(C_{11}H_9O_2)'''\\(C_8H_4O)''''\\(CH_3)_2H\end{matrix}\right\}N\Big\}O\Big\}O_3$$

By a singular distortion of an intellectual process, some have thought that the simple principles of mineral

chemistry might be employed to gradually unravel the greater complexities of organic combination. Professor Wanklyn has corrected this error, and shown that, in the simple salts and hydrates of soda, lie hidden the mysteries of triatomic and septatomic quantivalence: we must not go from the simple to the complex, but rather work out principles or fantasies from organic chemistry, and then apply them to the old binary compounds of mineral chemistry. Time was when the relation of acid to amide was a matter of great simplicity, but M. Erlenmeyer now sees much farther. Succinimide is—



and its origin from anhydrous succinic acid and ammonia is thus:—



To give but a faint description of these modern pleasantries of atomic mechanism would fill large volumes. We can only add in this brief glance, that they are from men of undoubted eminence and great practical ability.

Enough has been said to justify our hesitation in adopting any of these multifarious modes, and in the pressing desiderata to lay hold of some wide generic principles which may afford some comprehensive grasp of the whole contour of organic metamorphosis; we humbly, and *pro tem.*, fall back on the old binary principles of Berzilian and Lavoisierian chemistry, as best fitted for the widest and most comprehensive grasp.

We assume, until a wider and better theory can be offered, that such radicals as methyl (C_2H_3), ethyl (C_4H_5), propyl (C_6H_7), acetyl (C_4H_3), and a vast infinity of analogues do exist, and that, as hydrides, they are characteristic indifferent bodies, while with O, Cl, S, and other negative elements they form bases or acids, and other more neutral bodies, perfectly paralleled by the more simple elements of mineral chemistry.

The confidence and dogmatism with which such types and names as we have indicated are obtruded upon notice will be in no way imitated. We shall try to lay hold of leading types, ever bearing in mind that they must necessarily be subject to manifold ways of isomeric variation. The ground to occupy is of too wide and extensive a character to permit of special exactitude; but this attitude should in no way be opposed to rigid scrutiny or microscopic investigation at any stage of the process. The harvest is indeed ripe, and manifold labourers are wanted in every direction; workers in the laboratory and watchers of the wide horizon. Our meaning in this direction will perhaps be better understood by an illustration.

We deem, then, the term phenyl-propiolic acid almost as barbarous as the older term, "sulphuric ether." Now that we have an infinity of ethers, including a true sulphuric ether, it surely behoves us to carefully control their nomenclature.

In what way the radicals phenyl and propyl may combine to form the acid in question is a legitimate matter of detail, nor can we afford to wait long upon such minutiæ. To us the great question is, Is there a hydrocarbon radical ($C_{18}H_5$) comparable with acetyl (C_4H_3), or cinnamyl ($C_{18}H_7$), &c., &c.?

Our meaning may further be seen in regard to the body aceton, $C_6H_6O_2$. Its origin and subsequent reactions led very generally to the idea of its being a hydride of acetyl, $C_4H_3O_2,H$, in which the H was replaced by the gaseous methyl, $(C_2H_3) = C_4H_3O_2,C_2H_3$.

While recognising the validity and value of this aspect as one of the elements of isomeric variation, yet would we stoutly urge the great necessity for a due subordination of this phase of organic combination. To give it undue prominence, as is too often done, and coin a shibboleth of hard names, is positively confusing and detrimental.

It has only just transpired that, by the simple and direct oxidation of the hydrocarbon propane or hydride of propyl, we get a body possessing all the characters of acetone, $C_6H_5O_2,H$.

The distinction between the two types is one of great importance, because the hydrocarbons proper are comparatively few and capable of a simple generic classification, while such types as acetone, $C_4H_3O_2,C_2H_3$, are capable of an infinite variation, nor do I see any hope of embracing them in any generic arrangement.

It only remains in this short introduction to offer a few thoughts as to why we still adhere to the old notation in regard to O, S, C, and other doubled atoms of modern theory.

Among other reasons, O is doubled because its ordinary volume is half that of H. The same anomaly subsists in the volumetric character of the phosphorus, arsenic group, and some have pushed theory so far as even to double these, but that is generally discountenanced on the ground that the anomaly disappears in their various compounds, where the volumes agree with the atomic weights in a way perfectly comparable with the one volume, N.

			Density.	Atomic Weight.
Ammonia ..	H_3,N	2 vols.	17	17
Phosphonia ..	H_3P	,,	34	34
	&c., &c.			

We moot that the same argument is strictly applicable for oxygen also.

It is monatomic and replaces chlorine, &c., in organic radicals where the volumes correspond normally; in other words, the densities are as the atomic weights.

			Density.	Atomic Weight.
Hydride of acetyl	$(C_4H_3O_2)H$	2 vols.	22·04″	44
	$(C_4H_3Cl_2)H$	,,	49·70″	99
	&c., &c.			

Hydrides are normally two vols., whence their densities are half their atomic weights, but these radicals themselves are normally one vol., and their densities exactly correspond with the atomic weights.

		Density.	Atomic Weight.
H	1 vol.	1	1
$(C_4H_3O_2)$ ..	,,	43	43
$(C_4H_3Cl_2)$..	,,	98	98
	&c., &c.		

Also in organic acids the densities and atomic weights agree in innumerable cases of proto-, sesqui-, bi-, and tri-acid forms where chlorine and oxygen are perfectly paralleled.

Again, oxygen, in conjunction with C = 6, and S = 16 replaces H in ammoniacal types, and here also the densities and atomic weights agree.

	H_3N.		Density.	Atomic Weight.
Ammonia	HH_2,N	2 vols.	8·5″	17
Ethyl mustard oil	$(C_4H_5)(CS)_2,N$	,,	43·7″	87
Methyl ,,	$(C_2H_3)(CS)_2,N$	,,	37·8	73
Amyl ,,	$(C_{10}H_{11})(CS)_2,N$	,,	63·4	129
Butyl ,,	$(C_8H_9)(CS)_2,N$			
	&c., &c.			

and, by a generic action, these, by addition of ammonia, form fluosinnamin types of sulph-ureas.

Urea	$H(CO)_2H_3N_2$
Fluosinnamin ..	$(C_6H_5)(CS)_2H_3,N_2$
Butyl sinnamin ..	$(C_8H_9)(CS)_2H_3,N_2$
&c., &c.	

Lastly. Monatomic oxygen replaces H in the general phenomena of substitution, mainly like chlorine.

The oxidations, chlorodations, and sulphodations of carbydrogens, rich in hydrogen, present a unity of action; and the bases split up to negative or acid forms, by similar intermediate stages of hydride or indefinite bodies, where O = 8; S, 16; and Cl, 35·5, replace each other with volumes and atomic weights in perfect harmony.

We now take a glance at the amide and glucoside modes of production.

AMIDES.

The study of these bodies some years ago afforded the writer great interest:—

1. As possessing such new and varied phases of ammoniacal type.

2. As proving the adequacy of plain and simple principles to guide without ambiguity or mystification into the profound depths of the science.

3. As proving that *one generic formula of reaction* or production seems to give amides, hydramides, ureides, or ureas, amide acids, urethanes, &c., &c.

4. As providing the strongest arguments against the modern doctrines of mono-, bi-, and tri-basic acids, and the similar mono-, bi-, and tri-amines.

In this connection I can only refer to one aspect of this wide field, viz., its tendency to resolve hitherto unexplained groups of organic combination. If I mention two such groups it is not so much because success appears to attend the very onset, as to elicit a co-operative or corrective criticism.

On the one hand, I have long felt puzzled at the existence of an apparently aberrant group of carbohydrogens with even instead of odd ratios of H, and have marked out for investigation what may, perhaps, be called *the malic acid group*.

This group is exceptional in the even number of H atoms in the radical, whereas all other acid series have only odd numbers of H. A special study of this group might throw some light on the problem why all the carbon constituents have even numbers, and the H part odd numbers, while the oxygen seems normally to affect even numbers in the radical.

The first step in the process is evidently to apply the generic formula in question, and the peculiarity seems to stand that test, for

Malate of A − 2HO gives MALAMIDE .. .. $(C_4H_3O_3)H_2N$
Bimalate of A − 2HO „ MALAMIC ACID (ASPARTIC) $2(C_4H_3O_3)H_2N,O$
Aspartate of A − 2HO „ ASPARTAMIDE (ASPARAGIN) $2(C_4H_3O_3)H_4N_2$

Most books say that malamide or asparagin is found in the asparagus, in marsh mallow, and some other plants, but, although of the same composition, they are not identical, and I think my notation and a recognition of the ureal or atmonia type of asparagine will clear up the difficulty. I cannot see the least reason or advantage in doubling this acid to make it square with the modern notion of bibasic acids.

In "Fownes" (9th edition), its structure and derivation is compared with that of the oxamide series. In both cases, the acids and neutral salts are doubled, while the acid salts (binacids?) and their derived amides contain no more acid than the mono or neutral forms, and yet the prefix *bi* is retained.

I ought, perhaps, to have pointed out that, by an extension of the formula, when the acid is an ammoniacal one, then the result is an ureal amide, thus—

Carbamate of A − 2HO = UREA .. .. $2(CO)H_4N_2$
Aspartate of A − 2HO = ASPARTAMIDE (asparagin) $2(C_4H_3O_3)H_4N_2$
&c., &c.

On the other hand, there seems a tolerably wide range of combination with unusual and intractable ratios of oxygen, and with little or no H in the compound, as in the

Mellitates, $HO+C_4O_3$
Croconates, $HO+C_5O_4$
Rhodizonates, $HO+C_7O_7$
Saccharates, $HO+C_6H_4O_7$
&c., &c.

How, then, does this generic action apply to such cases?

Carbonate of Ammonium − 2HO, gives Carbamide.
Bicarbonate of „ „ „ Carbamic acid.
Oxalate of „ „ „ Oxamide.
Binoxalate of „ „ „ Oxamic acid.
Benzoate of „ „ „ Benzamide.
Bibenzoate of „ „ „ Benzamic acid.

$$H_4NO+CO_2-2HO=(CO)H_2N$$
$$H_4NO+2CO_2-2HO=2(CO)H_2N,O$$
$$H_4NO+C_2O_3-2HO=(C_2O_2)H_2N$$
$$H_4NO+2(C_2O_3)-2HO=2(C_2O_2)H_2N,O$$
$$H_4NO+C_{14}H_5O_3-2HO=(C_{14}H_5O_2)H_2N$$
$$H_4NO+2(C_{14}H_5O_3)-2HO=2(C_{14}H_5O_2)H_2N,O$$
&c., &c.

The infinity of amides thus produced are hydride, indifferent or non-combining bodies, mostly affecting the crystalline form of needles, and insoluble; in all probability they are of the type H_2N,H. Whatever ammonia is in type, constitution, and general properties, that, in all probability, are the amides.

The amic acids are ammoniums, H_4N,O, definite combining bodies, and de-doubling with basic, intermediate, or acid functions just in proportion as the substitutional equivalents rank higher or lower in the electro series.

Malate of Ammonium − 2HO gives Malamide.
Bi-malate of „ − 2HO „ Malamic (aspartic) acid
Succinate of „ − 2HO „ Succinnamide.
Bi-succinate of „ − 2HO „ Succinnamic acid.
&c., &c.

It is curious to compare these simple and consistent notations with the confused variations of modern theory. Any fundamental appeal to the guidance of law is wholly lost in the doubling of atoms, and the varied estimates of water of hydration in the several compounds submitted to the amide formula.

In extending this list considerably, I am well aware there are chemical reasons for doubling the atom in some cases where, indeed, that process may, in all probability, be necessitated: I only contend that this should be done with extreme caution, and not without a survey of the several relations.

As to the doubling of succinic acid, I find the following remark in my rough notes:—"M. Fehling, and also M. Cahours, seem quite sure that succinic acid is tribasic, like the phosphates $3HO+C_8H_3O_5$; and, between the chemical reasons urged by the bi- and tribasic claimants, I could not see a pin's difference whereon to found a preference; but, where all is so empirical, the simple truth may have a strong advocate in M. Dopling, from whose elaborate paper I copy an extended series of succinates $(MO+C_4H_2O_3)$, with the usual variation of type in ascending the series into the weaker bases, where two and three atoms of base are found, as in the corresponding acetates, sulphates, &c."

Many salts affect two volumes, but there are several whose densities are as one volume, as in the

Succinate of ethyl, $EO+C_4H_2O_3$,
Succinate of methyl, $MeO+C_4H_2O_3$,
Oxalate of ethyl, $EO+C_2O_3$,
Silicate of ethyl, $EO+SiO_2$,
Oenanthate of ethyl, $EO+C_{14}H_{13}O_3$,

and others.

The theoretical application of this formula to the second group would be thus—

Mellitate of A − 2HO = Mellitamide?
Bi-mellitate of A − 2HO = Mellitamic acid?
$$H_4NO+C_4O_3-2HO=(C_4O_2)H_2N?$$
$$H_4NO+2(C_4O_3)-2HO=2(C_4O_2)H_2N?$$

There is encouragement to think that these bodies may be obtained when duly sought for. Fownes says, "Mellitate of A yields, by distillation, two curious compounds—paramide, a white, amorphous, insoluble substance, containing C_8HNO_4 (*i.e.*, bimellitate of ammonia − 4HO), and

convertible, by boiling with water, into bimellitate of ammonia;" and euchronic acid, a colourless, soluble, crystalline body, containing, in the anhydrous state, $C_{12}NO_6,2HO$.

In this case, it is almost certain that paramide is the amide or ammonia form of mellitamic acid, evincing as it does the widely generic property of re-conversion, by boiling water, into bimellitate of A.

Here, then, we get a new substitutional representative of H; and, if one H can be replaced by (CO), (C_2O_2), or (C_4O_2), surely that does not end the series; and have we not more complex acids which may be explained by a similar process, and their radicals identified?

And, seeing that silicium is now so close a congener with carbon, may not a similar extension of law be applicable in the infinitely varied silicates of mineralogy?

Euchronic acid appears to be a varied mellitamic acid—thus, $3(C_4O_2)HN,O$.

Glucosides.

The manuals of chemistry present a strange variety of types in regard to the constitution of the sugars, and also complex acids containing higher ratios of oxygen; but there are considerations which seem to encourage the hope that both these intractable groups may, ere long, be embraced within the limits of simple law.

The hypothesis herein is twofold; 1st, That glycols, glycerines, mannites, and sugars are all monatomic alcohols; 2nd, That complex organic acids with high ratios of oxygen are substitutional variations of simpler types.

For a fuller exposition of these views, I must refer to a separate article on the constitution of the alcohols; but, for brevity, I here append a note on the aceto-nitrates, or, as I should prefer to call them,

Nitro-Acetates.

It is said that these belong to the water type $\left.\begin{matrix}H_6\\H_6\end{matrix}\right\}O_6$, in which H_6 is replaced by ferricum $Ffe^{vi.}$, and 1H is replaced by (NO_2)

No. 1.
$\left.\begin{matrix}H_6\\H_6\end{matrix}\right\}O_6$
Type.

No. 2.
$\left.\begin{matrix}Ffe^{vi.}\\H_6\end{matrix}\right\}O_6+2H_2O$
Normal ferric hydrate.

No. 3.
$\left.\begin{matrix}Ffe^{vi.}\\4(C_2H_3O)'\\(NO_2)'\end{matrix}\right\}O_6+4H_2O$
Tetra-aceto-nitrate of iron.

No. 4.
$\left.\begin{matrix}Ffe^{vi.}\\3(C_2H_3O)'\\(NH_2)'\\H_2\end{matrix}\right\}O_6+2H_2O$
Tri-aceto-nitrate of iron.

No. 5.
$\left.\begin{matrix}Sr''\\(C_2H_3O)'\\(NO_2)'\end{matrix}\right\}O_2$
Aceto-nitrate of strontian.

No. 6.
$\left.\begin{matrix}Ba''\\(C_2H_3O)'\\(NO_2)'\end{matrix}\right\}O_2$
Aceto-nitrate of barium.

If, in these compounds, (NO_4) really replaces 1H of acetic acid, and, further, presuming that, in the three and four atoms of acetic acid, only one atom is so modified, then the formulæ might be thus—

(No. 6). $2BaO+AcO_3,HO$
(No. 5). $2SrO+AcO_3,HO$
$\left.\begin{matrix}\\\\\end{matrix}\right\}AcO=C_4H_2(NO_4),O_3$

(No. 4). $2Fe_2O_3+3AcO_3,7HO$
(No. 3). $2Fe_2O_3+4AcO_3,HO$
$\left.\begin{matrix}\\\\\end{matrix}\right\}1AcO=C_4H_2(NO_4),O_3$

It only remains to compare these notations with the ordinary types of similar true acetates; and methinks all seems quite fair and simple; nothing strained, nothing outlandish. No new principles, no 6-atom water types are at all requisite! As to the 6-atom *normal* ferric hydrate, it is clearly $3HO+Fe_2O_3$.

What is this ferricum if it be not 2 atoms of ferrosum? and yet this latter is said to be tetratomic, while the former is hexatomic!

Ferrosum = $Fe^{iv.}$ = (56). Ferricum = $Ffe^{vi.}$ = (112). As a general rule in such cases of substitutional variation, I prefer to retain, if possible, the supposed normal type, with a dash referring to a marginal explanation; also to retain the dash in cases where some unknown substitutional variation may be presumed.

Some vigorous effort is needed to restrain the amazing fecundity by which the multiplication of types and hard names have become a pest to the science.

				Sources.	Acid.			Base.			
1.	Acetic Ether	C_4	H_4	O_4	—	Acetic acid	HO+ C_4	H_3 O_3	+	Alcohol	$C_6H_6O_2$	− 2HO

15.	Amygdalin		—		—	—	—	—		—	—	—
16.	Rubian		—		Madder root	Alizarin?	—	—	+	Sugar	—	—
17.	Indican		—		"Indigofera"	Indigo red?	—	—	+	"	—	—
18.	Antiarine		—		"Antiaris"	Yellow resin	—	—	+	"	—	—
19.	Murrayin	72	44	40	—	Murrayetin	HO+ 48	23 19	+	2 Sugar	2(12 12 12)	− 4HO

2 and 3.—It remains to be seen whether these substitutions take place in the acid or in the base—precedents are equally available for both cases; and this alternative applies to the whole series. The StO_3 of No. 3 would be

$$C_{36}\overbrace{H_{34}(C_{36}H_{35}O_2)}O_3,$$

that of No. 4 would be—

$$C_{36}H_{33}(C_{36}H_{35}O_2)_2O_3.$$

6.—The acid, 28 11 5, easily splits into benzoic acid, whence it may be that this acid is of type No. 5, with the radical of benzoic acid (14 5 2) replacing 1H.

7.—The acid, 30 13 9, splits into phloretic acid, HO+18 9 5, whence it may be that acid with 1 (12 5 4) replacing 1H. Phloridzine gives a characteristic ammonia phloridzeine, just as orcine gives a similar ammonia orceine; and I subsequently find orcine is associated with a lichen sugar!

18.—Antiarine is—C, 61·2; H, 8·1; O, 30·7. Its yellow resin is—C, 83·9; H, 9; O, 4·2.

These studies have afforded much pleasure in the prosecution; but, while our leading chemists are eagerly pursuing other routes, they are presented with diffidence and humility, in the hope that other minds may be induced to take stock of progress, and to enquire whither we are tending, and what are the materials elaborating in our workshops or laboratories for the popularisation of science.

PRELIMINARY NOTE ON NAMAQUALITE.

By A. H. CHURCH, M.A.

Some time ago I obtained from Mr. J. R. Gregory a few pieces of a beautiful blue silky mineral which he had obtained during his recent visit to South Africa, from one of the copper mines of Namaqualand. The qualitative examination of the mineral proved it to contain copper, aluminium, and water, with traces of calcium, magnesium, and iron. Several specimens were crushed into fragments, and the pure homogeneous parts picked out for quantitative analysis. The percentage numbers correspond pretty closely with the formula $Al_2H_6O_6,3CuH_2O_2,4aq$.

The constitution of this mineral appears to warrant the bestowal of a specific name; the locality of its occurrence suggests that of *Namaqualite*. I am engaged in completing the investigation of the physical and chemical characters of this compound; but I may now mention that it occurs in thin layers made up of short silky fibres, and is of a pale blue colour. The layers alternate with another copper mineral, which is amorphous, and is probably chrysocolla. Namaqualite has something of the aspect and texture of a soft variety of crocidolite, or of chrysotile. The absence of silica from namaqualite is remarkable. As far as at present made out, it would seem to be a cupric aluminic hydrate, hitherto unrecognised.

ON SOME MEANS FOR PREVENTING THE BUMPING OF BOILING LIQUIDS.

By HUGO MÜLLER, F.R.S.

The annoyance which arises from the bumping of certain liquids when submitted to distillation or boiling has often attracted the attention of chemists, and various means have been proposed for its prevention.

The value of pieces of platinum, charcoal, burnt clay, and other porous bodies for this purpose is well known, and, under certain circumstances are efficient enough; yet there occur very frequently cases in the laboratory when these means are unavailable.

About two years ago Pietro Pellogio (*Fresenius, Zeitschr.*, vi. Jahrg.) proposed a very simple contrivance, which was stated to act very satisfactorily indeed. It consisted of a moderately wide glass tube, passing through the cork of the tubular of the retort, and nearly reaching the bottom of it, the upper end being bent at right angles and drawn out into a capillary tube.

Having occasion to try the efficiency of this arrangement, I came to the conclusion that it was quite ineffective, and shortly after, G. Hager (*Pharmac. Centralhalle*, Bd. 9) confirmed the negative results I obtained.

Quite recently E. Winkelhofer (*Ber. d. Chem. Gesellsch. Berlin*, p. 194, 1869), proposed for the same purpose the application of an electric current, which, through the incipient decomposition of the liquid and consequent evolution of gas, causes the ebullition to become quite regular and steady. Dufour, for another, with another object in view, had made use of the same means.

The application of the electric current unfortunately pre-supposes that the liquid to be distilled is a sufficiently good conductor of electricity; and, if this is not the case, necessitates the introduction of such substances as shall cause the liquid to become a conductor. This circumstance, therefore, limits very considerably the use of this otherwise efficient arrangement, and it is on this account that I venture to bring under notice some other means which I have tested in a variety of cases, and which invariably proved satisfactory.

In cases where the introduction of any foreign matter into the liquid about to be distilled is undesirable, I introduce through the cork in the tubular of the retort a glass tube, which is drawn out to a long capillary tube and pressed tightly to the bottom of the retort. The upper end of the glass tube is connected, by means of an india-rubber tube, with a generator of carbonic acid, or hydrogen, or a gas-holder containing air, and whilst the distillation is going on, one of these gases is passed in a slow but continuous current through the liquid. Under these conditions, all bumping is avoided, and the distillation proceeds with the utmost facility.

For ordinary purposes, however, I have found it still more convenient to introduce into the liquid about to be distilled a small fragment of sodium amalgam or, in cases where the liquid is acid, a small piece of sodium-tin. Methylic alcohol is well known to be one of the most difficult liquids to distil, yet, on the introduction of a minute piece of sodium amalgam or sodium-tin, it can be distilled without the slightest inconvenience. I found on one occasion that more than 400 grammes of methylic alcohol distilled over with perfect steadiness, and without exhausting the activity of a fragment of sodium-tin, weighing not more than 0·060 grms.

It is, perhaps, hardly necessary to mention that the action of sodium amalgam and sodium-tin is due to a minute but continuous disengagement of hydrogen taking place during the process of distillation.

ON HEAT TREATED AS A SCIENCE OF KINETICS.*

By G. F. RODWELL, F.C.S.

(Continued from p. 26).

III. (Abstract).

This lecture was chiefly devoted to a consideration of the effects produced by heat within a mass of matter, and the various forms of action which it then assumes. The following definitions, which are taken from the "Notes," convey the principal points of the lecture.

The attractive force existing between the molecules of matter, like all other attractive forces, decreases in intensity as the distance between the attracting molecules increases, and *vice versâ*. Liquids become solids (*solidification*) when they lose so much of their molecular motion that the molecules approach sufficiently near to each other to produce the effect of rigidity, in place of the former molecular mobility. (α). When the resulting solid assumes a definite geometrical form (*crystallisation*), the attractive force of its molecules probably varies in intensity in different directions; thus, supposing the molecules to be spherical, the attractive force wold be greater or less in the direction of a diameter A than in the direction of a diameter B, cutting A at right angles; or, supposing the molecules to be ellipsoidal, the attractive force would be greater or less in the direction of the major axis than in the direction of the minor axis. (β). When the resulting solid does not assume a crystalline structure or form, the attractive force of the molecules probably does not vary in different directions, or the varying intensity may be equalised by extraneous causes (*amorphous solidification*).

When molecular motion is communicated to a substance, it is obvious that, before it can expand that substance, it must overcome the mutual attraction of its molecules at the particular distance at which they then exist; for expansion is the act of increasing the distance between individual molecules (*vide* Lecture II.) In thus separating the molecules, there is, consequently, a certain amount of work to be done (*the internal work of a mass of matter*), just as the separation of two masses—for instance, the raising of a weight to a height above the surface of the earth—involves the expenditure of an amount of work equal to the force of gravity which has been overcome, and, in both cases alike, heat is consumed in the per-

* A course of four lectures delivered at the London Institution.

formance of the work done. And as when a weight is raised above the surface of the earth it possesses potential energy (*vide* Lecture I.) competent, when converted into kinetic energy, to cause it to fall through the space which separates it from the earth, and to generate the heat consumed in raising it when its kinetic energy is arrested, so, likewise, the molecules of a substance expanded by heat possess potential energy (*molecular potential energy*) competent to cause them to recross the space through which they have been separated by the added molecular motion, and to generate the heat consumed in separating them when the kinetic energy thus induced is arrested.

And since all matter possesses a certain amount of molecular motion, and no two molecules are in contact, it follows that all molecules possess a certain amount of potential energy, and that the acts of heating and cooling, (addition and subtraction of molecular motion) may be expressed respectively as the increasing and the lessening of molecular potential energy, considered in regard to its amount at the time of such addition or subtraction. (The first part of this assertion may be otherwise expressed by saying that nothing is so cold that it cannot be made colder; ice may be called excessively hot when compared with solid carbonic anhydride; in a word, the former possesses a far larger amount of molecular motion than the latter. The *absolute zero of temperature* is believed to be $-273°$ C., and we must imagine that the molecules of matter would be in contact at this temperature. Matter thus constituted would be perfectly lifeless and inert; it would possess no motion, neither could its molecules transmit any motion. We have not yet succeeded in producing a degree of cold approaching the absolute zero. The rapid evaporation of liquid ammonia *in vacuo* in the presence of sulphuric acid produces a temperature of 87° C. below zero; liquid nitrous oxide in becoming gas reduces the temperature to $-88°$ C.; solid carbonic acid produces a temperature of $-90°$ C., and when mixed with ether and placed *in vacuo*, of $-100°$ C., while the greatest artificial cold has been obtained by the rapid evaporation *in vacuo* of a mixture of liquid nitrous oxide with disulphide of carbon, when the temperature fell to $-140°$ C. By the employment of a freezing mixture of solid carbonic anhydride and ether, simultaneously with excessively high pressures, Andrews has reduced nitric oxide to 1·680th of its original volume, oxygen to 1·554th, and hydrogen to 1·500th, but in no instance did these gases exhibit signs of liquefaction. It is obvious that in the case of compressible matter pressure will tend equally with loss of molecular motion to lessen the molecular potential energy).

From the above paragraphs it follows that, when molecular motion is added to molecules, it performs two functions, for a portion of it is converted into work (*vide* Lecture I.) which confers potential energy upon the molecules by separating them (*expansion*), while another portion increases the temperature of the substance (*vide* Lecture II.), by conferring upon the molecules a larger quantity of the motion which constitutes heat, and hence increasing their velocity. Thus a portion of the added molecular motion disappears as heat, and this is still known as *Latent Heat*—(*Lateo*, to lie hid, because it was imagined by those who adopted the material theory of heat (*vide* Lecture I.)that the heat thus designated was somehow hidden in the substance, as in a cave, and that it only came out under certain conditions, and this idea was one of the most notable of the many *idola specus* possessed by the Materialists).

The quantity of heat which is thus expended in interior work when a solid passes into the liquid, or a liquid into the gaseous condition, can be readily determined. Thus, if a pound of boiling water (212° F.) be mixed with a pound of ice-cold water (32° F.) the temperature of the resulting two pounds of water is found to be 122° F., that is, the mean of the two:— $\frac{212° + 32°}{2}$ F. = 122° F. But if a pound of ice (32° F.) be mixed with a pound of boiling water, the temperature of the resulting two pounds of water is found to be only 51° F. Now it is obvious that the difference in the total heat of the two mixtures is that required to raise two pounds of water, 122° − 51° F. = 71° F., or one pound through 142° F. In other words, in the act of liquefying a pound of ice at 32° F., an amount of heat is consumed as internal work which is competent to raise one pound of water through 142° F.; that is to say, 142 units of heat (*vide* Lecture I.), which represents as mechanical work one pound weight raised to a height of 772 × 142 feet = 109,624 feet (or more than 20 miles) above the surface of the earth (*vide* Lecture I.)

The actual amount of molecular motion possessed by different substances (*specific heat*) varies considerably, for not only do the molecules in a given space vary in quantity, but also in weight, and in their attraction for each other; hence, also, the amount of heat consumed in internal work varies, because it depends upon the relative attraction of the molecules.

The amount of molecular motion necessary to raise any substance through a known number of thermometric degrees (*vide* Lecture II.) compared with that necessary to raise the same weight of water through the same number of of degrees, is called the specific heat of that substance. Thus, to raise 1lb. of water 1° F. in temperature requires thirty-three times the amount of heat necessary to raise one pound of mercury 1° F. in temperature; hence, the specific heat of water being represented by 1·00, that of mercury will be 0·033.

Conduction of Heat is the transference of molecular motion from molecules possessing a certain amount of it to molecules possessing less of it, by direct communication of motion. Those molecules which are apt to receive and transmit the motion are called *conductors* of heat, while those which are unfitted for the reception and transmission of the motion (whether from their slight mobility, or from an inaptitude to accommodate themthemselves to that kind of motion) are called *non-conductors* of heat.

Convection (from *conveho*, to carry up) is an action induced by external means—the force of gravity—in virtue of which a congeries of molecules of liquid or gas, possessing a greater amount of molecular motion than surrounding congeries or system of congeries, rises *en masse*, because the motion of heat, by increasing the distance between the molecules of matter (*vide* Lecture II.) causes a given number thereof to occupy a larger space when they possess a certain amount of that motion than when they possess relatively less, whence ensues a difference of density and a consequent difference of action on the part of gravity, for in equal bulks there are now no longer equal weights of matter, and one mass is now attracted by the earth more powerfully than the other.

UTILISATION OF BLAST FURNACE SLAG.*

In this paper the author endeavours to point out some of the uses to which this almost valueless material, which is produced in very large quantity in the manufacture of iron, may be applied. He states that slag is a compound containing an excess of lime, and produced by the siliceous and earthy matters contained in the ironstone, combining with the lime of the limestone used as a flux. Grey slag contains, in 100 parts :—Silica, 38·25; alumina, 22·19; lime, 31·56; magnesia, 4·14; protoxide of iron, 1·09; manganese, a trace; sulphide of calcium, 2·95; but the composition of slag differs according to a variety of circumstances.

The author then discusses the means of converting slag into paving stones, applying it to the manufacture of sulphate of alumina, aluminate of soda, and pure silica for

* Abstract of a paper read before the Cleveland Institution of Engineers, by Mr. Crossley.

the manufacture of porcelain, for most of which purposes patents have been taken out. He then proceeds to point out a plan of his own invention in which the slag, after being brought into a suitable state of subdivision, is treated with hydrochloric acid, whereby silica is obtained in a gelatinous form, and the alumina, lime, magnesia, and iron dissolved; the solution is evaporated to dryness, washed with water to dissolve out the soluble salts, the insoluble residue is treated with sulphuric acid, by which means sulphate of alumina is formed, the solution of which may be decanted off; the silica after washing with water is left in a pure state. The sulphate of alumina may either be evaporated to obtain that salt in the solid and dry state, or it may be used for the manufacture of alum. By this process slag will give a product worth £3 per ton and another worth £7 per ton. The author uses hydrochloric instead of sulphuric acid, as it is, in many instances, a waste product. Every 100 tons of slag will yield 33 tons of silica and 147 tons of sulphate of alumina.

PROCEEDINGS OF SOCIETIES.

QUEKETT MICROSCOPICAL CLUB.

THE fourth annual general meeting was held on Friday evening last, in the library of University College. Mr. ARTHUR E. DURHAM, President, in the chair.

A report was read, which showed that 142 members had been elected since the last annual meeting, making a total of 512. The Treasurer's report showed that the finances were in a very satisfactory condition.

In vacating the chair which he had filled for two years the President delivered a highly impressive address, which was listened to with marked attention throughout.

The following gentlemen were elected to fill the offices named for the ensuing year:—

President—Mr. P. Le Neve Foster.

Vice-Presidents—Dr. R. Braithwaite, Mr. W. M. Bywater, Mr. A. E. Durham, Mr. H. F. Hailes.

Members of Committee—Mr. T. Crooke, Mr. B. T. Lowne, Mr. S. J. McIntire, Dr. J. Matthews.

Treasurer—Mr. R. Hardwicke.

Hon. Secretary—Mr. T. Charters White.

Hon. Secretary for Foreign Correspondence—Mr. M. C. Cooke.

A paper "*On the Ratio-Micro Polariscope*," by Mr. James J. Field, its inventor, was read, at the conclusion of which the instrument was exhibited. Ten new members were elected, after which the proceedings terminated.

NOTICES OF BOOKS.

Qualitative Chemical Analysis. By Dr. C. REMIGIUS FRESENIUS, Director of the Chemical Laboratory at Wiesbaden. Seventh edition. Edited by ARTHUR VACHER. London: John Churchill and Sons, 1869.

MANY years ago when analytical chemistry was but little studied in this country, and the few who practised it used Rose's "Handbuch der Analytischen Chemie," Mr. Lloyd Bullock introduced a translation of the works of Dr. Fresenius on "Qualitative and Quantitative Analysis." These are so well known to chemists, and have become such thoroughly standard authorities, that it is almost unnecessary to notice a new edition.

The "Qualitative Analysis," unlike the Quantitative, has diminished rather than increased in bulk, and this arises from an increased condensation and an alteration in some respects of the arrangement of the work. "This edition," says Mr. Vacher in the preface, "differs greatly from the last. . . . The language has been condensed, the notation and nomenclature have been modernised, the arrangement has been simplified."

We are glad to notice the removal of the great mass of cross references, which formerly added so much to the already sufficient difficulties of the beginner, and which always reminded us of one of the more complex pages of "Bradshaw."

The work, as now arranged, is divided into the following sections:—1. Reagents, apparatus, and manipulation; 2. Reactions and separations; 3. General analysis; 4. Special analysis; 5. Reactions and separation of rare inorganic bodies; 6. Reactions and separation of organic bodies; 7. Detection of poisons in bodies, food, &c.; 8. Tables. The few tables which are given are eminently serviceable, and might, with advantage, be printed separately on calico for laboratory use. It is a grand mistake to print tables on paper which are to be used side by side with the test-tube rack, and to bind them up with a book; we all know how soon they become torn, and discoloured, and acid stained. Such tables, together with works on chemical manipulation, might with advantage be printed upon calico or vegetable parchment.

Every book which is meant for constant laboratory use should have a special binding, as durable as binding can be made, and, best of all, literal boards of thin oak. We have the misfortune to possess a copy of Regnault's "Cours de Chimie," bound elaborately in white vellum. An *edition de luxe* of a work on chemistry is a far more useless object than an *edition de luxe* of a treatise on the infinitesimal calculus, and may be classed with silver trowels, ivory croquet mallets, Louis Quatorze clocks, and other ornamental but useless—at least, unpractical—things. A certain great king, we are told, once presented a certain great chemist with a laboratory, in which every vessel was of platinum; this was a laboratory *de luxe*; give us good glass, say we, with a judicious sprinkling of the above precious metal, with homely porcelain and still homelier Stourbridge clay, and we will leave king's gifts to king's chemists, albeit a little Royal patronage would not be unserviceable to our science.

To return to our book; we may observe that the "Qualitative Analysis" of Fresenius is not so much in vogue as his "Quantitative Analysis," and this arises from the fact that there have arisen in our native chemical literature,—sparse though it be—various works on "Chemical Manipulation," and "Laboratory Practice;" again, many teachers adopt a special form of their own, based, perhaps, upon that of Fresenius, but differing in character and arrangement therefrom. Still it looks well to have a seventh edition of any work on chemistry in this country, and we wish Messrs. Bullock and Vacher further success. We would suggest in conclusion that the utterly inadequate index of *less than two pages* should at least be trebled in size in the next edition.

Dictionnaire de Chimie Pure et Appliquée. Par Ad. WURTZ. Paris: L. Hachette.

THE first *fascicule* of this work gives us some idea of its ultimate extent: although printed in somewhat small type, and in double columns, the 160 pages carry us only as far as Allyle. We shall review the whole work at length when it appears in its entirety, meanwhile, we propose rather to call attention to its general character than to give a review. M. Wurtz is assisted in his labours by no less than seventeen *collaborateurs*, among whom we notice the names of Debray, Emile Kopp, Lauth, and Naquet. The subject matter includes—Inorganic and Organic Chemistry; Chemistry applied to the Arts, Manufactures, and to Agriculture; Analytical Chemistry, and "La Chimie Physique et la Minéralogie."

We notice in this number an admirable article by M. Salet on "Affinity," terminated by a list of works relating to the subject which commences with the *Pyrosophia* of

Barchusen (1698). We almost think that such a list is incomplete without the *Physica Subterranea* of Beccher, the *Tractatus Quinque Medico Physici* of Mayow, and the *Fundamenta Chemiæ* of Stahl, but it must be allowed that the idea of affinity possessed by these men was excessively crude and indefinite. Perhaps Otto Tachenius may also be quoted as having a glimmer of the action of predisposing affinity. The article on "Air" by M. Le Blanc is unfortunately short, and does not make mention of the more recent researches on impure and vitiated air. M. Caventon supplies an article on "Alkaloids," and he herein furnishes a very complete list of these bodies, including some which can scarcely be called familiar; for instance, Chiococcine (*Chiococca racemosa*); Ménispermine (*Menispermum cocculus*); and Surinamine (*Geoffræa Surinamensis*). In a somewhat elaborate article on "Alcohols" by Kopp, a very good description (accompanied by woodcuts) is given of the various stills which are used in the process of manufacture, among them the ingenious *appareil Champonnois*. We shall return to this work on its completion; meanwhile, we have no doubt that it will be found in every chemical library.

CORRESPONDENCE.

OLEOGRAPHS.

To the Editor of the Chemical News.

Sir,—During some months past there have been sent to me various paragraphs from general and trade newspapers, prices current, penny magazines, &c., praising Dr. Moffat's oleographs as being valuable in the oil trade, to druggists, &c., and associating them with my name. I have this day seen a notice which states that Dr. Moffat's oleographs are based on the cohesion figures of Mr. Tomlinson, "published last year!"

In the Chemical News for the 11th December last, (vol. xviii., p. 284) I gave the history of my discovery, dating from 1861, and published in that year, and in your number for 29th January last (vol. xix., p. 59) I recorded my opinion of these oleographs. I stated that they are without distinctive characters, and are consequently valueless as oil tests.

Unless Dr. Moffat has wonderfully improved on the specimens he sent to me I do not understand how he can sanction, or, at any rate, allow to pass uncontradicted, the puffing paragraphs to which I refer. I have not the means or the inclination to get counter statements inserted in the journals referred to, but I do hope that after this second protest in your columns Dr. Moffat will use his influence to correct the misapprehension which must arise from such paragraphs.

The cohesion figures of liquids are in themselves oil-tests; but when transferred to paper, as in these oleographs, the resemblance between the figure of one oil and that of another is so close that they may be taken as identical, and they are, therefore, for practical purposes, useless, as friends of mine connected with the oil trade have proved.

While heartily wishing success to oleography, I cannot see much prospect of it in the present state of the art, and I am sure that Dr. Moffat would not wish to describe as a finished picture that which is only a rough, and by no means correct sketch.—I am, &c.,

C. Tomlinson.

Highgate, N., July 26th, 1869.

GASEOUS SPECTRA.

To the Editor of the Chemical News.

Sir,—Our attention has been drawn to a letter from Mr. W. Huggins, in your impression of the 9th instant, stating that, in a recent note to the Royal Society (in which we announced that, by varying the conditions of pressure and temperature, we had reduced the spectrum of hydrogen, as seen in our instrument, to one line absolutely, and the spectrum of nitrogen to one line nearly), we did not notice similar observations of his own presented to the Royal Society in 1868. In reply, we beg to state—First, that we did notice Mr. Huggins's observations, and, secondly, that they were not similar to our own.

With regard to the first point. The account you were good enough to publish contained the following:—"The bearing of these latter observations on those made on the nebulæ by Mr. Huggins, Father Secchi, and Lord Rosse is at once obvious. The visibility of a single line of nitrogen has been taken by Mr. Huggins to indicate possibly—First, 'a form of matter more elementary than nitrogen, and which our analysis has not yet enabled us to detect;' and then, secondly, 'a power of extinction existing in cosmical space.'

"Our experiments on the gases themselves show not only that such assumptions are unnecessary, but that spectrum analysis here presents us with a means of largely increasing our knowledge of the physical constitution of these heavenly bodies."

We thus gave briefly the results of Mr. Huggins's enquiries, and references to where a complete account of his observations were to be found. This we considered to be sufficient, seeing that our communication was a preliminary note only. In the complete account of our researches to be subsequently presented to the Royal Society we shall, of course, dwell upon them at greater length.

With regard to the second point—the similarity of the observations. In 1864, Mr. Huggins first observed the spectrum of the nebulæ, and determined that one of the lines was coincident with one of the air lines due to nitrogen, the spark being taken close to the spectroscope. On this Mr. Huggins wrote:—"The speculation presents itself, whether the occurrence of this one line only in the nebulæ may not indicate a form of matter more elementary than nitrogen, and which our analysis has not yet enabled us to detect." Some time afterwards, Mr. Huggins, instead of taking the air spark close to the spectroscope, placed it outside the object glass of his telescope, and then only saw one line in the spectrum—the line in question. He next got similar results close to the spark by interposing a dark glass to cut off the light, still using the spark in air at the ordinary pressure, and remarked that it was "obvious" that the hydrogen spectrum would give similar results. Then, after stating "we cannot suppose that any lines have been extinguished by the effect of the *distance* of these objects from us," he refers to the possibility of a "power of extinction residing in cosmical space," and the hypothesis of the more simple form of nitrogen appears to be given up.

Now, with regard to our own observations, we have *not* taken the spark in air; we have *not* used a dark glass; we have *not* worked at atmospheric pressure; nor have we disturbed the normal distance of the experimental tube from the slit of our instrument until we had reduced the complicated spectrum of nitrogen to one bright line and three or four other extremely faint ones. Further, we have *not* rested content with any assumption with regard to hydrogen, nor have we regarded anything as obvious.

What we have done is to carefully watch both spectra changing as the pressure becomes less, trying the effect of increased and decreased temperature at every stage under various conditions, which we shall state in our detailed paper.

It may be as well to refer, in conclusion, to Plücker's important work on nitrogen, which shows that, under certain conditions, the green line of nitrogen vanishes altogether from the spectrum. This fact alone shows at once the importance of our method of inquiry.—We are, &c.,

E. Frankland.
J. Norman Lockyer.

Royal College of Chemistry, Oxford Street, July 23, 1869.

MISCELLANEOUS.

Preservation of Protosulphate of Iron.—M. Welborn states that proto-sulphate of iron is absolutely preserved and kept from even the very least trace of oxidation, by placing with it a piece of camphor wrapped in a piece of clean and dry paper.—*Deutsche Ind. Zeitung.*

Preservation of Meat.—M. Georges recommends to place the meat into a bath containing 86 parts of water, 10 parts of common salt, 4 parts of glyceric acid or *acide vineux*, (glyceric acid is prepared by the author by mixing equal parts of glycerine, water, and hydrochloric acid; *acide vineux* is made in the same way, but instead of glycerine alcohol is added); after this fluid has become thoroughly soaked into the meat it is pressed and squeezed, and next covered with a layer of fat.—*Deutsche Ind. Zeitung.*

Action of Carbolic Acid on Reptiles.—We have been favoured with extracts from an account of some very valuable experiments made by J. Fayrer, F.R.S.E., C.S.I., &c., on the value of carbolic acid in preventing the entry of serpents into dwellings, from which we find that a few drops of the acid are sufficient to quickly kill full-grown cobras and other poisonous snakes. Dr. Fayrer is continuing his experiments on the merits of carbolic acid as a therapeutic agent in snake bite, and, in the meantime, he suggests its use as a preventive against the entry of snakes into houses, &c. Dr. Calvert informs us that it is probable that the acid will save life by applying it, in a caustic state, to the wound caused by the bite of a serpent, and more satisfactory results will be obtained by following the method first put into practice by Dr. Tessier in the Mauritius, for the cure of a virulent intermittent fever. In this case, by injecting under the skin a solution of three-quarters of a grain of carbolic acid dissolved in 20 minims of water, the patients were rapidly cured, and the spread of the pestilence arrested.

Experiments with Flame.—Dr. Hofmann, F.R.S.—Take a piece of canvas, such as is used by ladies for Berlin wool work, and put it on to the top of the superior opening of the glass chimney of an argand gas burner, taking care to envelope the glass chimney previously with a very thin piece of copper foil, while the access of air at the bottom of the burner should be as much as possible prevented. On turning the gas on, it escapes readily through the small openings in the canvas, and the gas may be ignited above. The canvas, however, soon takes fire and burns off, but leaves a very complete circular disc, which remains white and unconsumed in the centre of the frame. If it is desired to demonstrate more completely the nature of the flame, it is done by placing, on the middle of the canvas disc, some gunpowder, and on it the heads of some lucifer matches. After having again turned on the gas, and left it to escape for a few moments, it may be kindled again, and will burn quietly, and even though, as in the first experiment, the excess of canvas again burns off, neither the gunpowder nor matches will catch fire until just at the moment the gas is gently turned off. In order to exhibit the reducing action of the interior portion of a Bunsen gas flame, a spirally rolled-up piece of copper wire is held in the interior portion of the flame by means of a pair of forceps. When this spiral is taken out of the flame while red-hot, and exposed to contact of air, it becomes covered with a black coating of oxide of copper; but if the spiral, instead of being taken out of the central portion of the flame is lowered down into the current of gas, and there cooled, it will exhibit on, withdrawal, a clean and bright metallic surface.—*Berichte der Deuts. Chem. Ges. zu Berlin.*

CHEMICAL NOTICES FROM FOREIGN SOURCES.

In accordance with the generally expressed wishes of our friends and readers, we have effected arrangements to enable us to give, under the above heading, notices of EVERY CHEMICAL PAPER IN THE WORLD, *as soon as possible after publication. Whenever possible, these notices will appear in the form of carefully prepared, although necessarily brief, abstracts; as respects papers either too long or too abstruse to render condensation possible, their titles will be chronicled; and in all cases accurate reference will be made to the original publication. The two half-yearly volumes of the* CHEMICAL NEWS, *with their copious indices, will therefore be equivalent to an English edition of the "Jahresberichte," with the additional advantage of keeping the readers week by week on a level with the latest advances of science.*

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Programme de la Société Hollandaise des Sciences de Harlem, Année, 1869.

On the 15th of May, the general yearly meeting of this scientific society was held at Harlem. The meeting approved of the proposal made by a committee, to found two additional medals, each of the intrinsic value of 500 florins (about £42), one of which will bear the name and effigy of Huyghens, the other that of Boerhaave. These medals are intended to be given, every alternate two years, to those scientific men, native or foreign, who, by their researches, discoveries, or inventions, shall, according to the opinion of the Society, have most contributed, during the last twenty years, to the advancement of a specific branch of physico-mathematical, or natural history sciences. The Huyghens medal will be awarded, in 1870, to natural philosophy; in 1874, to chemistry; in 1878, to astronomy; in 1882, to meteorology; and in 1886, to mathematics (pure and applied). The Boerhaave medal will be awarded, in 1872, to mineralogy and geology; in 1876, to botany; in 1880, to zoology; in 1884, to physiology; and in 1888, to anthropology. The preliminary award shall be made according to the advice of a committee to be appointed by the directors of the Society, of which committee the secretary of the Society shall be a permanent member. The final award shall be made at the general yearly meeting of the Society, after it shall have discussed the report and heard the full explanation given by the committee just alluded to.

Among the questions open for competition, and to be answered on or before the first of January, 1871, we notice the following:—

The Society asks for an accurate description of all chemical or physical operations, whereby either accidentally, or as a consequence of direct experiments, chemical compounds have been obtained, which, by their chemical and physical properties, agree with native minerals. The Society does not desire that new minerals should be artificially formed, but simply an accurate and critical review of the results already obtained; while it is also requested that all the published and printed memoirs wherein such artificially-made minerals have been described shall be fully mentioned.

The Society desires a monograph on albuminous substances; this work to include an historical sketch of all the researches made concerning these substances, and a critical review of the divers opinions which, at the present day, are current in science in reference to these materials.

The Society desires that the co-efficients of expansion, by heat, of divers kinds of glass, and more especially the glass used for making thermometer tubes, be very accurately determined, according to M. Fizeau's method, for temperatures according to the centigrade scale, from −30° downwards to 500° upwards.

Since more recent researches appear to confirm the opinion that the substances known as hydrates of carbon are polyatomic alcohols, the Society desires that new researches be made in order to clear up and fully elucidate this point.

Since the accurate determination of temperatures above 350° is a matter open to great improvement, the Society has decided to grant its gold medal to him who shall succeed in the construction of a simple apparatus whereby temperatures up to 500° are correctly indicated.

The Society asks accurate determinations of the various indices of refraction of water, for at least 12 points of the spectrum, over a range of 50°.

It is well known that the Aurora Borealis causes telluric electric currents, which occasionally disturb the proper action of the electric telegraph wires; the Society desires that, on telegraphic lines of great length, the force of these currents be determined, and that it be also ascertained how far these currents extend towards the equator.

The two questions which the Society desires to receive replies upon, on or before the 1st of January, 1873 (both bearing upon natural history), we need not quote, but specially notice the following questions to which answers are expected on or before the 1st of January next, these questions having been propounded and published last year:—

Since it cannot be denied that spectrum analysis, now almost the order of the day, has been overrated, and its value exaggerated, it is desired that, in order, also, to obtain more sound views on this matter, that which is true and that which is false therein be equitably sifted; that the limits be stated up to which this method is of legitimate use, and beyond which it fails to be applicable; and, lastly, that a critical review be made of all facts brought to light by this branch of experimental research, and, also, that it be pointed out what science has to expect of its extended application.

The electric current heats the metallic conductor which is traversed by it; hence the resistance the current experiences is increased, and in this manner the current reacts on itself. We may, on the other hand, suppose that the intensity of the current modifies the value of this resistance by virtue of an action which does not directly depend upon the heating. It is desired that the influence exercised by the intensity of the electric current on the degree of resistance be investigated in both points of view just mentioned. Among the metals which seem to offer the best chance of success for this kind of investigation, mercury holds a prominent place.

The repetition, extension, and criticism is asked of the experiments concerning the electrolysis of the fused haloid salts (Faraday's "Experimental Researches," T.I., art. 538 and following, and 978 and following); also an *exposé* of the theories of the nature of electrolysis which can be deduced therefrom. Faraday's law of electrolysis is very simple; but the question is not yet exhausted, and the whole phenomenon is obscure. It is therefore desired that it should be rigorously decided up to which point the above-mentioned experiments are in opposition with this higher view, and aided by a great many facts, according to which no real electrolysis whatever should take place unless the action of the current be only exerted upon double salts, or upon combinations equivalent and analogous therewith.

According to M. G. Ville (see his *Revue des Cours Scientifiques*, 1868, No. 7, p. 103), nitrogen, in its free or elementary state should be assimilated by some kinds of plants, especially those belonging to the *Leguminosæ*; the Society therefore asks that this opinion be submitted to a critical examination, and that the truth or falsity of this opinion be fully made out on theoretical as well as on experimental ground.

In reference to the extremely interesting and highly-valued experiments of Mr. Graham, Master of the Mint, the Society asks for new researches on the absorbing and dissolving power of molten metals for hydrogen gas, especially with the view to determine whether there

do exist definite combinations of hydrogen and metals. The Society desires to have experiments made with various metals, in order to ascertain, with certainty, the fact whether the assertion that metals become transparent at a sufficiently high temperature holds good, or is to be rejected.

Since there yet exists a great deal of uncertainty on the subject of the cause of the phosphorescence of substances called artificial phosphori, the Society requests that a thorough research be made to establish the fact that this phosphorescence is only due to a slow oxidation.

Whilst the pressure of the air, the direction and force of the wind, and the temperature of the air are continuously recorded at the meteorological observatories, by means of self-acting and self-registering instruments, the degree of moisture of the air is as yet only recorded by a few isolated observations made at certain hours of the day-time. The Society desires the construction, either upon an entirely new plan, or according to the principles indicated (see *Poggendorff's Annalen*, vol. xciii., p. 343), of a self-acting or self-registering instrument for determining the degree of moisture of the air, and the publishing of results of observations obtained by means of such instrument for at least one half-year continuously.

The Society desires to recommend, to the competitors for prizes, to omit, in their answers to questions, any matters not directly relating to the proposed question; it is, moreover, desired that, whatever be sent into the Society should be worked out with precision, and that every proposition be well defined and demonstrated, and not mixed with vague theories or badly digested and not well established facts. The memoirs sent in must on no account whatever be written in the handwriting of the authors themselves, since, if even these memoirs might be worthy of the award of the medal, and it turned out that such documents were written in the author's own handwriting, no award whatever could be made, according to the Society's rules. The envelopes added to the memoirs sent in, and appended thereto by a peculiar mark, and containing the author's name, will, in case no award is granted, be destroyed by fire, unopened. The memoirs to be sent in for competition may be written in Dutch, French, Latin, English, Italian, or German languages, at the author's option, provided, in the case of the German language, the italic, and not the peculiar German mode of writing, be used. All such documents, and the envelopes appended thereto, and just alluded to, should be sent, carriage or postage paid, to Dr. E. H. von Baumhauer, the Secretary of the Society, residing at Harlem, North Holland, Netherlands.

The prize offered for a satisfactory memoir, or answer, to each of the proposed questions, is the Society's gold medal, value 150 florins (£12 10s.), bearing the author's name and the year of issue, or, if the author might desire it, the full money value of the medal; in some cases, it is left to the umpires of the awards to grant an additional award of 150 florins. The competitor to whose memoir a prize shall have been awarded may not, without the express consent and authorisation of the Society, print or publish, either in whole or part, separately or in any periodical, the memoir to which the prize has been awarded.

Polytechnisches Journal von Dingler, vol. cxcii., No. 5, first part for June, 1869.

We notice the following original papers and communications in this number:—

Researches made in the Laboratory for Technical Chemistry at Brunswick.

a. **Abnormal Behaviour of Saccharate of Lime.**—M. Waldeck. It is a well-known fact that the combination of lime and sugar yields, with cold water, a clear solution, which, on being heated, becomes turbid, or even gelatinises. A solution having been prepared, by mixing, with a solution of pure sugar in water, an excess of slaked lime, shaking this mixture, and afterwards filtering it; on heating this solution, no turbidity ensued at all. This phenomenon gave, of course, rise to further investigation, when it was found that the lime which had been applied in this instance was chemically pure hydrate of lime. On mixing some of the same sugar solution with lime as ordinarily obtained from lime-kilns, it was found to exhibit again the phenomenon of becoming turbid on heating. At first sight, therefore, it would appear as if chemically pure lime behaved differently with sugar solution from what ordinary lime does; but further investigation into this matter brought to light the fact that, owing to the necessity of obtaining a fresh supply of sugar, this substance, and not the lime, was the cause of this discrepancy. The author found that, although at first sight no difference could be detected in the refined sugars applied, yet the last-obtained sample behaved, both with the chemically pure and ordinary lime, in the same manner, yielding a solution which becomes turbid on heating; both kinds of sugar were refined white loaf sugar obtained from the same place and at the same price. Of the first sample, yielding abnormal results, unfortunately no more was obtainable, and therefore the matter remains in some obscurity; but those who are connected with sugar refineries might take this hint, and, perhaps find a valuable means of distinguishing between various samples of refined sugar.

b. **Manufacture of Soda from Sulphate of Soda and Oxide of Iron.**—M. Waldeck.—The author points out that the manufacture of soda from its sulphate, and by the intermedium of carbon (charcoal or small coal) and oxide of iron, would be, in many aspects, a great improvement upon the Leblanc process. He next mentions some experiments to illustrate his views on this subject. He took 105 parts, by weight (three atoms), of sulphate of soda; 40 parts, by weight (1 atom), of peroxide of iron; and 25 parts, by weight (eight atoms) of carbon. This mixture fused readily; treated with water, it yielded a solution which, on passing therein a current of carbonic acid gas, became quite clear, leaving only 2·79 per cent of insoluble residue. However fair the results these experiments gave on the small scale, the author is himself unable to solve a difficulty which, on the large scale, would be an absolute impediment to the action; to wit, that neither cast nor wrought-iron vessels—and, worse yet, no fire-clay crucibles, or furnaces built with fire-bricks—will stand the action which is called into play, leaving out of the question the necessity of absolute exclusion of air during the fusion.

On a Dolomitic Marl, and its Use in the Making of Cement. L. Gatschenberger.—In the neighbourhood of Heidelberg, a marl occurs which, after being prepared for that purpose, yields a cement of the following composition, in 100 parts:—Lime, 44·22; magnesia, 17·77; peroxide of iron, 3·07; alumina, 5·75; protoxide of manganese, 2·33; soda and potassa, 4·72; silica, 22·14. The author had the opportunity of experimenting with the marl itself; and he states—"I find there are two different modes of obtaining from this marl an excellent hydraulic lime—1st, to burn the marl at a temperature below 400°, whereby the magnesia only loses its carbonic acid, while that from the lime is not expelled; 2nd, to burn the marl at a very elevated temperature, whereby the material is even somewhat fluxed. In the first instance, the magnesia is the active matter, since I have found that it hardens under water with carbonate of lime perfectly well, but not with caustic lime. In the second instance, the magnesia loses, indeed, its hydraulic properties, but, instead thereof, its activity towards silica is so increased as to behave therewith as lime does in such cases. The author finds that the cement obtained by the application of the very high temperature, is preferable to the ordinarily-obtained hydraulic cements. A very good cement made at high temperature contains, for 100 parts of SiO_2,R_2O_3, 304 parts CaO,MgO, whereby the proportion between lime and magnesia is as 2 to 1.

On Alkanin.—Prof. Boettger.—The author states that M. Hirzel, at Leipzig, prepares alkanin, the extract of the alkanet root *anchusa tinctoria*, on the large scale. This extract is dissolved in absolute alcohol; and with this solution strips of Swedish filtering paper are saturated, and made use of, after drying, for detecting even the very faintest traces of ammonia. The alcoholic solution exhibits a beautiful red colour, which, even by the ammonia present in tobacco-smoke, or in illuminating gas, is instantly converted into a beautiful blue. The alcoholic solution and the test-paper have, of course, to be kept carefully excluded from all ammoniacal fumes. The red paper may be turned into blue by a very weak aqueous solution of carbonate of soda, and it then becomes an excellent test for even the faintest trace of any acid, turning red therewith at once.

Preparation of Pure Oxygen Gas at the Ordinary Temperature.—Prof. Bœttger.—The author says that, when a mixture is made of equal parts, by weight, of peroxide of lead and peroxide of barium, and there is poured on this mixture dilute nitric acid of a strength of 9° Beaumé, and specific gravity 1·067, a current of pure oxygen, free from ozone and antozone, is given off abundantly. The mixture of the two peroxides alluded to may be kept together in a stoppered bottle in dry state for any length of time.

Analysis of Palm-Nut Meal and Palm-Nut Cake.—Prof. Hohmann.—Palm-nut meal contains, in 100 parts—Water, 8·55; albumen, 19·56; fatty matters, 1·19; starch, 47·73 woody-fibre, 20·04; ash, 2·93. Palm-nut cake contains, in 100 parts—Water, 10·0; albumen, 15·1; fatty matters, 15·9; starch, 41·0; woody-fibre and ash, 18·0. These substances are obtained from the *Elaïs equienensis*, and used as fodder for cattle.

Vol. cxcii., No. 6, second number for June, 1869.

This periodical contains the following papers bearing upon chemistry, and sciences intimately allied thereto:—

Coating of Glass, Porcelain, or Earthenware with a Thin Film of Lustrous Metallic Platinum.—Prof. Bœttger.—Dry chloride of platinum, freed from excess of acid, is mixed, in a small porcelain mortar, with essential oil of rosemarine (*Oleum anthos*) until the original brown-red colour of the salt has entirely disappeared, and has been converted into a black, pitch-like looking mass. In order to effect this result, it will be necessary to renew the essential oil at least three times. When the pitch-like mass has been obtained, the oil is entirely removed, and the pasty mass is weighed, and afterwards mixed with at least five times its weight of lavender oil, and mixed therewith to a homogeneous fluid; this, after having been quietly standing for half-an-hour, is applied with a hair brush on the glass or porcelain objects to which it is desired to give a coating of lustrous platinum; and, after the very thinly and evenly laid on film is dry, the objects are either placed in a red-hot muffle, or heated in the flame of a glassblower's lamp, care being taken not to exceed a red heat.

Black Patina upon Zinc.—M. Neumann.—The author has instituted a series of researches to find out the best and most suitable material to produce upon zinc—or rather upon statuary and ornamental objects made of that metal—a pleasing blackish coating, without the necessity of impairing the effect of the natural colour of the metal, as would be the case when an oil-paint or varnish is used. The best results were obtained by the author when nitrate of protoxide of manganese was used: this salt, on being heated, is decomposed, yielding black peroxide of manganese, and the degree of heat required is not so high as to affect the zinc. To 1 litre of pure water, 54 grammes of the nitrate alluded to, and containing six equivalents of water of crystallisation, is, according to the author, the best solution for this purpose; and the specific gravity of that solution, at 14° R., is stated by the author to be 1·125.

Saponification of Fats when in the state of Emulsion.—M. Waldeck.—This paper confirms the results formerly obtained by M Mège-Mouriès. The author of this memoir points out that

forming an emulsion of fats by means of substances such as gum, for instance, would be impracticable for the manufacture of soap, entailing, as it would do, loss of lye as well as of the gum or other similar substance; he, therefore, in consequence of the results obtained by him in experiments expressly instituted, advises the use of alkaline lye for the purpose of forming emulsion; but, if that plan be resorted to for soap-making purposes, the use of distilled water is an absolute requisite, but, of course, no impediment at all, since, where steam is used, distilled water is readily enough obtainable. The emulsed fats are very rapidly and readily saponified.

Portuguese Graphite.—M. Knublauch.—In 100 parts, this material was found to contain—Water (hygroscopic as well as of combination), 10·21; carbon, 38·47; ash, 50·81.

Consumption of Divers Materials used as Substances for the Production of Artificial Light.—Dr. Willigk.—This paper, although very interesting, is too lengthy to admit of useful abstraction.

On a So-Called Disinfecting Soap.—Dr. Pincus.—The author very properly calls attention to an error committed by a chemist and a soap manufacturer, who state that they have succeeded in obtaining a soap which contains permanganate of potassa as an active and disinfecting ingredient. On investigation by the author, he found, as might be expected, that even the freshly made soap only contained oxide of manganese, and a mere trace of permanganate. This latter salt, of course, cannot be kept for any length of time in contact with an organic material, as soap is, without becoming decomposed. The soap was made by incorporating into well-made, hard soap, quite dry, and cut into shreds, powdered permanganate, and then forming this mixture into a cake by strong pressure.

Annales du Génie Civil, No. 6, June, 1869.

This periodical contains a lengthy paper—

On Wine.—M. Boucherie.—Composition of must and of wine the former contains—Sugar, a nitrogenous principle which is fit for; fermentation, ferment, or active yeast, a colouring matter contained in the skin of the grape, but, as yet, not dissolved in the liquid, and oxygen and nitrogen. Wine contains carbonic acid, a small quantity of grape sugar alcohol, amylic alcohol ($C_{10}H_{12}O_2$), butylic alcohol ($C_8H_{10}O_2$), propylic alcohol ($C_6H_8O_4$), campholic alcohol ($C_{20}H_{18}O_2$), several essential oils (the nature of which is not precisely known), oenanthic ether, aldehyde, valeric acid, acetic acid, butyric acid, glycerine, and the colouring matter of the skin of the grapes dissolved in the alcohol formed by the fermentation. Wine and must, moreover, constantly contain water, organic non-crystallisable matter, gum-like substances (as pectin and dextrin), mannite, and nitrogenous substances; and also the following crystallisable organic acids:—Tartaric, racemic, tannic, malic, pectic, and citric. No *free* mineral acids. The following salts of organic acids and inorganic bases:—Bitartrate of potassa, tartrate of lime, tartrate of alumina, malate of potassa, malate of lime, pectate of potassa, pectate of lime; divers acetates, further nitrates, phosphates, sulphates, silicates of the above-named bases, and also chlorides, iodides, bromides, and fluorides of these bases; while wine contains infinitesimal doses of soda, oxide of iron, alumina, oxide of manganese, magnesia, and ammonia. The quantity of alcohol naturally present in 100 parts of wine varies very considerably, and varies according to the locality where it is grown, the climate during the time when it was grown, and the variety of grape from which it is obtained. For red Bordeaux wines of average good quality, the quantity of alcohol varies from 8·10 to 10·85 per cent (the author does not state whether he means by bulk or by weight). For white Bordeaux wines, it varies from 9·25 to 15 per cent on average good wine and divers brands. For Burgundy wines (red variety), the quantity of alcohol varies from 10·10 to 13·09 per cent; white variety from 12·22 to 14·90. Good Roussillon contains about from 16·20 to 17·25 per cent of natural alcohol. White hermitage wine contains, on an average, 16·0 per cent of alcohol. Effervescing champagne contains 11·20 per cent of alcohol, while genuine port wine contains naturally from 22·50 to 23 per cent of alcohol, and marsala as much as 25·09 per cent. This alcohol, be it understood, is absolute and anhydrous.

The other papers of this periodical are devoted, as might be surmised from the title, to matters quite foreign to the subject just briefly abstracted, and of no direct interest to our readers.

Zeitschrift fur Chemie, von Beilstein, No. 11, June 26, 1869.

This periodical contains the following original papers:—

Synthesis of Crotonic Acid.—M. Stacewicz.—The author says—My starting point is taken from the well-known constitution of the acrylic acid series, and this made me expect to succeed in synthetically preparing crotonic acid, according to the scheme expressed in the following formulæ—

$$\left.\begin{matrix}C_2H_2\\H\end{matrix}\right\}ClO + C_2H_4Cl + 2Ag = C_2H_2(C_2H_3)\left.\begin{matrix}O\\H\end{matrix}\right\}O + AgCl.$$

The experiment was crowned with success, but the acid obtained differs from that prepared from cyanide of allyl. The mixture of chloracetic acid, chloraceten, and silver is heated, in a sealed tube, up to 140°, and, after the end of the reaction, the contents of the tube are submitted to fractional distillation. At 127°, an oily fluid is obtained, soluble in water, exhibiting a feebly aromatic smell; this fluid reddens blue litmus paper, and acts, when in contact with the skin of the human body, as a blistering agent. The silver-salt of this acid, $C_4H_3AgO_2$, is difficultly soluble in water, and crystallises in dendritic groups; the formula for crotonic acid is, therefore—

$$C\left\{\begin{matrix}H\\CH_3.CH_2\\O\\OH\end{matrix}\right.$$

On Chlorinated Toluidine, and a New Mode of Preparation of Bromobenzoic Acid.—M. Wroblevsky.—Chlorinated toluidine is prepared by passing through acetotoluid, $(C_2H_3O)HN.C_7H_7$, chlorine gas, whereby chloracetotoluid is obtained, which is purified by repeated re-crystallisation from its solution in water. This substance, which is composed according to the formula—

$$C_6H_3Cl.(CH_3).NH(C_2H_3O),$$

crystallises in large foliated crystals, fuses at 99°, is readily soluble in alcohol, less so in water; on being boiled with an alcoholic caustic potassa solution, acetic acid is formed, and chlorotoluidine—

$$C_6H_3Cl(CH_3)NH_2.$$

It is a colourless fluid, boils at 222°, is soluble in alcohol, but almost insoluble in water. From ortho-bromotoluol, a colourless liquid, which boils at 182°, the author prepared, by treating it with bichromate of potassa and sulphuric acid, ortho-bromobenzoic acid; this is a solid substance, which fuses at 153°, and then sublimes in long needle-shaped crystals, identical with those of the same compounds as obtained from benzoic acid.

On Sulphate of Lime and Potassa.—M. H. Struve.—This double salt was first discovered by M. Phillips, in the year 1850. The author of this paper says—When crystals of sulphate of lime are put into a saturated solution of sulphate of potassa at 12° (the specific gravity of that solution being 1·0716, and containing 9·41 per cent of the anhydrous sulphate of potassa), the crystals of sulphate of lime are soon converted into somewhat bulky pseudomorphic crystals of the double salt of sulphate of lime and potassa. When the solution of sulphate of potassa is more dilute, the change takes place more slowly; and when, in 100 c.c. of water, only 2·365 grms. of sulphate of potassa are dissolved, the sulphate of lime is simply dissolved therein without forming a double salt; burnt gypsum and native anhydrite behave in the same manner. The formation of similar double-salts takes place, but more slowly, when sulphate of lime is put into concentrated solutions of the chloride, bromide, and iodide of potassium; the same takes place with solution of nitrate of potassa.

New Mode of Formation of Anhydrite.—M. Struve.—100 parts of sulphuric acid (sp. gr. 1·82) dissolve, at ordinary temperature, 1·992 parts of artificial anhydrite (anhydrous sulphate of lime) and 1·953 parts of native anhydrite. When, to a quantity of 4 grms. of crystallised gypsum, were added 135 grms. of the same sulphuric acid, a solution was obtained which contains, for 100 parts of acid, 1·059 parts of $CaOSO_3$. When the solution of $CaOSO_3$ in SO_3HO is diluted with its own weight of water, a complete precipitation of gypsum took place after a time; no lime could be detected in the filtrate.

Preliminary Notices.—M. Wislicenus.—This paper treats briefly—

On Sulphaceton, and on the Conversion of β Oxybutyric Acid into Crotonic Acid.—As, however, the author states that his researches are as yet incomplete, and will be treated more fully hereafter, we abstain at present from further notice of them.

Researches on Piperinic Acid.—MM. Fittig and Mielck.—This is a lengthy memoir, chiefly treating on the products of oxidation of piperinic acid, which, when acted upon by permanganate of potassa in aqueous solution, yields a crystalline substance (formula, $C_8H_6O_4$), which body the authors called *piperonal*. It is difficultly soluble in cold water, more readily in boiling water, and very soluble in alcohol; it is in every way soluble in the latter fluid and in ether at the boiling temperature of these fluids. Piperonal fuses at 37°, and boils, without decomposition, at 263°. Piperonylic acid, $C_8H_6O_4$, is obtained in small quantity, simultaneously with the last-named substance, during the action of permanganate of potassa; moreover, piperonylic acid is readily obtained from piperonal by the action of permanganate. The acid just alluded to is a solid substance, crystalline, soluble in water and alcohol, fusing at 227·5°, subliming already below its point of fusion; it is a monobasic acid. Nitric acid acts most energetically upon piperinic acid, even when the former is dilute; the result of this reaction is the formation of an amorphous reddish-coloured substance, which baffled the efforts of the authors in obtaining reliable analytical results. After having, at great length, described the bromine reaction upon piperinic acid, the authors state that their researches are not as yet sufficiently complete to enable them to speak with confidence about some of their results.

Synthesis of Acids Homologous with Cinnamic Acid.—MM. Fittig and Bieber.—According to M. Bertagni's statement, cinnamic acid is formed when oil of bitter almonds is heated with chloride of acetyl; relying on this fully borne out statement the authors thought that when, instead of acetylchloride, homologous chlorides were taken, homologues of cinnamic acid would be formed; this idea has been experimentally tested, and the authors met with correct results; when equal equivalents of oil of bitter almonds and butyryl chloride are mixed and heated in sealed tubes, first to 100°, the reaction takes place, but only slowly; at from 130° to 140°, the reaction is more rapid, but yet takes several days for its completion; an acid was obtained of the formula, $C_{11}H_{12}O_2$, which the authors have named phenylangelic acid, because it stands in the same relation to cinnamic acid as angelic acid stands to acrylic acid; the quantity of acid obtained in this reaction is very small, the greater portion of the oil of bitter almonds being converted into a blackish resin, insoluble in solution of carbonate of soda.

On Ethyl-Phenol.—MM. Fittig and Kiesow.—Ethylphenol is prepared in pure state from ethyl benzol sulphate of potassium, which is

submitted to distillation at from 270° to 280° after having been mixed with thrice its weight of hydrate of potassa; the purification of the raw product thus obtained is a slow and tedious process; at length a solid substance, partaking of a regular crystalline form and fusing at about 48° is obtained; this body is the ethyl-phenol—

$$C_8H_{10}O = C_6H_4 \begin{cases} C_2H_5 \\ HO \end{cases}$$

it boils at 210°, but volatilises even at ordinary temperature.

On Amido-Benzoic and Nitrophtalic Acids.—M. Faust.—When nitrophtalic acid is reduced by means of tin and hydrochloric acid, amido-benzoic acid is formed, which is in every respect identical with amido-benzoic acid obtained by other means; it is a crystalline solid, containing, in 100 parts, C, 61·3; H, 5·1; O, 34·6. The author says he desires to rectify a statement made in a former number of this periodical, wherein he described as an ether what has afterwards been ascertained to be nitrophtalic acid—$C_8H_5(NO_4)O_4.C_8H_8.H$.

Conversion of Aldehyde into Aceton.—M. Schloemilch.—The author states, as a preliminary notice, *pour prendre date*, "I have succeeded in doing what is indicated under this heading, but am as yet occupied with further researches on this subject." This observation also extends to the contents of the brief notices of the following subjects:—

On Lepides and Oxylepides.—M. Limpricht.

On the Bromo-Substitution Products of Dibenzyl.—Same author.

Synthesis of Anhydrous Lactic Acid.—Dr. Von der Brüggen.—The author says, when anhydrous lactic acid is considered as being an ether, it follows that it must be possible to obtain this acid by the action of bromo-propionic acid on lactate of potassa; this, the author states he has actually carried out experimentally. His paper, however interesting, is so filled with formulæ, exhibited somewhat in the style of genealogical tables, that it would take up more room than we can afford, and therefore content ourselves with announcing in this brief notice the scientific *fait accompli*.

Preparation of Oxalate of Acetonin.—M. E. Mulder.—Aceton is added to sulpho-carbaminate of ammonium; the crude sulpho-carbaminate of acetonin thus obtained is washed with alcohol of 90 per cent, next dissolved in water, precipitated by means of perchloride of mercury, filtered; H_2S is passed through the filtrate; the latter is evaporated to dryness on a water-bath, the residue treated with absolute alcohol (which leaves $ClNH_4$ undissolved, and keeps hydrochlorate of acetonin in solution): water is next added, then again evaporated to dryness, the residue treated with $C_2O_4Ag_2$ in excess, filtered, the filtrate again evaporated to dryness, and afterwards exhausted with absolute alcohol until nothing more is dissolved; the oxalate of acetonin deposits from the solution and is purified by re-crystallisation; it exhibits a beautifully crystalline mass. Formula—

$$C_2O_2.C_9H_{20}N_2O_2 + 2H_2O.$$

The following are only preliminary notices on the respective subjects, of which more full research is going on:—

Kreatin and Aldehyde.—MM. Mulder and Moutheran.

Action of Bromine on Butyrate and Valerianate of Silver.—M. Borodin.

Isomers of Valerianic Acid.—Dr. Schneider.—The remainder and smallest portion of this number is, as usual, devoted to abstracts from divers papers, *Comptes Rendus*, &c., which are chiefly of last year's date, and already noticed by us.

No. 12, June 30, 1869.

This number does not contain any original papers at all, but we find in it some communications taken from a paper or periodical published in Switzerland, but, as stated, only printed for private circulation among the members of a society for the diffusion of useful knowledge, established at Zürich. The first of these papers is on the

Solutions of Iodine in Water and Aqueous Solution of Iodide of Potassium.—Messrs. Dossios and Weith.—The authors prepared, in the first place, perfectly pure distilled water, and employed pure iodine, free from chlorine, which they dissolved in the water, and which they ascertained to be, by means of volumetrical estimation with hyposulphite of soda, 0·01519173 grm. of iodine in 1000 c.c. of water. They found this quantity of dissolved iodine increased already after two days, and gradually increasing more and more, so much so that, about three months after having been first made, the solution contained nearly twice as much iodine. The authors ascertained the presence of hydriodic acid, conclusively proving that decomposition of water takes place. The authors also instituted a series of experiments to ascertain whether solutions of iodine in aqueous solutions of iodide of potassium are chemical combinations, or simply mixtures. The result of their experiments is not favourable to the idea that these solutions should be chemical combinations, since it is readily possible to withdraw the iodine from these solutions not only by simple solvents of iodine, but even by the passing through of a current of air. From some quantitative experiments made with perfectly pure materials, it appears that, at a temperature of 7·9°, and with solutions wherein the quantity of iodide of potassium varies from 1·802 to 12·643 per cent, the quantity of pure iodine thereby dissolved ranges from 1·173 to 12·060 per cent.

Combinations of Ammonia with Cyanide of Silver and Sulphocyanide of Silver.—M. Weith.—The author says that, when cyanides in solution are treated with ammoniacal solution of silver, a crystalline compound of cyanide of silver and ammonia, $CNAgNH_3$, is obtained, which, either on exposure to dry air, or by being placed in water, loses the ammonia; but this compound is, after all, the author states, a true combination, and not a mixture. Sulphocyanide of silver and ammonium, $CNS.Ag.NH_3$, is obtained when sulphide of silver is dissolved in warm and concentrated ammonia. It is a crystalline solid body, which is readily decomposed on exposure to air, but which may be heated up to 200° when surrounded by ammonia solution.

Behaviour of some Double Cyanides towards Ammoniacal Solution of Silver.—M. Weith.—With the view of separating the cyanogen from ferrocyanide of silver by means of peroxide of mercury, according to a plan published by Prof. Rose, the author of this paper found that this decomposition only takes place very incompletely and slowly. The same was observed when it was tried to decompose the aforesaid ferrocyanide by means of hydrate of potassa. The decomposition is, however, very readily and completely effected by boiling the ferrocyanide of silver with liquid ammonia; in that instance, the iron is separated as oxide; while the solution contains cyanide of silver and cyanide of ammonium—

$$Cy_2FeAg_4 + 2NH_3 + H_2O = FeO + 4AgCy + 2NH_4Cy.$$

The author calls attention to the fact that it is stated that ferrocyanide of silver is insoluble in liquid ammonia. This is right to a certain extent; but even in the cold, and more so on being gently heated, this fluid will exhibit, after filtration, and on addition of a few drops of dilute sulphuric acid, a more or less copious precipitate of cyanide of silver. When ferrocyanide of silver is mixed with an ammoniacal solution of nitrate of silver, instead of with ammonia only, and heat is applied, the iron is separated as oxide; while from this solution the whole quantity of cyanogen may be separated, on addition of a few drops of dilute nitric acid, as cyanide of silver. Ammoniacal solution of nitrate of silver behaves with ferro- and ferricyanides of potassium, with ferrocyanide of iron (Berlin blue), and other similar compounds (cobalticyanide of potassium inclusive), in a similar manner. Ferrocyanide of copper, however, cannot be treated in this manner, since the presence of copper gives rise to separation of silver in the metallic state.

The subject matter of all the other papers contained in this number has been treated in our columns already.

Journal de Pharmacie et de Chimie, June, 1869.

This periodical contains the following original papers:—

Researches on Protoxide of Nitrogen in Solution.—M. S. Limonsin.—The author says that the great solubility of this gas in water, especially if its temperature is rather low, induced him to try what the physiological effects of such a solution would be upon men (the author himself) and upon animals. With the main portion of his paper (being, strictly speaking, a chemico-physiologico experimental essay) we will not occupy ourselves. The solution of the protoxide of nitrogen in cold water, and obtained under ordinary pressure of the atmosphere, tastes sweetish, and decidedly saccharine, if, by means of pressure, water has been made to absorb a large bulk of this gas; as might be expected, this solution is readily decomposed by substances capable of taking up oxygen. The main point of importance in this paper is the anæsthetic action of the gas and solution alluded to.

Action of Chloroform upon Frommhers's Fluid.—M. Beaudrimont.—Frommherz's fluid is the *cupro-potassic tartrate*. The author's paper contains the results of some experiments made with the view to prove that, when even a very small quantity of chloroform—for instance, two drops—are mixed with 100 c.c. of water, and there is added thereto a small quantity of the double tartrate of potassa and copper, reduction of the latter takes place almost instantaneously when gentle heat is applied. The author has based upon this property a volumetrical method for the estimation of chloroform; and, notwithstanding the great volatility of that fluid somewhat interferes, the author has succeeded in his object. One equivalent of chloroform (119·5) reduces four equivalents of copper; 10 c.c. of Frommherz's liquid, containing 0·15 grm. of metallic copper, required 12 c.c. of a solution of chloroform, containing 1·195 grms. of chloroform, for 100 c.c.; while, of a solution of chloroform of twice the strength just stated—to wit, containing 2·39 grms. for 100 c.c.—just 6 c.c. were required.

Arsenical Aniline Reds—Aniline Red of M. Coupier prepared without Arsenic.—M. Roussin.—This being rather a practical receipt than a scientific memoir is not well suitable for abstraction.

The remainder of this periodical is filled, partly with abstracts from the *Comptes Rendus*, already noticed by us, and partly with papers relating to toxicology and *materia medica*.

NOTES AND QUERIES.

Testing Acetic Acid.—Can any of your correspondents oblige me by giving through your columns the readiest means of testing the purity and strength of acetic acid.—A. A.

Pattinson's Method for Extracting Magnesia from Magnesian Limestone.—The magnesian limestone is calcined at a dull red heat for some time. By this process the carbonic acid is expelled from the carbonate of magnesia only, but not from the carbonate of lime, which thus remains insoluble. The calcined mass is next reduced to a milk, with water, in a suitable cistern, and the carbonic acid resulting from its own calcination forced into it under powerful pressure. The result is a saturated solution of magnesia, the lime remaining unacted on so long as the magnesia is in excess. The solution, by evaporation, yields heavy carbonate, whilst carbonic acid gas is expelled and may be again used in the same manufacture. Our correspondent should bear in mind that only magnesian limestones can be thus operated upon.

THE CHEMICAL NEWS.

VOL. XX. No. 506.

THE SPECIFIC GRAVITIES OF LIQUIDS AND SOLIDS THEORETICALLY CONSIDERED.

By Dr. J. G. MACVICAR, Moffat, N.B.

IT is generally understood that Euclid shaped his Elements expressly to the end that ultimately he might be able to demonstrate the properties of the regular polyhedra, whose importance in every system of morphology he saw clearly; while Plato flew at them directly as the very forms of the elements of Nature. There is, therefore, nothing contrary to the traditions of philosophy in its highest walks in the supposition that the forms of the molecules of bodies, when they have been so far perfected as to have become individualised, possess the forms of the regular polyhedra. Now, if we suppose that the ultimate material element or unit of atomic weight or force is the same in all substances whatever—a supposition which has, also, the highest sanctions of philosophy in its favour, and which, though set aside for a time, begins again to be more and more favourably considered every day—and adopt the law of symmetry as the law by which these units of weight shall aggregate into groups or molecules which shall be more or less stable, we shall be conducted, by the progress of the synthesis, whether we will or no, to these regular polyhedra as the forms and structures in which that synthesis culminates, and specially to the *tetrahedron*, the *icosahedron*, and the *dodecahedron*, which are intimately related to each other.

Nor is there anything to be regretted in this conclusion; on the contrary, it is impossible for any one who has mastered the details of chemistry considered as a science of phenomena, and not of hypothesis, not to perceive—if he will but consent to look at that which implies a great revolution in this science—that this doctrine of polyhedral molecules explains a multitude of facts and phenomena, which, in all the lights the hitherto amorphous chemistry can bring to bear upon them, are utterly dark, and merely matters of wonder.

But, instead of indulging in general statements, let us prove this statement in reference to the weights of bodies, one of their most important physical properties. It will be admitted that the popular chemistry can tell whether a liquid or solid is light or heavy only after having weighed it either by the hand or the balance. Why a piece of sulphur should weigh less than twice as much as an equal volume of water, while a piece of zinc, whose atomic weight is about the same as that of sulphur, should weigh more than seven times as much, and, indeed, generally, why the weight of any body should be what it is, and not otherwise, chemistry can assign no reason. It has, indeed, a hypothesis of atomic volume by which (though not without continual embarrassments) specific gravities may be calculated; but that atomic volume is itself a function of the specific gravity as ascertained by weighing the substance; it is, therefore, merely a complication, not an explanation.

Now, the molecular philosophy which is here advocated solves the problem of specific gravities in the most satisfactory manner; for it does so not by introducing any new formula on this subject into science, but solely by the extension to liquids and solids of the law by which the specific gravities of aëriforms have been calculated ever since the days of Gay Lussac. Having found the right molecules which constitute liquids and crystals (the regular polyhedra, namely), it shows that their volumes tend to be equal, and either actually are equal or in a simple ratio to each other, just as has been long ago found in the case of aëriforms.

I have had occasion already to name sulphur: I will show the truth of what I have now affirmed in reference to sulphur and its companion oxygen, two elements which, after hydrogen itself, are the first to show themselves in our synthesis of the elements.

In the nascent state, they are so related morphologically that they may be viewed as the complements of each other, and the reciprocal forms of the same materials. They have accordingly in this their primal state the same atomic weight, and that is 8 when hydrogen is taken as unity. But so defective is the single atom of oxygen in a proper length of axis that, as often as two meet in the same neighbourhood, they must, under the law of symmetry, couple on the same axis; and thus the unit volume of oxygen gas will weigh $2\times8=16$ when $H=1$. Similarly so defective is the single atom of sulphur (which, to prevent confusion, we may call sulph) in its equatorial region that each atom must tend to fix three others into this region; so that sulph is to be expected in nature usually in tetratoms, the atomic weight of the tetratom being $4\times8=32$, which is an atom of sulphur, a state of things which it will be desirable to indicate in symbols, thus—

The tetratom of sulph, $S_4=\dot{S}$, one atom of sulphur.

And here I may remark that, in constituting the tetratom, the atom of sulph has come to constitute a form which is more highly oblate or negative than the single atom was prolate or positive; so that in order to lengthen the axis tetratoms, when rising into the aëriform state, tend to form unit volumes, not consisting of two atoms merely, as in the case of normal oxygen gas, but three, as in the case of that ozone which weighs 1½ times as much as oxygen gas; a mode of association being normal in the case of sulphur (except at a high temperature) which is exceptional in the case of oxygen.

If it be asked how do I come to know, or, at least, to believe, all that, the answer is that I have done so by thinking upon the subject during the leisure of a lifetime, keeping thought all the time abreast of the phenomena of nature and the laboratory. You say it is all a mere imagination, not entitled to the regard of men of science. Well, if you say so after having given this communication a fair reading to its close, I shall leave you, without further molestation, to the free enjoyment of your opinion.

I am now to deduce *à priori* the specific gravity of sulphur and its well-known combinations with hydrogen and oxygen. It is necessary only to premise further that of the two orders of forms—the trigonal and the pentagonal—under one or other of which all terrestrial elements are included, sulphur and hydrogen belong to the trigonal, oxygen and most other elements to the pentagonal. Hence, sulphic and sulphuric molecules and those in which atoms of hydrogen are centrad, must be icosahedral or tetrahedral, for, in these polyhedra, the facets are triangles, while oxygen and most other elements tend to form dodecahedral molecules, for in these the facets are pentagonal. With regard to water, whose molecule gives the unit volume for specific gravities, it is doubly trigonal (hexagonal), whence it tends to stretch out into laminæ rather than to turn round into molecules; and to constitute one particle of water no fewer than 36 atoms of vapour are required, the atomic weight of the aqueous unit consequently being $36\times9=324$, when $H=1$. No doubt without such evidence as I cannot here reproduce, you will refuse to believe all this. But you will perceive that this reference to the weight of the unit volume of the aqueous element is not necessary to substantiate the fact of my being able to deduce the relative weights of liquids and solids. It is only necessary to enable me to present specific gravities in the usual form, that is, in relation to water as unity. And here I may mention that in giving specific gravities it is usually unnecessary to go beyond the second decimal place, because even it depends on the temperature of the experimental determination as

also on peculiarities of internal molecular structure and action which we cannot enter into.

Sulphur.—Its atomic weight is 32; its form is of the trigonal order. Its molecule of culmination is therefore icosahedral, and its volume may be inferred to be normal, that is, equal to the unit volume of water, which is the great assimilative agent on the terraqueous globe. This gives—

Sulphur $G = \frac{\$_{20}}{AQ} = \frac{20 \times 32}{324} = 1{\cdot}96$. Exp. 1·96. 2·0

Here, then, we deduce the specific gravity of sulphur, as found by the balance. I have shown also that the dimorphism of the crystals of sulphur and its plasticity, when fixed by sudden cooling under molecular change at a certain temperature, are involved in the form of this element.

Hydrosulphuric Acid.—The form of the atom of sulphur being oblate or negative, it comes to pass that, in order to lengthen its axis, it must tend to fix an atom of hydrogen on each pole, giving $H\$H = H_2\$$, which is the well-known formula of sulphuretted hydrogen. Now, of this combination, as of sulphur itself, the molecule must be icosahedral, for an atom of H must be centrad, and H is trigonal as well as \$. But the molecule, consisting as it does of 20 parts, and with three elements stuck into the axis of each, must be much larger than merely the icosatom of sulphur. Allowing, then, to this molecule that which after one in simplicity of ratio comes next to one, viz., two normal or aqueous volumes, we obtain for—

Hydrosulphuric solid $G = \frac{(H\$H)_{20}}{2AQ} = \frac{20(1+32+1)}{2\times324} = 1{\cdot}05$

Now this fœtid gas when forced down into a liquid has been estimated at 0·9, and the solid has been found to sink in the liquid. Our theoretical specific gravity may therefore be regarded as accurate. But in these forced liquids and solids it is impossible to know how much aëriform matter may be included in them, increasing their bulk without a proportional increase of weight. For this reason I shall pass lightly over sulphurous acid also. Our theory gives 1·58 as its specific gravity. The liquid has been estimated at 1·45, and the solid was seen to be heavier. The theoretical number may therefore be accepted.

Sulphuric Acid, or Anhydride.—The combination SO_3 of the most modern notation is $S_4O_6 = \$O_6$ of ours. Its form is so oblate that if two come into the same neighbourhood they must couple, giving $\$O_{12}\$ = 2SO_3$ Auct. And here we obviously have the proper molecule of oxygen, namely, the dodecatom as the body of the combination, carrying a tetratom of sulph or an atom of sulphur on each pole differentiating that dodecatom. Now, these molecules are so large that if they were to form into icosatoms, as their trigonal poles would oblige them to do, they would be out of all keeping with the unit volume of water. Rather than the last of the trigonal series of polyhedrons, then the icosahedral, let us expect the first, viz., the tetrahedral molecule; we thus obtain—

Sulphuric acid $\frac{(\$O_{12}\$)_4}{AQ} = \frac{4(32+96+32)}{324} = 1{\cdot}97$. Exp. 1·97.

The tetrahedral molecule presents itself in the case of other analogous substances, that is, differentiated dodecatoms composed in great measure of elements tending to the free or aëriform state. Thus the strongest (monohydrated) nitric acid by doubling the chemical formula, as usual, gives $N_2O_{10},2HO$, which, when written symmetrically, gives—

Nitric acid $G = \frac{(HONO_{10}NOH)_4}{AQ} = 1{\cdot}55$. Exp. 1·55. 1·52.

But to return to sulphuric anhydride—

Such a structure in the terraqueous globe must necessarily be very restless, and though it is found in nature (taurocholic acid, &c.) as well as has been constructed in the laboratory, the combination of sulphur and oxygen usually stops in the production of sulphates, or, as I should say, sulphurates, which are very finely differentiated, and, therefore, very stable combinations, secure from the further attacks of oxygen by being already covered on the poles by the oxygen of the metallic oxide which enters into their composition. Following the mineralogists in using a dot for an atom of oxygen, some idea of the structure of an element of a sulphurate may be given thus—

A sulphurate .. .. $\overset{\cdot\cdot}{\underset{\cdot\cdot}{OM\$MO}} = M_2SO_4$ Auct.

Their poles being oxygens their molecules must be dodecatoms. And as they have all undergone a severe ordeal these dodecatoms may be expected to be differentiated by the fixing of a single element of the sulphurate on each pole. Taking three of the most familiar sulphates of nature, if you make the calculation you will obtain the following results—

Anhydrite.. $G = \frac{(Ca_2SO_4)_{1+12+1}}{AQ} = 2{\cdot}95$. Exp. 2·90.

Celestine .. $G = \frac{(Sr_2SO_4)_{1+12+1}}{AQ} = 3{\cdot}97$. ,, 3·95.

Barytes .. $G = \frac{(Ba_2SO_4)_{1+12+1}}{AQ} = 4{\cdot}64$. ,, 4·70.

It is time to remark, however, that both in nature and the laboratory the atom of sulphur often resolves itself into the four atoms of sulph of which it consists, and thus we have sulphous and sulphic acids as well as sulphurous and sulphuric. The presence of moisture especially assists in this partitionment. Taking sulphuric anhydride as the type in the absence of moisture, then, on the access of moisture to it, an atom of aq may be expected to attack and to fix itself on each of the four summits of the four atoms of sulph which constitute the poles. And after this it is only to be expected that the differentiated dodecatom, now rendered too diffuse, shall break up into four atoms of di-hydrated sulphic acid or glacial oil of vitriol, which, therefore, we must regard as the normal or most natural hydrate.

Glacial Oil of Vitriol.—It may be shown that one of its poles is sulphic and the other aqueous. Its molecule may therefore possibly be either the icosatom, consisting of 20, or the aqueous, consisting of 36 elements. But of these the latter plainly could not endure the high temperature of boiling oil of vitriol. Its molecule therefore must be icosahedral. Now

Glacial Oil of Vitriol $G = \frac{(SO_32HO)_{20}}{2AQ} = 1{\cdot}79$. Exp. 1·75.

When, however, this acid is produced in the cool of nature, and its stability increased by the incrustation of the molecule by lime, we obtain evidence that the aqua-form molecule has been constructed, the sulpho-calcic molecule being so large as to occupy four aqueous volumes. Thus—

Gypsum $G = \frac{(CaOSO_3.2HO)_{36}}{4AQ} = 2{\cdot}39$. Exp. 2·3. 2·4.

As to the strongest oil of vitriol which can be obtained by boiling, it has been observed by the best chemists that they cannot drive off the whole of the second atom of the water which is in the glacial acid. It has been observed that, strange to say, just 1-12th of an atom of water remains for every atom of monohydrate obtained. Now, here, when viewed in the light of our molecular morphology there is nothing strange. An atom of moisture has just twelve points or summits to which such bodies as atoms of oil of vitriol could attach themselves. And what has happened under the heat and violence of the long-continued boiling is obviously this, that the icosatoms of the glacial acid have been broken up, and the single elements of oil of vitriol, thus set free, have gathered round particles of moisture as nuclei, each atom of Aq being competent to accommodate 12 atoms of oil of vitriol around it.

That this is the true interpretation of the phenomenon is proved by the specific gravity. Thus—

Strongest oil of vitriol } $G = \frac{(SO_3.HO)_{12} + Aq.}{AQ} = 1{\cdot}843$. Exp. 1·843.

That there are sulphurides and sulphides also, as well as sulphurates and sulphates, is shown by the same test.

Sulphuride of zinc $\frac{(Zn\S Zn)_{1+12+1}}{AQ} = 4{\cdot}15$. Exp. 4·16.

But the same formula applied to galena gives G = 10·34, or, possibly, 5·17 if occupying two normal volumes, while the balance gives G = 7·4. Now, placing the metal as the body of the molecule and an atom of sulph in each pole (which must give the same percentages on analysis), we obtain—

Sulphide of lead $\frac{(SPbS)_{20}}{AQ} = 7{\cdot}4$. Exp. 7·4.

I only add that selenium comes out as baric, and tellurium as barytic sulphur, and that thallium comes out as one of a series of five metals, of which lead, gold, cadmium, indium, are other members, the body of the atom of thallium being an icosatom of sulph, and the poles atoms of sodium welded on that body.

ON

HEAT TREATED AS A SCIENCE OF KINETICS.*

By G. F. RODWELL, F.C.S.

(Concluded from p. 54).

IV. (ABSTRACT).

THIS lecture was entirely devoted to radiant heat: the principal definitions are given below.

If a mass of matter possessing a greater amount of molecular motion than the matter around it (a heated ball of metal, for example) be placed in a space devoid of all directly recognisable matter (a vacuum), it is found that it rapidly loses its motion until it assumes the temperature of proximate surrounding bodies; and, inasmuch as that motion proceeds in straight lines in every direction, like the radii of a circle, the action is known as *radiation*, and the motion thus transmitted as *radiant heat*. (*Radius*, a rod, the spoke of a wheel, related to *ραβδος*. *Radio*, to emit beams, to shine, is not unfrequently used by the Ancients; thus Lucretius "*rubent radiati lumina solis*").

It is impossible, *à priori*, that in this case there can be direct transmission of heat by conduction (Lecture III.) or by convection (Lecture III.). The motion is not communicated to visible and readily-recognisable matter, but to that infinitely subtle matter called the *ether* or *interstellar* medium (*Αιθηρ* of the Ancients—Lecture I.); and it is believed to travel in progressive waves, that is, such waves as are produced when a long cord fixed at one end is rapidly jerked up and down. There is no transference of matter, only of motion; and each particle of the ether actuated by the motion moves at right angles to the direction of transmission. (The belief in the existence of a matter infinitely more subtle than air has pervaded philosophy from the very earliest times; it is distinctly enunciated in several of the older systems of Hindoo philosophy, at least 900 years B.C. It appears in Greek philosophy—most notably in that of Aristotle; and many of the Middle Age systems are founded upon this assumption. In the "Materia Cœlestis" of Descartes, we have the ether endued with various properties, inducing conditions of physical change; among others, he has assigned to it the production of all motion, an idea which accords well with Aristotle's derivation of *Αιθηρ* from *αει* and *θεω*. In the "Phlogiston" of Stahl, we have the ether endued with various properties, inducing conditions of chemical change, the chemical phase of the "Materia Cœlestis." In some form or other, the assumption is essential to physical philosophy; for without it all radiant actions would be quite inexplicable. In support of the existence of the ether, we have—(*α*) Various phenomena connected with light, as has been shown by Euler, Huyghens, Young, and others; (*β*) the shortening of the path of Encke's comet, the period of revolution of which is 3¼ years, which is diminished by about 0·11 of a day at each revolution; and it is probable that all the visible motions of the Universe are likewise becoming lessened by the same resistance; (*γ*) the experiment of Foucault on the production of heat by the rotation of a copper disc between the poles of a magnet).*

Radiant heat is closely related to light; indeed, we have every reason for believing that the motion which constitutes heat is only a slower form of the motion which constitutes light; in a word, that the difference is one of degree rather than of form. Thus, if we heat a mass of metal, it gradually assimilates molecular motion until, at a certain point (*red heat*), it emits light, and the more motion it receives, the more intense does the light become, until at length it emits white light (*white heat*). Again, when light is decomposed by a prism, that is, when the various ether waves which, in virtue of difference of oscillation, constitute differently coloured lights, are separated, so that waves of one definite velocity appear in one definite place, it is found that, beyond the slowest waves of light, there are waves of radiant heat of extreme power.

Radiant heat is capable of *reflection* (*reflecto*, to turn back); and it obeys the same laws as light. Reflection may be defined as the turning back of the ether waves by molecules which cannot assimilate the motion thus conveyed; as when a cord is fixed to a rigid body, and caused to undulate, the wave which travels along it stops when it reaches the fixed end, and then returns, because the rigid body is incompetent to assimilate the motion which the molecules of the cord convey. (This is well illustrated by causing waves to propagate themselves by rapidly jerking a cord of hemp or india-rubber fixed at one end; the cord may be from 4 to 6 millimetres in diameter; or a small brass chain, from 5 to 10 metres in length, may be advantageously employed. It should be fixed horizontally, the room darkened, and a beam of light from the electric or oxyhydrogen lamp should be caused to illumine the path of the chain. Communicated undulations are now seen with great clearness to travel to the fixed end of the chain, and, finding there nothing which can assimilate the motion, to return as a reflected wave. The undulations of a row of particles can be shown by fixing at one end a broad and lengthy band of paper, and communicating undulatory motion, as in the case of the cord. The paper best adapted for this purpose is a kind of thin drawing-paper, sold in lengths of 36 feet, and 3½ feet broad. In regard to the mirrors to be used for showing the reflection of heat, it is quite essential to success that their axes should coincide *perfectly* (in the experiment, for example, in which a hot ball of metal is placed in the focus of one mirror, and the bulb of a differential air thermometer or a thermo-pile in the focus of another and distant mirror): this can only be the case when the curves are similar, when their centres are in the same horizontal plane, and when the lines joining the opposite extremities of each curve are parallel. The focus may be indicated to the audience by allowing a cylinder of rays of light, of the

* A course of four lectures delivered at the London Institution.

* The experiments of Balfour Stewart and Tait on the production of heat by the rapid revolution of a disc *in vacuo* appeared to support the hypothesis of an ether; but a paper in the *Philosophical Magazine* for this month (January, 1869) traces the production of heat to other causes than ethereal friction. The velocity of an ether particle must be inconceivably great, since it has been calculated by Clausius that the velocity of a particle of hydrogen at the freezing temperature is 6050 feet per second; and the ether must be conceived to be infinitely less dense than hydrogen.

same diameter as the mirror, to fall upon it, while some fine dust, such as lycopodium or a little volatilised chloride of ammonium, is diffused in the air in front of the mirror; the precise position for the thermometer in the succeeding experiment of reflected heat is thus indicated. The mirrors should be parabolic, not spherical; that is to say, their surface should be generated by the revolution of an arc of a parabola about its axis, not by the revolution of an arc of a circle about the radius which unites the middle of it to the centre of the circle to which it belongs. The smaller mirrors which are sold in this country for experiments on radiant heat are, for the most part, spherical; but very good parabolic mirrors can be obtained in Paris).

Radiant heat is capable of being *refracted* (*frango*, to break up; akin to *ραγω*); that is, the motion of the ether waves may be turned, by their passage through certain media, so as to proceed in a different direction, and in an extended form.

The *absorption* (*absorbeo*, to swallow up, or devour) of heat is the reception of the motion from the ether by molecules of matter. It is thus a reverse action to reflection; for absorption pre-supposes that the molecules of the absorbing body readily assimilate the motion. Such molecules may be represented by small wooden balls suspended in the path of a cord, which latter, when caused to undulate, communicates its motion to the balls. (This action may well be shown by fixing a tense india-rubber cord in such a way that its ends may be free; this can be done by connecting it with four rigid supports by thick string, which is fastened near each extremity, and passes away to the supports, making an angle of about 60° with the cord. This tense cord represents a row of particles of ether. A leaden ball, about 3 centimetres diameter, is suspended by two strings, so as to cause it to oscillate in one plane, the end of the india-rubber cord being the limit of vibration in one direction—that is, the oscillating ball can be caused to impinge upon one end of the tense cord. At the other end of the cord, and in various positions along its path, small wooden balls, about 3 centimetres diameter, are suspended. When the oscillating leaden ball strikes the tense cord, the latter is thrown into vibration, and communicates motion to the small balls in contact with it, thus illustrating both radiation and absorption; for the lead ball represents a molecule radiating heat (viz., communicating its motion to the ether), while the wooden balls represent molecules absorbing heat (viz., receiving motion from the ether). These illustrations may appear crude, but they at least assist an audience to realise some more or less obscure molecular actions, and a mere statement of them is scarcely sufficient).

Of the total radiation of the sun, only $\frac{1}{2,300,000,000}$ths is received by the earth. In one year, the amount of heat thus received would liquefy a layer of ice 100 feet thick, covering the entire surface of the earth. With the exception of the energy of tides (that is, the energy derived from the ebb and flow of the tides, which results from the attraction of the moon, and tends to diminish the energy of the earth's revolution), the sun is the source of all our available energy—the energy of food and fuel, of water and air in motion. The most dominant attractive forces against which this energy is exerted are—(α) *Gravity*, the attraction existing between the masses of matter (Lecture I.); (β) *Chemical affinity*, the attraction existing between dissimilar molecules of matter (Lecture I.); and (γ) *Cohesion*, the attraction existing between similar molecules of matter (Lectures II. and III.) This last,—that is, the energy expended in the internal work of a mass of matter (Lecture III.),—enormous as it is, is obviously unavailable to mankind.

The concluding remarks are given below *in extenso*.

The phenomena of the Universe, infinite as they are in variety, in form, in magnitude, and in effect, appear to be almost all produced by the interaction of attractive forces with forces of motion, the former tending to produce conditions of stability, the latter conditions of instability. These forces undergo a ceaseless round of change, in which their form alone is altered, while their actual energy, whether it be kinetic or potential, remains the same; for the sum of the energy of the Universe is a constant quantity. Circular motion may become elliptic; elliptic motion may become rectilinear; molecules may possess individual motion, or they may move in groups, or they may be actuated by both motions simultaneously; or, again, they may be influenced in innumerable ways by contiguous molecules, which may lessen their motion in one direction and augment it in another, and may change its form, intensity, character, or duration; but, throughout all these changes, the actual initial amount of energy is present in some form or other. The changes are precise and definite, and they follow unvarying and immutable laws; does it not, therefore, appear reasonable that the Pythagoreans made the most prominent feature of their philosophy the belief that unity and law and an eternal harmony prevail in the affairs of nature?

In the foregoing lectures we have briefly considered one of the dominant motions of the Universe; and we have seen how it is generated, how it influences matter, and how it passes into other forms. From first to last, we cannot fail to have noticed that it is most inimical to rest; that it ever tends to convert a condition of rest into a condition of, at least, temporary unrest. Indeed, we are almost disposed to regard *it*—a motion of molecules—as a condensed form of the motion of masses, since we have learnt that an increase of warmth in a mass of matter too slight to be felt, truly represents a force competent to lift that same mass to a height of many hundred feet; and the old Parmenidean dogma that heat is the cause of all the motion in the Universe* appears more reasonable than ever before. Not only has heat become a science of kinetics, but physical science itself is daily becoming more kinetic in its character, and there can be no doubt that other of the so-called physical forces besides light and heat will, sooner or later, be resolved into forms of motion. I have before spoken of the physical philosophy of Descartes as, perhaps, the most comprehensive kinetic system which has appeared in the whole history of science; and I am often reminded that, in our treatment of certain branches of science (specially in that of heat), we follow closely in his footsteps; in fact, our modern physical philosophy may almost be called *Neo-Cartesianism*. It is much to be wished that we adopted the Cartesian metaphysics to the same extent, in place of the pernicious Positivism† which now prevails. The philosophic spirit of the age tends towards the establishment of a syncretism between the philosophy of matter and the philosophy of mind; and, while the former has scarcely been elevated by the means, the latter has undeniably been degraded and materialised. A moment's comparison with the Platonic philosophy will convince us of this. The Positivists would have us apply to both mental and physical philosophy the same laws and the same modes of treatment; they would have us believe that only which is capable of direct demonstration; they would make the intellect infallible, and the senses all but infallible, forgetting how utterly relative is all our knowledge, and how we necessarily judge of things more in relation to ourselves than in relation to the great Universe around us.‡

* Parmenides, of Elea, according to Aristotle, Diogenes Laertius, and others, propounded this idea. It was afterwards adopted by Telesius of Cosenza, and other Middle Age philosophers, and in a modified form by Descartes.

† A good account of the most modern phases of Positivism is given by Ravaisson in his "Philosophie en France au XIXieme. Siècle."

‡ The following extract from the treatise "De Sapientia Veterum" of Francis Bacon would appear to be peculiarly applicable to a certain sect of philosophers of our day. At the same time, we do not wish to give to the word φιλοσοφος the same significance as did some of the Greek Fathers—S. Chrysostom, for example, in his charmingly eloquent Ὁμιλια εις Ευτροπιον. Pentheus, it will be remembered, hid himself in a wood, in order to be a spectator of the hidden mysteries of a Bacchanalian revel, but, being perceived, he was smitten with a

It is a hard, unyielding philosophy, which weakens some of the finer attributes of our nature, and destroys faith; it is a philosophy which engenders intense intellectual pride, for it induces our finite intellect to place itself on a level with Infinite Intellect. Rather than this, I say, let us adopt the Cartesian philosophy, and take, as our first principle of certainty, *Cogito ergo sum.** "To think," says a learned divine of our day, "is to see the chain of facts in creation, and, passing along its golden links, to find the hand of God at the beginning, as we saw his handiwork in its course."† In this spirit did Descartes think; in this spirit did he propound the first proposition of his system—"Cogito ergo sum."

The path of pure and divine philosophy is rugged with mounds which men have raised from time to time in the hope of seeing further than their fellows—back into the past, forward into the future; and many of these contain within them the festering remains of dead philosophies, which the world has buried out of her sight for their very loathsomeness. Albeit travellers often ascend these lofty tombs, allured by the hope of getting a clearer view of the distant land they seek; and, when they reach the summit, they are wearied, the time is far spent, and, as the light of day fades from their eyes, and darkness obscures the road, they lie them down, and rest side by side with the corpse of the philosophy which has seduced them. Almost at the outset of our journey, we pass a neglected mound, upon which the traveller has long ceased to rest; and it bears, in nearly effaced characters, the names of Gorgias and Protagoras. Near it, we see a greater eminence, raised by Socrates, and augmented by Cynics, and Megarics, and Cyrenaics. A very mountain bears the name of Aristotle. Many such mounds we pass; some overgrown with underwood, from which peep the ruins of forgotten shrines; some covered with asphodels and cypresses, some with myrtles and with bays, while others, again, are mere morasses, dangerous to tread upon, and rife with disease. Such an one is seen in a misshapen mound, reeking with decay, and too loathsome to approach; the home of vultures, and of ghouls, and of unclean beasts; and it bears the names of Diderot, La Mettrie.‡ Somewhat near to this, we see an eminence which, although new, is gigantic in its proportions; it is the resort of innumerable travellers of every race and of every creed, and they help to raise it higher, for they would fain climb to heaven by its means; and upon it we read the name of Auguste Comte. But what graceful peak rears its head sublime above the plain? it pierces the very clouds; it is clothed with amaranths, and it bears upon its summit a fane dedicated to Immortality. Lo! the calm, the sovereign, the ineffable spirit of Plato dwells therein. Here, as *we* travel along the path of philosophy, let us rest; here let us throw down our burden of modern Positivism, and then start afresh, Platonised in spirit and in thought.

kind of frenzy, one result of which was that he saw everything double and thus vacillated between the unreal and the real. A detail account of his doings is given both by Euripides and by Ovid, and the force of the following passage will be scarcely realised unless the reader be familiar with one or other of these accounts. "Alia est Penthei calamitas. Qui enim ausu temerario, mortalitatis parum memores per excelsa Naturæ et Philosophiæ fastigia (tanquam arbore conscensa) ad mysteria divina adspirant, iis pœna proposita est, perpetuæ inconstantiæ, et judicii vacillantis, et perplexi. Cum enim aliud sit lumen Naturæ, aliud Divinum; ita cum illis sic, ac si duos Soles viderent. Cumque actiones vitæ et decreta voluntatis ab intellectu pendeant: sequitur etiam ut non minus voluntate, quam opinione hæsitent nec sibi omnino constent: Itaque et duas Thebas similiter vident. Per Thebas enim actionum fines describuntur (cum Thebis Pentheo esset domus et perfugium). Hinc fit, ut nesciant, quo se vertant, sed de summa rerum inc erti et fluctuantes, tantum subitis mentis impulsibus in singulis circumagantur."

* "Sic autem regicientes illa omnia, de quibus aliquo modo possumus dubitare, ac etiam falsa esse fingentes; facilè quidem supponimus nullum esse Deum, nullum cœlum, nulla corpora; nosque etiam ipsos non habere manus, nec pedes, nec denique ullum corpus; non autem ideo nos qui talia cogitamus nihil esse: repugnat enim, ut putemus id quod cogitat, eo ipso tempore quo cogitat, non existere. Ac projinide hæc cognitio, *Ego cogito, ergo sum*, est omnium prima et certissima, quæ cuilibet ordine philosophanti occurrat."—*Principia Philosophiæ*, lib. i., p. 7.

† "The Limits of Philosophical Inquiry," an address delivered to the Members of the Edinburgh Philosophical Institution, on November 6th, 1868, by William, Lord Archbishop of York.

‡ The "Système de la Nature" of La Mettrie is one of the most vilely assumptive and irrational works which has appeared in the whole history of thought. Published during the most gross and rampant period of French materialism, it aimed at the destruction of ideas spiritual, ethical, and philosophical, which have ever been inseparable from the human mind; which have been cherished by races the most diverse in every age and every civilised country. Ideas which belong as much to Koung-fou-tzeu, to Zoroaster, and to the Vedic Brahmans as to Plato, Socrates, and Seneca, or to the thinkers of our day.

PROCESS FOR DETERMINING THE CARBON CHEMICALLY COMBINED WITH IRON.*

By Professor EGGERTZ,
Director of School of Mines, Falun, Sweden.

WHEN steel or pig-iron containing carbon in chemical combination is dissolved in nitric acid, a soluble brown colouring matter is formed whose colouring power is quite intense, and the solution assumes a tint which is dark in proportion to the quantity of the chemically-combined carbon.

Iron and graphite (or free carbon) do not influence this colouring; for the solution of nitrate of iron is colourless, or, at most, slightly greenish, unless extremely concentrated, and graphite is insoluble in nitric acid.

Thus, in dissolving two pieces of different steels of the same weight in nitric acid, taking care to dilute the darker solution until the two liquids present exactly the same colour, it is very evident that the more highly carburetted steel will furnish the larger quantity of liquid, and that the proportion of the volumes will indicate the relative proportion of colour in the two steels.

If now the composition and content of carbon of one of the steels is known, the absolute percentage of carbon in the other steel may be immediately deduced.

Suppose that 1 grm. of each of two steels (*a* and *b*) have been dissolved, and that the volumes of the two solutions brought to the same degree of colouring bear the relation to each other $a : b :: 5 : 7$. Knowing that the steel (*a*) contains 1 per cent carbon, you at once deduce that the steel (*b*) contains 1·4 per cent of carbon.

In applying this method of analysis, certain precautions must be taken, which we proceed briefly to point out.

In a cylindrical test-tube, dissolve gradually in the cold 10 centigrammes of wrought-iron, steel, or cast-iron reduced to a fine powder, in 1½ to 5 c.c. of nitric acid of 1·2 specific gravity (about 25° Baumé). The use of nitric acid containing hydrochloric acid must be avoided, because the solution of iron would have a yellow tint.

In proportion as the metal contains more carbon, more nitric acid must be used. After some time, when the chief part of the metal appears to be attacked, place the tube in a water-bath to the depth of about 15 m.m., and warm it to 80° C. In this position, only the lower part of the tube is in contact with the warm water; a movement takes place in the acid which favours its reaction upon the metal; a slight disengagement of carbonic acid from all the particles of carbon may be observed. The operation should always be conducted under the same circumstances as to heat and length of time.

The evolution of gas having ceased (in operating upon steel, the reaction must continue two to three hours), place the tube in a large vase filled with water, to bring the solution always to the same temperature. This precaution is indispensable, because the same liquid is darker when warm than when cold. Afterward, pour off, as exactly as possible, the clear liquid into a graduated burette. Upon the black residue remaining in the tube, pour some drops of nitric acid, and heat carefully over a lamp. If there is no further liberation of gas, the residue

* From the *Bulletin of the Chemical Society of Paris*; translated for the *American Journal of Science* by J. Wharton, Esq.

consists of nothing but graphite or silica. Cool the new solution, and add it to that which is already in the burette.

The liquid is then diluted with water until its colour corresponds exactly with that of the normal liquid, which latter should be of such a degree of concentration that each cubic centimetre represents 0·0001 grm. of carbon.

If, for instance, this normal liquid is prepared from cast-steel containing exactly 0·85 of one per cent of carbon, 1 decigramme of that steel must be dissolved in 8·5 c.c. of nitric acid; 100 grms. of steel containing 85 centigrammes of carbon would thus be dissolved in 8500 c.c. of the normal solution, 100 c.c. of that solution would represent 1 centigramme of carbon, and, consequently, 1 c.c. of the normal solution would represent 0·0001 grm. of carbon.

The normal solution does not keep, and should be often renewed, since it becomes perceptibly paler even within twenty-four hours. For it, however, may be substituted a dilute alcoholic solution of sugar properly caramelised brought to exactly the same tint; this solution keeps much longer without sensible change.

As 1 grm. of iron cannot readily be dissolved in less than 15 c.c. of nitric acid, it follows that a proportion of carbon less than 0·15 of one per cent* cannot be estimated by means of the normal liquid; but this minimum is seldom found in practice.

If the proportion of carbon exceeds 0·5 of one per cent, the ferruginous solution is so concentrated that it has a light greenish tint, which renders its comparison with the normal liquid difficult. In that case, a normal liquid of one-third the strength is prepared by diluting the normal liquid with twice its volume of water; then each cubic centimetre of the liquid represents only one-third of the ten thousandth part of a gramme of carbon. When the proportion of carbon in the specimen to be analysed is very large (as, for instance, in white cast-iron), only 0·5 grm. of the metal must be taken for analysis, and, in that case, half a cubic centimetre of its solution corresponds to a cubic centimetre of the normal solution. If the metal to be analysed contains graphite, the latter must be collected on a filter before the solution is put into the burette.

This method is more exact in proportion as the percentage of carbon is smaller. With an accurate balance, and with suitable arrangements, a great number of determinations of carbon close enough for practice can be effected in a time relatively very short.

All the Bessemer steel made at Edskin, in Sweden is marked, after hammering (*apres l' étirage*), by figures expressing its hardness, as ascertained by this colour-measuring analysis of Professor Eggertz.

It is obvious that only burettes of perfectly colourless glass must be used, or, at least, they must all have exactly the same tint.

* O. D. Allen, of the Freedom Iron Works, Pennsylvania, has found it quite practicable, by a modification of this method, to distinguish between irons containing respectively 0·10 and 0·15 of one per cent of carbon.

NOTICES OF BOOKS.

What is Matter? By an Inner Templar, Author of "More Light: a Dream in Science."

We are informed by his biographers that when the author of "The Raven" composed his extraordinary lecture on Cosmogony, he started by denying that the arcana of the universe can be explored by induction. He informed his imagination with the various results of science, and then "entered with unhesitating boldness, though with no guide but the divinest instinct, into the sea of speculation, and there built up of according laws and their phenomena, as under the influence of a scientific inspiration, his theory of nature."

But Poe, although a poet, was, in his lucid intervals, well aware of the difference between poetical speculation and hard scientific truth, and, with characteristic audacity and clearsightedness, dedicated his work "To those who feel, rather than to those who think." Poe's work was in perfect logical harmony with the rules he laid down for himself as a poet, and we therefore accept it. The work before us is in logical harmony with no laws human or divine, and we therefore reject it. When a man writes nonsense and, by publishing it, challenges criticism, it is our duty to consider whether, "though it be madness, there is method in it;" and we are forced to admit that there is method in the work before us—but not much.

When a man writes nonsense, we are also bound to consider the tone in which he writes it. If he offers us his views on the more difficult problems of the universe, and those views are obviously incorrect, still, if propounded modestly, and argued cleverly, we receive them for what they are worth, and are loth to handle their author too roughly. But the views of the author of "What is Matter?" are neither propounded modestly, nor argued cleverly, and we therefore do not feel bound to be specially lenient to him.

Doubtless the Inner Templar considers that to fairly review his book, we should analyse each chapter *seriatim* and disprove his arguments as they arise; this, however, is impossible. A long review of such a work would not only be unreadable but utterly useless, and we think that if we convict our author of want of modesty, of want of judgment, and of ignorance of the subject on which he writes, we have done as much as can be expected under the circumstances.

When a man feels that those problems which have puzzled the wisest of mankind are to him easy of solution, we can forgive him for being (for a short time) so elated as to be moved by a crowd of foolish impulses, and if, in addition, he finds that all physical phenomena, including the secret of the nature of matter, are to him as self-evident things, we can forgive him for believing himself the wisest of mankind. But, on the other hand, if we find him announcing almost incredible discoveries, as revelations from an angel, and describing the revealer and the manner of the revelation in language of that childishly pompous character which our American friends stigmatise as "high falutin," we begin to doubt whether such absolute want of judgment can co-exist with superhuman clearsightedness.

The first announcement of the work before us was contained in a pamphlet called "More Light," which we noticed a few weeks ago, and we feel bound, after again looking at it, to say that it was one of the silliest productions ever written; and yet *The Tablet* (we quote from the opinions of the press) considers itself bound to "do the writer the justice to say, that his brief narrative is pleasantly written, and constitutes a lively contribution to a class of works rarely attractive to any but scientific readers." We feel bound to do the writer of the notice in the *Tablet* the justice to say that the only redeeming point in his notice is the fact that he offers "no opinion as to the scientific value of this little treatise." In fact, it is most unpleasantly written, and constitutes anything but a lively contribution to a class of works rarely attractive to any readers whatever.

"What is Matter?" is a neat little octavo volume of 195 pages. It is excellently printed on good paper, and all rights are reserved.

The work is divided into three books, each of which is sub-divided into chapters, and there is a very complete table of contents.

The first book is principally devoted to a sketch of the opinions of the principal philosophers of antiquity, and we need not say that the continual repetition of such names as Thales, Anaximenes, Diogenes, Heraclitus, Anaxagoras, Zenophanes, Pythagoras, Empedocles, Leucippus, Socrates, Plato, Aristotle, Epicurus, Zeno., &c., &c.,

gives an air of dignity to the work which we hasten to acknowledge.

In Chapter VII. we come to a discussion on the views of Faraday, and Dr. Daubeny is severely handled for deficiency of imagination, and prejudice, and we are told that "It is painful to notice how he clings to existing notions, and appeals to common sense." We shall show further on that the last mentioned fault of the lamented Professor is one which can never be justly urged against our Inner Templar. Our author is not nearly so dogmatic upon some of the questions he discusses as might be expected from the favoured pupil of Oriel (see "More Light" *passim.*) In examining the question as to whether interplanetary space is on vacuum or a plenum, Sir John Herschel is quoted as of opinion that the sun is in a continually excited electrical state, which may account for the tails of comets being always directed away from the sun. "But" says our author "this loses a great deal of its force, as that which produces the plenum is ether; but when a vacuum is produced by experiment, it is always supposed that the vacuum is a plenum so far as the ether is concerned, for no pump has ever been constructed which touched that point, and, in fact, if the vacuum be not a plenum of ether, what becomes of the undulatory theory, for light passes through a vacuum, as is very clear, or we should not be able to see a light on the other side of the receiver, and it must on that theory have ether to be set in vibration. And if we suppose the vacuum to be a plenum of ether when the air is removed, we have had two plena occupying the same space, which, surely, is not orthodox; and if it be argued that the ether was hidden in the pores of the air, how is it that this ether continued to stay behind when the air was driven out? If, then, every vacuum must be a plenum of ether, as the undulatory theory requires, and electricity will not pass through such a vacuum; it seems clear that light and electricity differ greatly, for it appears that electricity requires *ordinary* matter for its medium, but light not. May not, then, electricity be regarded as a sublimating of ordinary matter, and light such matter sublimated? for electricity produces light, but it does not appear that light must necessarily produce electricity. Altogether, what with plena, and vacua, and ether, the subject is in as highly organised a state of confusion as the bitterest opponent of the undulatory theory could wish for."

We have made this long quotation solely that it may not be said that we have condemned a book without sufficient reason. Is it too much to say that the "highly organised confusion" is in the bewildered brain of the Inner Templar? The query as to whether electricity may not be regarded as a sublimating of ordinary matter, and light as such matter sublimated is charming, and will, we trust, be put to "Oriel" at his next meeting with our author.

We must, absolutely, make one more quotation. Our author, speaking of a ray of light proceeding from the sun, says, "Such a ray, I conceive, consists of a continuous stream of atoms travelling with different velocities, and at the same time revolving with different velocities upon axes at right angles to their line of projection. These particles are but ultimate atoms of the different forms of matter existing in our solar system, and, though so minute as to be beyond all power of weight, have, I doubt not, a considerable influence in renewing the energy which is being continually expended by our globe. This incessant pouring of millions upon millions of ultimate particles of the elements into our atmosphere, and into even the solid body of the earth, must, I think, greatly assist in explaining not only the almost universal presence of sodium —doubtless the chief cause of the yellow rays of the sun— but the presence of many other forms of matter which exist to such an extent in the atmosphere that it has been remarked that, in a cubic yard of air, might be traced the presence of almost every elementary substance. And, again, in regard to the ocean, which occupies three-fourths of the surface of our globe, who can say that the floods of light poured into its depths ages ago, when the sun's power must have been much greater, not to mention its present influence, may not have had a great effect upon its constitution—we know how its temperature is affected—and greatly contributed to the presence of those metals—especially sodium—which are a part of its constitution?" When we remember that, in "More Light," our author distinctly asserts the original matter to be nothing revolving upon an axis, that he also, in this work, states that he regards light to consist of the ultimate atoms revolving upon axes, and that these atoms are beyond the power of weight because they are so small, and that the sodium in the sea is derived from the sun's rays, we think we have proved to every reasonable person that our author is devoid of judgment in general, and that he is ignorant of the subject upon which he writes. As regards his modesty, let us quote one more paragraph from the author's "conclusion." "I have not hesitated to take the heterogeneous mass of materials supplied by every eminent man from Thales to Kant, and out of it to construct an edifice which, harmonising in all its parts, will, I trust, defy all the insidious workings of time with all the power that either talent can produce or ingenuity afford; but it is to the labours of Snellius, Newton, Faraday, and other great workers in the scientific world, that I am chiefly indebted." We ask our readers if this is not without a parallel in scientific literature?

In conclusion, there is internal evidence in "More Light" and "What is Matter?" to show that the author is a very young man. He has read much, and is by no means devoid of enthusiasm and a certain kind of cleverness. He is, however, unfortunately utterly devoid of modesty, and will, therefore, not accept advice. If he would, he might even now, perhaps, become a useful labourer in the field of science. Let him, instead of making a childish boast of never having made a single experiment, let him, we say, take up a physical or chemical question and experiment upon it earnestly and faithfully, and his mind will become disciplined, and, possibly, in his maturer years he may even acquire modesty. If he wishes to learn a great truth, let him experiment upon a subject which he has made all his own. Let him take pure water and see if, by passing the sun's rays through it, he can condense the chloride of sodium; if so, it is evident that, by the aid of "more light," he will obtain sea water. When he has condensed enough salt to be detectable by the spectroscope we will revise our review, retract our strictures, and unreservedly follow the Inner Templar as our guide, philosopher, and friend!

Revue Scientifique et Industrielle. Par EMILE KOPP, Professeur du Musée Royal et Industriel Italien à Turin. Extraits du *Courrier du Bas-Rhin.* Strasbourg: 1869.

IN this work—in which, (as somebody says) there is a thin rivulet of text meandering through a broad meadow of margin—we find nine articles, three of which, on "*Le Blanchissage Domestique*" we cordially recommend to the notice of housewives in general, and of all foreign nations —especially Sicily—in particular. Why M. Kopp has given this prominence to the subject we are at a loss to imagine unless he has fond recollections of *Blanchisseuses de fin*, and *Closerie de Lilas.* At all events, he has done good service, and shown an utter absence of pride by descending from the lofty heights of organic chemistry to the washing of linen; and what an astonishingly practical man he his! He treats of "*Inconvenients d'un trop riche Assortiment de Linge*," which, it must be confessed, few have discovered; he treats of *savonnage*, *rinçage*, *azurage*, *tordage*, and *sécharge.* We have found a frequent appeal to the dictionary necessary, and sometimes useless; let any of our readers tell us off-hand the English of *essangeage*: we had not the least idea that the French language was so rich in ablutory words, and we accept it as a happy omen. M. Kopp *must* become the hero of laundresses from his admirable ideas of economy; look here, for instance— "A la vérité le savon bien sec, surtout le bon savon de

Marseille, se dissout bien moins rapidement, et on realise ainsi une économie notable." Will some *bon savant* tell us all about "le bon savon de Marseille?"

The other articles treat of the "Anomalous Properties of Water," of "Meteorites," of "Explosive and Fulminating Substances," of "Fire Arms," of "Nitroglycerine," and of "Gun Cotton." They contain, for the most part, a good *resumé* of recent research in connection with each subject, and may be perused with advantage.

CORRESPONDENCE.

ROYAL SULPHUR SPRING, HARROGATE.

To the Editor of the Chemical News.

SIR,—In my communication on the above spring, published in your valuable journal of the 16th of July (CHEMICAL NEWS, vol. xx., p. 26), by some mishap I omitted the analysis; it is appended:—

Saline Ingredients in the Imperial Gallon.

	Grains.
Carbonate of lime	18·649
Carbonate of magnesia	1·783
Carbonate of baryta	0·291
Carbonate of strontia	trace
Chloride of sodium	538·180
Chloride of potassium	3·103
Chloride of calcium	32·327
Chloride of magnesium	27·872
Chloride of barium	0·494
Chloride of strontium	trace
Chloride of lithium	faint trace
Sulphide of sodium	9·135
Iodides, bromides, &c.	traces
Total grains per gallon	631·834

—I am, &c.,

SHERIDAN MUSPRATT, M.D.

College of Chemistry, Liverpool,
July 26, 1869.

OLEOGRAPHS.

To the Editor of the Chemical News.

SIR,—Having been from town, I have only to-day seen the CHEMICAL NEWS, and I beg you will allow me to reply briefly to Mr. Tomlinson's letter in reference to oleographs. Like every other new and valuable discovery, oleography is praised, and by others condemned. Oleography is yet in its infancy, and, just as a new and perfect process for the ultimate analysis of a complex organic substance cannot be devised in—it may be years, so we cannot expect perfection at once in this beautiful method for testing oils. I can assure Mr. Tomlinson that it is no fault of mine that he is pestered with numerous paragraphs from all varieties of journals condemning oleography. I never sent any article to one of them but the CHEMICAL NEWS on the subject, nor have I seen them. My opinion is yet the same that oleography is, in its present and very much improved state, an excellent conjunctive test for the purity of oils. No one can doubt for a moment, who has really worked at the subject carefully, that an oil figure on water can be transferred in an instant, perfectly uninjured, to paper. In the examination of trade oils, besides using oleography to assist me, I also employ the following among other tests:—

Appearance, gravity, taste, odour, rate of passage through narrow tubes, weak and strong solutions of potassic, sodic, and ammonic hydrates; shaking the oil, rise in temperature with hydric sulphate, boiling in alcohol, boiling point, burning in lamp, freezing point, passing chlorine, calcic hydrate, euchlorine, calcic hypochlorite, mercurous nitrate, hydric phosphate.

I trust Mr. Tomlinson is satisfied that I have no desire to associate his name with oleography further than to acknowledge that his name is intimately connected with cohesion figures. At many lectures I have given, here and elsewhere, in which I introduced oleography, I always took care to mention Mr. Tomlinson's name while referring to cohesion figures only. I perfectly agree with him in not wishing to describe oleography as having arrived at perfection. It is quite a young art yet; it has fulfilled all I have said, and it promises greater things.—I am, &c.,

R. CARTER MOFFAT.

Laboratory, Glasgow Mechanics' Institution,
August, 4th, 1869.

MISCELLANEOUS.

Hallogenin.—Under this name is sold in Germany a mixture of salts intended to prevent the formation of incrustations in steam-boilers. The mixture consists of 65 per cent of sal-ammoniac, 17 per cent of chloride of barium, and 18 per cent of catechu; it is said to answer its purpose very well.—*Deutsche Ind. Zeitung.*

Removal of Nitrate of Silver Stains from Woven Tissues.—According to M. Grimm, chloride of copper completely removes, even from coloured woven cotton tissues, stains occasioned by nitrate of silver; the tissue is to be afterwards washed with a solution of hyposulphite of soda, and next thoroughly washed with water. From white cotton and linen tissues, nitrate of silver stains are more readily and effectively removed by applying dilute solutions of permanganate of potassa and hydrochloric acid, followed by washing with hyposulphite of soda solution, and rinsing in plenty of fresh water. By these means the use of the highly poisonous cyanide of potassium is rendered unnecessary.—*Polyt. Notizblatt.*

Protection of Wood from Fire.—We learn from the *Deutsche Industrie Zeitung* of July 1, that at one of the collieries at Ibbenbüren, Westphalia, the woodwork is protected from fire by being painted with a mixture consisting of 5 parts of alum, 7 parts of rye-meal paste, and 30 parts of previously washed, *i.e.*, finely divided, clay (this mixture is used for woodwork not exposed to open air); for woodwork, so exposed, a mixture is used consisting of 2½ parts of crystallised sal-ammoniac, 1 part of white vitriol (commercial sulphate of zinc), 2 parts of joiners' glue, 20 parts of zinc-white, and 30 parts of water. These mixtures have been found to prevent wood bursting into flame on ignition, and to greatly delay its destruction even when severe fires are raging.

Thermoscope for Lecture Rooms.—Dr. A. W. Hofmann states that he frequently makes use of the following arrangement for the purpose of exhibiting, in a ready manner, the evolution of heat which takes place in chemical combinations and decompositions.—Some ether is poured into a tall test tube, and this tube is placed, for instance, in a recently-made mixture of sulphuric acid and water, the ether begins to boil, and its vapour may be ignited; in order to regulate the boiling of the ether it is best to place in it a platinum wire spiral. When, in a beaker glass, some sulphuric acid is first poured, and next, carefully on the top thereof, a layer of water, and these fluids are suddenly mixed by stirring the same with the ether tube, a flame of half a metre length may be suddenly evolved from the tube. The author has frequently applied this contrivance to exhibit the disengagement of heat on the sudden solidification of saturated solution of acetate of soda.—*Berichte der Deutsche Chem. Ges. zu Berlin.*

[This device was frequently adopted by Faraday during his Christmas Lectures.—*Ed.* C.N.]

Application of Leichtenberg's Experiment to the Mineralogical Analysis of Rocks.—M. S. Meunier proposes to make use of the well-known experiment of Leichtenberg's electric figures to separate from each other the divers mineralogical constituents of some kinds of rock. We briefly remind our readers that the experiment alluded to consists in charging with electricity a cake of resin or sealing-wax, by means of a previously-charged Leyden jar; it is thus possible to charge certain portions of the cake with positive, others with negative, electricity. In order to exhibit this to sight it is usual to blow, by means of a small pair of bellows, on to the cake of resin, a mixture of very finely-powdered red lead and sulphur; the friction, on leaving the nozzle, causes the powders to become electrified, and the sulphur being negatively electric is attracted by the curved figures positively electric on the cake, while the red lead follows the opposite course. M. Meunier has tried thus to separate sulphur-bearing trachite into its mineral constituents, and succeeded perfectly in getting the sulphide and feldspar from each other; he states that he has equally well succeeded with rocks made up of two different silicates.—*Cosmos.*

Analysis of Polcura.—Under the name of polcura there has been lately brought from St. Jago de Chili a mineral, met with, at a height of from 12,000 to 14,000 feet above sea level, in the Cordilleras de los Andes, imbedded between porphyry and melaphyr; this mineral exhibits a dirty yellow-coloured grainy somewhat crystalline mass; is acid and astringent to the taste; heated to 150° C., it loses 19·5lo per cent of water. 24·184 per cent of the substance is soluble in boiling water;

from the portion insoluble in that fluid, equal to 62·251 per cent, hydrochloric acid dissolves 12·351 per cent, while the remaining 49·900 per cent is silica. The portion soluble in water yielded, on being quantitatively analysed, results as follows:—Sulphate of potassa, 2·5 per cent; sulphate of soda, 2·7; sulphate of lime, 26·1; sulphate of magnesia, 16·1; sulphate of alumina, 40·2; persulphate of iron, 4·6; chloride of sodium, 0·4; and soluble silica, 7·4. The portion insoluble in water, 62·251 per cent, consists of the following substances:—Alumina, 2·007; peroxide of iron and trace of manganese, 6·700; sulphuric acid, 3·330; silica, 49·900; and water, 13·560. The polcura is applied, in the country where it is found, to the tawing of the skins of sheep, goats, and calves; from the composition of its constituents soluble in water it will be readily seen that it is eminently fit to serve this purpose.—*Dingl. Polyt. Journ.*

Bubbles of Mercury Floating on Water.—When the lecture room of a chemical laboratory is provided with a sufficient supply of water under strong pressure, it is possible to make, and exhibit there, an experiment which, owing to a deficient pressure of water in such rooms, has been almost unnoticed. The experiment is the following:—Under an ordinary water-tap, the opening of which has from 10 to 12 m.m. diameter, a large-sized porcelain basin is placed, containing from 15 to 20 kilos. of mercury; the water-tap being suddenly opened, a strong flow of water is caused to fall into the basin at a height of from 8 to 10 centimetres from its bottom. On turning off the flow of water again, it will be seen that on the surface of that fluid there float about bubbles of mercury, usually exhibiting a diameter of only 1 centimetre, but occasionally some are found of two or three times that size. As a rule these bubbles are very ephemeral; now and then, however, it happens that some may be caught, along with a quantity of water, in a small beaker glass, and, on the mercurial bubbles bursting, it will be seen how very small a quantity of mercury these bubbles consist of. Professor Hofmann mentions that he saw this experiment first exhibited in the lecture room of the Royal College of Chemistry, London, when, some twenty years ago, Professor Melsens, from Bruxelles, was on a visit there. The pressure of water at the lecture room just named is from 10 to 12 metres; in the new laboratory of Berlin University the pressure of the water circulating in the tubes and pipes is from 20 to 25 metres.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

In accordance with the generally expressed wishes of our friends and readers, we have effected arrangements to enable us to give, under the above heading, notices of EVERY CHEMICAL PAPER IN THE WORLD, *as soon as possible after publication. Whenever possible, these notices will appear in the form of carefully prepared, although necessarily brief, abstracts; as respects papers either too long or too abstruse to render condensation possible, their titles will be chronicled; and in all cases accurate reference will be made to the original publication. The two half-yearly volumes of the* CHEMICAL NEWS, *with their copious indices, will therefore be equivalent to an English edition of the "Jahresberichte," with the additional advantage of keeping the readers week by week on a level with the latest advances of science.*

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus des Séances de l'Académie des Sciences, vol. lxix., No. 2, July 12, 1869.

This number opens with a brief notice of the death of Prof. Bérard, at Montpellier, already recorded in our paper; but we meet here with the following particulars, which are of general interest:—The father of the deceased was associated with the celebrated Chaptal, in the business of an extensive chemical factory, yet in existence near Montpellier, where the manufacture of sulphuric acid was first started on the continuous principle, and whereby has been effected the cheap production of that acid, and, by its means, of almost all chemicals. The deceased Dean of the medical faculty established in the city just alluded to, had been, since 1819, one of the corresponding members of the scientific body which now is the Académie des Sciences, but which in 1819 was l'Académie, an institution of very ancient date. A very great portion of this number is again devoted to the rather barren controversy about some letters and papers, purporting to be written by men who died some 150 years ago at the least. Among the papers and communications, we notice:—

Researches on the Products of the Alcoholic Fermentation of Beet-Root Juice.—MM. Pierre and Puchot.—The authors state that they have obtained from that juice, after alcoholic fermentation—(1) vinic aldehyde, ready formed; (2) vinic alcohol; (3) propylic alcohol; (4) butylic alcohol; (5) amylic alcohol. The authors devote this paper more especially to the study of the propylic alcohol, which they say boils, in its normal state, at 98°, while its sp. gr. at 0° is 0·820; its volume at 0° being taken as equal to 1000, it becomes 1115 at 98°, at which temperature its sp. gr. is 0·735. The authors further state that, theoretically speaking, propylic alcohol can be directly formed from sugar, by simply fixation of water and elimination of carbonic acid.

New Researches on the Properties of Explosive Compounds.—Mr. Abel.—The contents of this abstract, which is published in this number at the express desire of the members of the Institute, are already well known to our readers.

Compressibility of Gases at High Temperatures.—M. Blaserna.—The author first refers in this paper to a series of researches made by him on this subject in former years, and published by him in the *Annales de Chimie et de Physique*. He next calls attention to a series of researches on this very same subject recently made by M. Amagat, which confirm both the author's researches and those made long ago by M. Victor Regnault. The author next passes to researches on the motion of gases, which, however, is a mathematico-physical paper, and not suitable for condensation in our columns.

Researches on Sulphur.—M. Chevrier.—The author has studied the action of vapour of sulphur on oxygen, hydrogen, nitrogen, protoxide and deutoxide of nitrogen, carbonic oxide, and carbonic acid. Vapour of sulphur and oxygen gas form a slightly explosive mixture under some conditions, but usually the vapour of sulphur burns off quietly, forming sulphurous acid. Hydrogen and vapour of sulphur yield sulphuretted hydrogen gas very readily and abundantly. With vapour of sulphur and nitrogen the author found no action at all. Vapour of sulphur and the two oxides of nitrogen just alluded to form, in the first place, sulphurous acid; nitrogen is set free, and if a frigorific mixture be applied to the apparatus containing the mixed gases and vapours, large so-called lead-chamber crystals are obtained. Oxide of carbon yields, with vapour of sulphur, oxysulphide of carbon. Carbonic acid and vapour of sulphur, exposed to the discharges of electric sparks, yield oxysulphide of carbon and sulphurous acid. The author of this paper adds a short notice on an—

Improvement of the Preparation of Carbonic Oxide.—When the gas just alluded to is evolved from a mixture of oxalic and sulphuric acids, as is well known, a mixture of carbonic acid and carbonic oxide gases is obtained. This mixture of gases the author causes to pass through a tube made red-hot in a suitable furnace and filled with charcoal previously well re-burnt; and, after having washed the gas through a solution of potassa, and also lime-water, he thus obtains a bulk of the pure carbonic oxide gas three times larger than would be the case if the carbonic acid simultaneously formed were not decomposed by the red-hot charcoal, which must be free from yielding any carburetted hydrogen gases.

No. 3, July 19, 1869.

This number contains the following papers, the contents of which belong to chemistry and sciences allied therewith:—

Explosive Properties of Chloride of Nitrogen and its Propulsive Force.—MM. St. Claire-Deville and P. Hautefeuille.—Chloride of nitrogen was discovered in the year 1812, by M. Dulong; It is the most unstable compound we are acquainted with, exploding most violently by very slight causes. The authors have, however, succeeded—and record in this memoir the means applied for this purpose—to estimate and measure with accuracy the force exerted by this substance when it changes its liquid for a gaseous state of aggregation. This they have effected by estimating exactly the quantity of caloric units which are set free at the moment of the explosion of the chloride of nitrogen; this quantity amounts to 38,700. The temperature of the gases, when the explosion takes place in closed vessels, amounts to 2128°, and the pressure of the gases is then equal to 3500 atmospheres, or equal to a pressure of 52,500 English lbs. to the square inch.

Spectrum Observations of Small Stars.—Rev. Father Secchi, S.J.—In a letter dated from Rome, July 13th, the eminent astronomer states that he has succeeded in studying the spectra of stars which are only of the 8th and 9th magnitude. The light emitted by such stars being very feeble, it is gratifying to learn that observation has proved that, among the spectral lines, those of carbon occur, and that the spectra, as seen, appear to prove a common origin for these small stars which are, comparatively, situated near to each other.

On Jacobsite, a New Mineral.—M. A. Damour.—This mineral owes its name to the fact that it has been found at Jakobsburg, in Nordmark, province of Wermland, Sweden. It exhibits regular octahedral crystalline shape; its colour is dark, with a metallic lustre; when pulverised, its colour is blackish brown; it scratches glass; its sp. gr. is 4·75 at 16°; it is attracted by the magnetic needle; is infusible before blowpipe flame, and loses no weight when strongly ignited in a platinum crucible; fuses readily to a bead with borax and phosphor-salt, yielding a yellowish green coloured glass; is insoluble in nitric acid, but slowly, yet completely dissolved by hydrochloric acid, while, at the same time, chlorine gas is given off. This mineral consists, in 100 parts, of:—Peroxide of iron, 68·25; protoxide of manganese, 20·57; peroxide of manganese, 4·21; magnesia, 6·41; and traces of oxide of zinc.

New Process for Obtaining Iron from its Ores.—M. Ponsard.—The author of this paper has applied Siemens's furnace to the manufacture of iron; he states that he has succeeded in producing 1 ton of cast-iron of excellent quality with a consumption of only 1 ton of fuel. The author summarises his results in the following manner:—(1) A great saving of fuel can be made, and iron obtained from its ores, without the use of blast furnace; (2) that, since the heat produced by flame is sufficient to effect all the chemical reactions and melt the metal, there may be used all kinds of fuel which produce gas—that is to say, all kinds of coal no matter whatever their quality, wood, lignite, peat, hydrogen gas, and mineral oils; (3) it is possible to obtain, at will, a more or less carburetted metal, according to the quantity of carbonaceous matter which is mixed with the ore and placed in the crucibles to act as chemical agent only. Specimens of iron of very good quality, obtained by the process as carried on by

the author, were exhibited to the members of the Academy at this meeting.

Magnetic Oxide of Iron and its Salts.—M. Lefort.—The author first reviews some experiments made by him on this subject so far back as the year 1852; he next states that, as a result from these researches, he had found that it was possible to obtain perfectly soluble and well-crystallised salts, which prove that the so-called magnetic oxide of iron (proto-sesqui-oxide) is capable of forming salts. The author prepares the proto-sesqui-oxide by precipitating, by means of caustic potassa, a solution containing a ferrous-ferric salt. The reason why preference is given to potassa is, that an oxide is obtained which is less readily affected by air, and more stable. This oxide, $FeO+Fe_2O_3+HO$, yields, after having dissolved in hydrochloric acid, and on being left to crystallise while standing over sulphuric acid, a crystalline mass made up according to the formula—

$$ClFe+Cl_3Fe_2+18HO.$$

The author has also obtained a sulphate of the following composition:—

$$SO_3FeO+3(SO_3),Fe_2O_3+2SO_3+15HO;$$

this salt, and in fact all the salts the magnetic oxide is capable of forming, are decomposed by heat far below the boiling-point of water.

Electricity.—M. Tourdes.—This is a short paper on a curious case of death by lightning, which took place on the 13th inst., at Kehl Bridge, near Strasbourg. The curious point is, that while quite close to the spot where three soldiers were seated under a rather low chestnut tree, two of whom were killed, while the third was rendered insensible and temporarily partly paralysed, there is a building provided with lightning conductors, and near, also, a very large iron railway bridge; yet the tree was struck, and the men seated under it on a bench killed, notwithstanding large masses of metal and excellent conductors of electricity were, at a far greater elevation, at hand for the electric fluid to run along. The author's opinion is that the metal buttons, and other ornaments made of metal, on the soldiers' dresses were the cause of their death by lightning.

New Acid from Sulphur.—M. Schützenberger.—While at a future date we may give a fuller account of the interesting facts contained in this rather lengthy memoir, we now confine ourselves to stating that the author has succeeded in forming a compound made up of a double atom of sulphurous acid, wherein 1 atom of oxygen is replaced by 1 atom of hydrogen; this free and anhydrous acid should be represented by S_2O_3H. The author has proposed to name this substance hydrosulphurous acid; some of its salts have been prepared by the author and obtained in crystalline state; the free acid is a very unstable compound, exerting strong reducing action.

Crystallisation of Metallic Oxides.—M. Sidot.—In this paper, the author records a series of experiments made by him in order to obtain artificially crystallised metallic oxides, starting from the well-known fact that most native oxides and sulphurets exhibit a crystalline form. The author has been occupied in researches with the view to obtain these forms by artificial means, and has succeeded, in many instances, by simply submitting some oxides—for instance, the peroxide of iron—to long-continued and strong heat. By this means, the said peroxide loses a portion of its oxygen, magnetic oxide is formed and simultaneously obtained in a crystalline shape; the sesquioxide of manganese, the oxides of cadmium and zinc, have also been obtained in distinctly crystalline state, by various manipulations and the application of suitable very high degrees of temperature.

Acetic Fermentation of Methylic Alcohol.—M. Béchamp.—The author states that on the 5th of September, 1868, he introduced into a vessel which could be properly closed, a mixture of methylic alcohol, pulp of sheep's liver, chalk, and water; and on the 15th of June last he opened the vessel and proceeded to test its contents, which he found to consist chiefly of acetic acid and non-decomposed methylic alcohol. His object was to ascertain whether methylic alcohol yields, under these conditions, any higher oxidised compound than acetic acid, which is ascertained to be the ultimate term of oxidation under the influence of the ferments used.

Journal für Praktische Chemie, No. 8, 1869.

This paper contains the following original papers and essays:—

Isomerism of the Derivatives from Naphthaline.—M. L. Schæffer.—This paper treats on naphthols, $C_{10}H_7.OH$, distinguishing—α naphthol, $C_{10}H_8O$; β naphthol; naphtholates; naphthol-ethyl ether, $C_{10}H_7OC_4H_5$; distinguished again into α and β. The paper is written with the view of proving that the isomerism of each class of bodies derived from naphthaline is a persistent character thereof; the paper is, however, too lengthy for further condensation.

Protein compounds met with in Zea-Maise, Indian Corn.—M. Ritthausen.—The author first reviews the labours of MM. Gorham, Bizio, Berzelius, and Stepf on this subject; and next states that he applied, for his researches, several varieties of maise grown in the botanic garden of Bonn University, at Poppelsdorf. The author obtained a substance which he names fibrine of Indian corn, and which contains, in 100 parts:—C, 54·66; H, 7·45; N, 15·50; S, 0·69; O, 21·70. This substance is insoluble in water, and soluble in alcohol and very weak alkaline solutions.

Alloy of Zinc and Iron.—M. Bayer.—The material here described was accidentally obtained at a Belgian iron smelting works, among a job lot of old iron. The alloy was of a very bright metallic and crystalline appearance, very brittle, so that it could be readily reduced to powder; sp. gr., 7·485; nearly entirely soluble, without residue, in dilute sulphuric and hydrochloric acids. Composition, in 100 parts:—Zinc, 83·66; iron, 13·00; lead, 2·70; tin, 0·05; insoluble residue, carbonaceous matter, 0·20.

No. 9, 1869.

This number opens with a list of the—

Symbols and Equivalents of the Elements.

And further contains the following original papers:—

On a Double Sulphide of Iron and Potassium.—M. Preis.—In order to obtain this compound, five parts, by weight, of iron, five parts of carbonate of potassa, and one part of iron (in the state of *ferrum redactum hydrogenio*) are intimately mixed, and placed in a crucible, and submitted to a gradually-increasing heat, and kept for at least one hour at bright red heat. The substance thus obtained is a compound, containing, on an average, in 100 parts:—Sulphur, 39·90; iron, 35·34; potassium, 24·16. Empirical formula, KFe_2S_4; rational formula, $KS.Fe_2S_2$.

Protein compounds contained in Oats.—Dr. Kreusler.—After reviewing the labours of Messrs. Johnston, Norton, von Bibra, and others, on this subject, the author states that he found that alcohol of ordinary strength (80 per cent) extracted the protein compounds from coarsely-ground oatmeal completely. After purifying the substance so obtained, its composition, on submitting it to elementary analysis, was found to be, in 100 parts:—C, 52·59; H, 7·65; N, 17·71; S, 1·66; O, 20·39.

The remainder of the papers are not original, and have been already abstracted by us from the original sources from which they are taken.

Les Mondes, July 15, 1869.

Although the brief notice of the following subject does not exactly belong to the subject matter usually treated in our pages, we cannot refrain from noticing the—

Steam Boiler Furnace.—Invented by M. de Pindray.—The reverend and learned editor of this periodical devotes two pages to this very interesting subject, from which we abstract the following:—Two steam boilers, of the same size, and in every respect identical to each other, were fitted up—one upon M. de Pindray's plan, the other upon the system hitherto considered the best in France—and both submitted, under precisely identical conditions, to a trial, the fuel used being the Friokaisin coal, from the neighbourhood of Charleroy, Belgium. During the trial, which lasted fully four hours, the production of steam by the Pindray system amounted to 9·440 kilos. of steam for every kilo. of coal burned; by the other system, it amounted to a production of 8·001 kilos. of steam for every kilo. of coal consumed. The indicated horse-power was (the pressure on each boiler being rigorously kept up to 4½ atmospheres) for the Pindray boiler, 124; for the other, 81. The production of steam for every square metre of heating surface amounted, in the case of the Pindray system, to 40·460 kilos., in the other case to 28·530 kilos. While the boiler fitted up to compete with M. Pindray's system of fitting up was confessedly the best, yet the latter gained 16 per cent of economy of fuel, and 42 per cent more effective force. These few data may suffice here; a saving of fuel, and a better application of heat for the purposes of production of steam are of so manifestly great interest, that we think we need not apologise for thus briefly entering for a moment on the domain of steam-boiler and furnace engineering.

July 22, 1869.

We notice from this number the following subjects:—

Wood Engraving by means of an Acid Composition.—M. Dulaurier.—The author states that, by some observations made by him previously, he was induced to try a mixture composed of sulphuric acid, several chromates, and persulphate of iron, to bite away some portions of wood upon which, after having first covered its surface with an asphalte varnish, which protects from the action of the acid composition those parts from which this varnish is not afterwards removed by an engraver's tool, he had engraved his name. This experiment, the author states, succeeded so well that very shortly wood engraving may become a greatly-improved manipulation, by means of the assistance of the biting action of acids. Unfortunately, the author neither states what kind of wood he used, nor also the precise composition of the acid mixture he has applied.

From the *accuse's de réception* of this periodical, we learn that the fifth part of the third volume of the *Archives Néerlandaises des Sciences Exactes et Naturelles*, by Dr. E. H. von Baumhauer, contains:—

Chemical Researches on the Poisonous Principle of the Root of the Cicuta Virosa.—M. Van Ankum.—This principle is an essential oil belonging to the camphine series, and is composed according to the formula $C_{10}H_{18}$; it exhibits rotatory power to the right. The root does not, according to this author, contain any alkaloid at all, either fixed or volatile.

Improved Stove and Chimney.—M. Ch. Joly.—The author states that, as a rule, the millions of chimneys applied in dwelling-houses are so badly constructed that, at the least, the useful calorific effect of the fuel is only from 5 to 10 per cent. In Paris alone, 500,000 cubic metres of wood are annually burnt, exclusive of coke and coals consumed for domestic purposes. The author has invented a combination of stove and chimney well worthy of imitation, and brought into use everywhere. His invention is based on sound principles; but, unless we reproduce the woodcuts annexed to the original, we could not make this matter well understood.

Manufacture of Chocolate.—M. Tresca.—Although this matter appears very heterogeneous, and even trivial, we must not neglect to

say a few words on this subject, taken from the ably-written report made by the gentleman just named, on the chocolate mills and factory belonging to M. Ménier, situated at Noisiel. The proprietor, well known by name, also, in this country, is the owner, also, of a large estate in Central America, entirely devoted to the cultivation of the cacao tree (*Theobroma cacao*), from which the nuts are obtained which serve for the manufacture of an article of diet which contains every element required for the due nourishment of the body. The factory at Noisiel employs 300 workpeople, and during the last ten months the quantity of chocolate made has amounted to 2,388,347 kilos. (fully 2388 tons); the quantity of tin-foil used for packing amounts to a value of 10,000 francs a month; and the duty paid by M. Ménier alone to the French *donane* amounts, for cacao alone, to a sum of nearly one and a half millions of francs yearly, exclusive of the sugar duties. M. Tresca states that the article is prepared with great care as regards the production of a really first-class and genuine material.

Cosmos, July 24, 1869.

Native Copper in Belgium.—While some drainage works were being executed at Vielsalm, province of Liège, the workmen found, at no great depth under the surface, a piece of native copper weighing about 2 kilos., and partly hollow inside, exhibiting crystals. This discovery has led to further research, the result of which is the finding of some veins of malachite.

Meteoric Appearance.—M. E. Arnoult, the well-known editor of *l'Institut*, writes from Vendôme, Département de Loir et Cher, about 80 miles south-west of Paris, stating that on the 15th of July, at 8·45 p.m., there was seen there a very bright meteor, which moved slowly from east to north, at an angle of about 45° above the horizon; it emitted a yellowish white light, so strong as entirely to overpower the light of the moon in her first quarter; it disappeared, without any perceptible noise or sound, in a few seconds, giving off a large number of very brilliant sparks. Since the writer of this brief communication is a good and trustworthy observer, and since he learned afterwards that several other parties had recognised this meteor at about the same time, there can be no doubt about the fact that a peculiar appearance had been observed.

Geological Map.—We learn from this periodical that a very greatly improved and enlarged geological map of Central Europe has been prepared and edited by the well-known geologist, *emeritus* Director-General of Mines for Prussia, M. von Dechen. This new map is on a scale of 2,500,000ths, and embraces the whole of Germany, France, England, and adjacent countries. The same author has recently finished a large geological map, in 32 large sheets, of Rhenish Prussia and Westphalia, which may be considered as one of the best ever executed of the kind, and one of the finest specimens of chromo-lithography ever published. The price of these works being very moderate, will ensure them a largely-extended sale.

Berichte der Deutschen Chemischen Gesellschaft zu Berlin, No. 10, June 12, 1869.

This is a double number of this periodical, containing, in the first place, a very interesting and lengthy account of a *soirée* given by the president of the Society, on the 15th of May last, at the chemical laboratory of Berlin University. Following the plan of the printed periodical, we quote, in the first place, the catalogue of the brilliant exhibition of objects of interest to the scientific party assembled; this catalogue is divided into three sections, comprising:—A. Exhibition of Chemical Preparations of High Scientific Interest.—(1) M. Baeyer, Berlin, "Preparations of Indol, honystone, preparations of mellithic acid;" (2) M. Darmstädter, Berlin, "Chlormethyl-isaethionate of sodium;" (3) M. H. Wichelhaus, Berlin, "β-binitronaphthalin and derivatives of naphthol;" (4) M. Frank, Stassfurt, "Collection of bromates and other bromine compounds;" (5) M. Gräbe, Berlin, "Compounds of chinon and artificial alizarine;" (6) M. Ladenburg, Heidelberg, "Preparations of silicium;" (7) M. Liebreich, Berlin, "Protagon, neurin, oxyneurin, and salts thereof;" (8) M. Martius, Berlin, "Victoria yellow, and compounds of binitro-kresol;" (9) M. Oppenheim, Berlin, "Mentha-camphor and derivatives of propylen;" (10) M. Schaibler, Berlin, "Collection of divers kinds of sugar, and models of the crystalline form some of these exhibit;" (11) M. Wichelhaus, Berlin. "Bibromo-pyroracemic acid and naphthol." B. Exhibition of Drugs, and of Products of Chemical Works.—This catalogue is by far too lengthy for reproduction; moreover, a great many of the substances exhibited are, if not better, at least equally well manufactured in this country; we notice, however, the following rare substances manufactured on the large scale:—M. E. Jacobsen, Berlin, "Peroxide of hydrogen, made by a new and peculiar process." Among the extensive series of substances exhibited by MM. Lampe, Kaufmann, and Co., Berlin, we notice a collection of thirty different preparations of quinine; *ferrum dialysotum*; pure pepsin; a large collection of chemically pure essential oils, among which *oleum cajeputi*, *oleum calami*, *oleum neroli*, and a large number of others; a fine collection of rare kinds of opium, among these some of German cultivation. Dr. Marquart, Bonn, the owner of very extensive and eminently well-conducted chemical works, exhibited large quantities of ethyl-benzol, zinc-methyl (chemically pure), zinc-ethyl, ethyl-methylaniline, anhydrous sulphuric acid, anhydrous phosphoric acid, hydrochlorate of ethylamine, chloride of carbon, several distinct compounds of chlorine and phosphorus, aldehyde, carbonic acid ether, oxide of mesityl, and a number of similar rare compounds, all perfectly pure and fit for scientific research. M. Schering, operative chemist, Berlin, exhibited a group of crystals of re-sublimed iodine, 2 feet in diameter; several rare compounds of bromine with metals; chemically pure tannic and gallic acids; rare preparations of cadmium and mercury. C. Exhibition of Physical and Chemical Apparatus and Glass and Porcelain Ware.—This portion of the exhibition surpassed even the two former, not only for extent, but also for the exquisite novelty and finish and utility of the apparatus exhibited; we can only quote a couple out of the very many:—M. Elster, manufacturer of gas-meters, Berlin, exhibited a highly-sensitive photometer, and experimented with it during the evening in one of the rooms of the laboratory. M. Geissler, Berlin, exhibited his large mercurial air-pump, and showed experiments with it in the laboratory set apart for gas analysis.

We abstract the following from the speech of the President of the Society, Dr. A. W. Hofmann. After having welcomed his scientific guests, the Doctor first alluded to the fact that the laboratory wherein they met had not been opened in a more official manner, and a meeting held therein honoured by the presence of high and mighty officials and rulers of the empire; but, he said, it was far more agreeable to him to see assembled together, on the evening of the day upon which the finishing touch had been laid by the workpeople to this temple of science, men who would appreciate with him the importance of this achievement for the University of Berlin specially, and for the scientific world in general. The eminent speaker then entered into the history of the causes which so long delayed the building of really good laboratories at Berlin and Bonn, long after the four* other ancient universities of the Prussian empire, as it existed before the late conquests, had been amply provided with laboratories which were worthy of the advance of chemical science of the present day. The building of the Berlin laboratory, just finished though it has been in partial use for one year, occupies a space of 21·680 sq. ft. The building, of which, with the present number of the above-quoted periodical, three lithographic prints are given, exhibiting, respectively, its frontage and the plans of the ground-floor and first-floor, has cost 318,000 thalers (£47,700), which sum the Prussian Government has granted for the purpose. The speaker next commenced a lecture on divers scientific subjects, from which we quote the following:—

Increase of Weight During Combustion.—The main feature of this brief *exposé* is the description of an experiment. A small horse-shoe magnet is hung up at the beam of a balance sufficiently sensitive to turn with centigrammes; the poles of the magnet are immersed for a moment in the *limatura ferri* of the chemists' shops, and a beard of small particles of iron is caused to adhere to the poles; by means of proper weights placed on the scale-pan at the other end of the beam the equilibrium is restored. This having been done, the finely-divided iron is kindled, by approaching to it the flame of a Bunsen gas-burner, and continues to burn. While burning, it will be seen that the arm of the balance on which the magnet is suspended considerably deviates from the horizontal position, thus indicating an increase of weight on the side where the experiment is going on. This experiment succeeds best with a magnet of moderate dimensions; the horseshoe magnet applied in this instance weighed, without its armature, 210 grms., and can bear a load of 12·5 grms. of iron; when this is altogether converted in magnetic oxide, by combustion, the increase in weight will be about 4·7 grms.

Formation of Ferric Acid.—An intimate mixture is made of one part of *ferrum limatum*, and two parts of nitrate of potassa. The speaker said he took, of both together, usually from 20 to 30 grms.; these are heated in a small glass flask over a strong gas flame; the mixture soon becomes quite incandescent, emits, out of the mouth of the flask, a firework of sparks, and leaves, at last, a mass partly fused together with the glass of the flask, consisting of ferrate of potassium. After cooling, this mass is reduced to powder, and, being exhausted with water, yields a deep reddish violet coloured, nearly transparent solution. Unless great care be taken to let the mass become quite cold before any water is added, the operation is spoiled.

We regret we can only quote the titles of the following subjects briefly alluded to by the eminent lecturer, on account of the impossibility of properly giving any condensed review without reproducing the woodcuts annexed to the originals:—

Volumetrical Analysis of Hydrochloric Acid and Ammonia by means of Electrolysis.

Condensation of Hydrogen and Oxygen when forming Water-Gas (vapour of water at very high temperature).

Lecture-Room Analysis of Marsh Gas and Olefiant Gas.

Lecture-Room Eudiometer.

Equality of Volume of Oxygen, and of the Carbonic Acid and Sulphurous Acid obtained from it.

Oxidation of Ammonia.

Evolution of Oxygen from Nitric and Sulphuric Acids.

Experiments on Flame.

Lecture-Room Thermoscope.

Comparison of the Volume of Different Gases submitted to the same Changes of Temperature and Pressure.

Compression of Gases by means of the Pressure exercised by a Column of Mercury.

Liquefied Sulphurous Acid Gas.

Bubbles of Mercury Floating on Water.

Local Ventilation as Lecture-Room Experiment.—This last paper contains a brief *resumé* of the excellent mode of ventilation adopted in the lecture-room of the Berlin laboratory.

---

* Prussia Proper has Universities at Breslau, Königsberg, Greifswald, Halle, Bonn, and Berlin; and, in addition, the universities of Göttingen, Marburg, formerly belonging to the Kingdom of Hanover and the Duchy of Hesse Cassel, are now Prussian Universities.

On the 24th of May last the Society held one of its ordinary meetings, at which the following papers were read and communications made:—

Behaviour of the Trichlorinated Acetic Acid Salts and of Chloral with the Animal Organism.—M. Liebreich.—This physiologico-chemical paper is partly an answer to the question the author put to himself—Whether, during the splitting-up of such chemicals, of which the physiological effects of the bodies they separately yield on being split up is well known, the splitting-up thereof in the animal organism itself brings on the same phenomena as if the component substances were individually administered to an animal? As far as the author's experiments go, they seem to prove that the splitting-up of substances as those experimented with and named in the heading to this paragraph, actually produce phenomena, from which it is just to infer that they are produced by products derived from the splitting-up of the substances experimented with.

Action of Sulphide of Carbon upon Oxamide and Acetamide.—M. Ladenburg.—The decomposition of oxamide sets in at 180°, and is not quite finished at 200°. In order to avoid explosions, the sealed tubes have to be opened after several hours' exposure to heat. Among the gases which escape on opening the tubes, oxysulphide of carbon is the chief, mixed, however, with some oxide of carbon and hydrosulphuric acid. The reaction may be represented by the following formula:—$C_2O_2N_2H_4 + CS_2 = CSNH.NH_4 + COS + CO$. As to the reaction of acetamide and sulphide of carbon, the author states—"I have never been able to get it satisfactorily ended; it begins below 200°, at 210° a strong disengagement of gas takes place, and at a higher temperature the tubes always exploded. The disengaged gases contain much H_2S, COS, and CO, also vapours of hydrocyanic acid, and combustible gases not absorbable by baryta-water and protochloride of copper. In the residue in the tube, only sulphocyanide of ammonium and acetamide were left.

Formulæ of Benzol.—M. Ladenburg.—It is impossible to give a proper abstract of this paper without reproducing the woodcuts representing certain mathematical figures essentially belonging to this paper.

Contribution to the History of the Salicyl Compounds.—M. Henry.—After referring to a series of experiments made by the author with the view of exhibiting the action of pentachloride of phosphorus upon salicylic-aldehyde, the author now communicates the results of his researches on the action of pentabromide of phosphorus upon salicylic aldehyde. This action, he says, although less violent than that of the pentachloride of phosphorus, is yet rather strong. On purifying, first with water, and afterwards with ether, the substance resulting from this reaction, he obtained monobromated salicylic aldehyde—

$$C_6H_3Br\begin{cases}OH\\CHO.\end{cases}$$

When two equivalents of pentabromide of phosphorus were made to act upon one equivalent of salicylic acid, a substance was obtained which, after having been purified by means of ether and alcohol, exhibited a crystalline appearance, fusing at about 165°, and subliming at between 150° and 155°; formula—

$$C_6H_3Br\begin{cases}HO\\COHO.\end{cases}$$

Salicylic acid methyl-ether is not acted upon in the cold by pentabromide of phosphorus, but, on heating, among a series of secondary products, a substance is obtained named monobromo-salicylic acid ether—

$$C_6H_3BrCO(CH_3)O.$$

It is a solid, fusing at between 36° and 38°, and boiling at about 266°; its alcoholic solution is coloured beautifully violet on addition of a few drops of an alcoholic solution of perchloride of iron.

Researches on some Ethereal Derivatives of Polyatomic Acids and Alcohols.—M. Henry.—Unless we were to fill about a column of our pages with formulæ only, the condensed reproduction of this paper would neither do credit to its author nor be of use to our readers; we therefore only quote the title.

Contribution to the Chemical History of Diallyl.—M. Henry.—This is a preliminary notice on diallyl, C_6H_{10}, from which we learn that diallyl readily combines with N_2O_4, yielding a solid mass of white crystals composed according to the formula $C_6H_{10}(NO_2)_4$. Diallyl also combines with hypochlorous acid, yielding a fluid heavier than water, formula—

$$C_6H_{10}\begin{cases}(OH)_2\\Cl_2.\end{cases}$$

On the Stilben Series.—M. Grimaux.—This paper, owing to the large number of formulæ necessarily belonging to it, is not well suited for abstraction.

Annalen der Physik und Chemie, von Poggendorff, No. 5, June 15, 1869.

This periodical contains the following original papers:—

Definition of the Course of the Boomerang.—Dr. E. O. Erdmann.—A purely mathematico-mechanical essay.

Researches on the Behaviour of Vapours as regards the Law of Mariotte.—Dr. H. Herwig.—A lengthy physico-mathematical monograph on this subject, not suited for abstraction.

Nature of the Liquids found Enclosed in certain Minerals.—MM. Vogelsang and Geissler.—The authors review, in this paper, first, the labours of Davy, Simmler, Brewster, and others on this subject, and next state that they have applied for their researches spectrum analysis and microscopic research. Without a reproduction of the engravings accompanying this paper, it would be impossible to make the apparatus, and the mode of action thereof, understood. It appears as chief result of the researches made by these authors, that liquefied carbonic acid and water are very commonly met with enclosed in various minerals.

Researches on the conditions Influencing the Evolution of Bubbles of Gas and Vapour, and on the Forces which thereby come into Play.—M. H. Schröder.—This paper is the first instalment of a lengthy essay on a rather intricate subject. Since the author intimates that he will give a condensed *resumé* of the main results of his researches at the end of his essay, we prefer not to go into particulars just now.

Reduction of Accurately-Made Weights, and Determination of the Error of Absolute and Relative Weighing without Reduction.—Dr. K. L. Bauer.

Construction of Galvanoscopes which are Extremely Sensitive.—M. H. Weber.—These are purely mathematical papers.

Form and Constitution of the Puddling-Dross Crystals obtained at the Steel-Works, Hombourg-Haut, near St. Avold, Département de la Moselle.—M. Kosman.—After reviewing the labours of others on this subject, the author first enters into a lengthy and purely crystallographical description of the crystals alluded to in the title. The specific gravity of this material is 4·44, the colour of the powder bluish green. In 100 parts, the substance contains:—Metallic iron, 0·29; monosulphuret of iron, 1·43; phosphuret of iron, 3·31; peroxide of iron and sesquioxide of manganese, 5·99; Fe_2O_3, 4·79; protoxide of manganese,* 0·75; lime,* 1·16; phosphoric acid,* 1·48; silica, 24·04; protoxide of iron, 47·50; protoxide of manganese, 7·35; lime, 0·82; magnesia, 1·49.

Determination of Galvanic Resistance.—M. J. Sirks.—A mathematical paper.

Spectrum of the Aurora Borealis.—M. J. A. Angstrom.—This paper is taken from the author's work, highly spoken of by M. Poggendorff, "Researches sur le Spectre Solaire," 4to, Upsal, 1868, avec Atlas de Six planches. The light exhibited by the Aurora Borealis is almost monochromatic, and shows one single bright line to the left of well-known lines of the calcium group.

Fluorescent Liquids for Geissler's Tubes.—Dr. Seilhorst.—The researches of this author have brought to light the fact that a good deal of deception is practised by the makers of the tubes, who make inaccurate statements as to the nature of the fluids they contain. The author found that *tinctura rad. curcumæ* answers best for yellowish green, *tinctura sem. daturæ* for deep green, *tinctura guajaci* for deep blue, *tinctura ligni quassiæ* for bright blue, *tinctura corticis Æsculi* for bluish green, and petroleum for bright blue. The author could not obtain a red fluorescence; all the tinctures are alcoholic.

Bulletin de la Société d'Encouragement pour l'Industrie Nationale, No. 198, June, 1869.

This periodical contains the following original papers:—

Report on the Chocolate Manufactory of M. Ménier, at Noisiel (Seine et Marne).—MM. Tresca and Duchesne.—This report has been already alluded to by us, abstracted from another paper.

Report on a Peculiar Process of Dyeing a Fast Grey.—M. Barreswil.—The author states that MM. Bretonnière and Co., at Laval (Mayenne), have introduced very successfully the use of protonitrate of mercury as a mordant; and they apply, as dye, a solution of sulphuret of potassium, using 1 kilo. of that salt to 18 kilos. of woven tissue, or yarn, dissolving the salt, of course, in a sufficient quantity of water. The colour thus produced is essentially due to the formation of sulphuret of mercury on and in the tissues; and, according to the author of this paper, the colour is fast, that is to say, not destroyed by washing with soap or alkaline lyes, and resisting acids, but destroyed by chlorine.

Purifying of Syrups and Molasses by means of the Osmogène.—M. de Luynes.—This paper describes the details of M. Dubrunfaut's method of refining coarse syrups and molasses, by an apparatus called osmogène; but, unless the engravings annexed to this paper were reproduced by us, it would be impossible to understand the description properly.

The remaining papers in this number are—The continuation of a lengthy paper on—

Electro-Magnetic and Magneto-Electric Apparatus for Medicinal Applications;

A continuation of a report—

On the Culture of Truffles;

And a paper relating to locomotive engines.

NOTES AND QUERIES.

Vacuol.—I have met frequently in recent Continental journals with the terms "vacuol" and "vacuolised," in reference to fungi or the cells of fungi. I cannot find these words in Watts's "Dictionary," or in any of the foreign scientific dictionaries. Can any of your readers tell me the meaning of these terms, and with whom they originated?—Carbon.

---

* The analyst considers that these three, equal to 3·39 per cent, are combined together according to the formula—

$$(3MnO,PO_5)+2(3CaO,PO_5).$$

THE CHEMICAL NEWS.

VOL. XX. No. 507.

ON THE
METHODS OF ANALYSIS
AND THE
COMPOSITION OF VARIOUS CHEMICAL MANUFACTURING PRODUCTS.

By M. GASTON TISSANDIER.

OUR object in publishing these memoirs from the *Moniteur Scientifique* is to furnish manufacturers and manufacturing chemists with practical methods of analysing with rapidity and certainty the most important productions of commercial chemistry, and also to give an account of their composition. Special treatises are not wanting containing methods of estimating and separating substances which are subjects of investigation to chemists; but we know of the existence of no collection where the description of a process for analysing such and such a commercial product may be met with. It should be added that the methods here published are not original, and offer nothing in the way of novelty, but are employed by most chemical experts. All that we have done is to make a few trifling modifications in a small number of cases. The efficacy of these processes we can in all cases guarantee by the practice acquired by us three years ago in the *Laboratoire d'Essais et Analyses Chimiques de l'Union National*, where we have already performed more than three thousand experiments of all kinds.

I. ON CRUDE POTASHES.

Manufacture of Beet-Root Salts.—Almost all the salts of potash now manufactured are extracted from beet-root, the crude salts or potashes being made by calcining the residues of the evaporation of weak vinegars proceeding from the distillation of molasses. These vinegars were formerly evaporated in copper basins; but the acids developed by too active or imperfect fermentation, or thrown in to hasten decomposition, were found to attack the copper, which soon led to the substitution of wooden vats—an important change, which was first effected by M. Coupier. Not long afterwards, another important step was taken by M. Porion, of Vardrecques, who, in the manufacture of salts, evaporated the vinegar partly by the direct action of fire, and partly by the combustion of the charcoal which exists in the organic substance of the vinegar. The Porion stove, which is now almost universally employed, consists of a long vaulted chamber, having at one end from two to three reverberatory furnaces, and terminating in a chimney, near to which is the tap which turns on the vinegar. This chamber is traversed through its largest extent by a paddle shaft, which agitates the vinegar violently, and causes it to fall in showers into that part of the stove which is subject to the direct action of the flames from the reverberatory furnaces. When the vinegar subjected to this preliminary process is sufficiently evaporated, it is placed upon the sole of the furnaces, where, under the action of the fire and vigorous stirring, it soon assumes a pasty form; after which it quickly takes fire, and becomes itself a source of heat, by means of which fresh quantities of vinegar may be evaporated. Calcination being at an end, the salts are thrown upon the ground, and spread out upon a large space, where a final combustion occurs spontaneously.

The calcination of vinegar residues in the Porion stove requires great intelligence and practice on the part of the operators, on account of the difficulty as well as importance of seizing the proper moment for stopping the calcination. If this latter be carried too far, the potash will melt, thereby producing a substance difficult to lixiviate. The appearance of the melted potash is that of a very hard, close stone, of a light grey colour, veined with white, on concussion giving a dull sound. If, on the contrary, calcination be too soon arrested, the product is a pasty mass, which quickly cools and agglomerates, yielding brown and frothy lixiviums, difficult to treat in refining. The refined products which ensue are never white, but always of a greenish blue tinge, due to the presence of certain unoxidised or non-volatilised sulphides. The appearance of an imperfectly calcined salt is that of an earthy, brown, close substance, not very hard, tinged throughout with reddish tints, and veined with green and violet lines. If a salt of this kind be wetted, an evolution occurs of the characteristic odour of rotten eggs.

In the preparation of salts, it is most important to remove them from the furnace just at the proper time; and the duration of the calcination varies in accordance with the kind of beet-root employed; thus, when the residue under treatment is that made from Picardy beet-root, which is rich in carbonate of soda, the removal must take place sooner than with residue from the beet-root of Artois.

The disposition of the salts in the heaps where combustion takes place also requires careful superintendence; because, if a heap gets too hot, the potash will run; and if, on the other hand, the temperature does not rise enough, the potash will be imperfectly separated. Salts rich in carbonate of potash are heaped in beds from 30 to 50 centimetres thick; the poorer salts in beds of 2 metres thickness.

A well-made salt ought to present the appearance of a porous stone, very light, friable, and sonorous as pumice-stone; its prevailing colour should be greyish red. Salts contain alkaline carbonates, chlorides, sulphates, substances insoluble in water (charcoal and carbonate of lime); also small quantities of sulphates, and, accidentally, cyanides, sulphides, silicates, ammonia, &c.

Mode of Analysis.—The sample to be analysed should be pounded and sifted. About 30 grms. must be taken and finely pulverised in a porcelain mortar. 25 grms. of this impalpable powder are weighed off, and placed in a flask capable of holding 500 grms., and containing about 200 grms. of distilled water; it is then boiled for a quarter of an hour, and left to settle, that the insoluble substances may collect at the bottom of the vessel. The clear lixivium is decanted upon a filter placed on a measuring-glass, guaged to ½ litre. The insoluble substances are again treated with cold water, and so on, for three or four times. Lastly, the insoluble substances are thrown upon the filter, and washed with boiling water until the filtered lixivium occupies exactly the volume of ½ litre. This lixivium, when cool, is stirred until it becomes homogeneous, and divided, by means of a pipette, in the following way:—

1. Deduct 100 c.c. (corresponding with 5 grms. of salts), in order to obtain the alkalimetrical standard; these 100 c.c. must be transferred to a ½ litre flask.
2. Another 100 c.c. to be poured into a ½ litre glass, to estimate the sulphuric acid.
3. Fifty c.c. (equal to 2 grms., 5 decigrammes) of salts to be poured into a stoppered bottle of 250 c.c., to estimate the chlorine.
4. Ten c.c. (equal to 5 decigrammes) to be poured into a porcelain capsule of 200 c.c., to estimate the potassium.

Insoluble Substances.—These must be dried at 100°, removed from the filter, and weighed. By calcining them, and weighing the ashes, the proportion of charcoal and organic matter will be obtained by difference.

Determination of the Alkalimetrical Standard.—A standard liquid must first be prepared containing exactly 100 grms. of sulphuric acid per litre (SO_3HO). For the preparation of this liquid, we refer to chemical treatises, only remarking that it should be carefully tested before

use. This may be done either by taking as a standard perfectly dry and pure carbonate of soda, or by estimating the sulphuric acid contained by means of chloride of barium. A graduated alkalimetrical measure is filled with the liquid, which is poured, after the addition of a few drops of litmus solution, into the phial containing the 100 c.c. of lixivium or 5 grms. of salts. When the solution has become purple, it is boiled, in order to remove the carbonic acid, and then recovers its original blue colour. Fresh quantities of sulphuric acid are now added, and it is again boiled. This is repeated until the addition of another drop of standard liquid causes the solution to turn from blue to vinous red, and boiling fails to restore it to blue. By reading the number of divisions corresponding to the volume employed of standard liquid, the alkalimetric standard is obtained: thus, if 44 divisions, or 44 cubic demi-centimetres, are used, the standard will be 44°.

Estimation of Chlorine.—One of the best processes for estimating chlorine in potashes is the employment of a standard silver liquid and a solution of neutral chromate of potash. 47·886 grms. of fused nitrate of silver are first dissolved in distilled water, and then diluted so as to form a liquid 1 litre in quantity. 1 c.c. of this liquid will precipitate 1 centigramme of chlorine. Several cubic centimetres of a saturated solution of chromate of potash are poured into the flask containing 50 c.c. of saline lixivium; and the silver liquid is then added, drop by drop, by means of a measure graduated in tenths of cubic centimetres, until the lixivium, augmented by the chromate of potash, turns red. If 14 c.c. of silver liquid, or 140 divisions, be used, 2·5 grms. of the salts will be found to contain 14 centigrammes of chlorine, reckoned in the summary as chloride of potassium.

The chromate of potash may be dispensed with; in that case, the portion of lixivium in which the chlorine is to be estimated is acidulated by pure nitric acid; the standard silver liquid is poured immediately into it, and the precipitated chloride of silver collected at the bottom of the vessel by quick stirring. The exact quantity of silver necessary to precipitate all the chlorine is easily ascertained; and care must be taken to stir the precipitate whenever fresh drops of the silver liquid are introduced. With practice, this method will be found as quick and accurate as the preceding.

Estimation of Sulphuric Acid.—This may be effected by means of chloride of barium. The 100 c.c. of lixivium are acidulated with pure chlorhydric acid, and chloride of barium is added. The precipitated sulphate of baryta is allowed to settle for twelve hours, and need then only be collected on a filter, washed with boiling water, and weighed after desiccation and calcination.

Estimation of Potassium.—By means of bichloride of platinum, the potassium is deposited under the form of chloroplatinate of potash. The 100 c.c. of lixivium corresponding to the 5 centigrammes of salts are acidulated with pure chlorhydric acid; an excess of bichloride of platinum dissolved in water is added in the same capsule, and the whole is then evaporated almost to dryness in a water-bath; at the same time, it is very important not to desiccate the precipitate, which, when taken out of the water-bath, should be moistened with at least 1 c.c. of liquid. On attaining this point, it is washed by decantation with ethereal alcohol (4 volumes of alcohol at 40°, and 1 of ordinary sulphuric ether), and thrown upon a small filter. It is again washed upon the filter with a small quantity of ethereal alcohol, dried at 100° in the water-bath, carefully removed from the filter, and weighed in a sensitive balance. It answers to the formula $KCl,PtCl_2$, and the amount of potassium contained in it may be easily calculated. Some chemists do not filter the chloroplatinate of potassium, but wash it by decantation in a vessel of Bohemian glass, where it is evaporated, and dry it in the same vessel in the water-bath. The very light precipitating vessel is tared before the operation, and, by weighing it together with the contained precipitate, the difference obtained is the weight of the latter. In treatises on chemistry, the chloroplatinate of potash is generally recommended to be filtered on a tared double filter—an unnecessary precaution with the proportions here mentioned. When the quantity of salts employed is 5 decigrammes, the precipitate obtained always weighs about 1 grm.; and the amount of substances which adhere to the paper is quite insignificant. To effect this process under good conditions, the best plan is to use a standard solution of bichloride of platinum, in order to be certain beforehand of using neither a too weak nor too powerful reagent. The platinum may be dissolved in the state of sponge by means of aqua regia, in the proportion of 60 grms. per litre, and diluted with water after evaporation: 10 c.c. of this liquid will be required to estimate the potassium.

Moisture.—The moisture contained in a salt may be estimated by drying 5 grms. on a stove, heated to 120°, failing which a small closed tube may be used, into which 5 grms. of salts are placed, and dried over a jet of gas, the water condensed at the upper end of the tube being soaked up with a plug of filtering-paper. The tube is weighed empty, and again with the desiccated portion of the salt, and the difference given is the proportion of water.

Calculation of the Analysis.—The estimated chlorine is transformed into chloride of potassium, the sulphuric acid into sulphate of potash. The quantity of potassium contained in the chloride and sulphate is calculated, and then deducted from the total of potassium yielded by the chloroplatinate. The excess of potassium is transformed into carbonate of potash. The standard corresponding with the carbonate of potash is calculated, and subtracted from the total standard, and the excess of the standard is transformed into carbonate of soda. The form of the analysis is drawn up in the manner indicated below.

Phosphates are sometimes contained in salts, but in small quantities, and, in analyses for purposes of manufacture, it is generally useless to pay any attention to them.

The mode of analysis here described gives very precise results; and, when practice has been acquired, the separation of potassium and sodium occurs with great exactitude. It has been proposed to separate the potassium by means of tartaric acid; but we believe that this process would be neither so practical, nor so rigorously exact as the one we have described, whilst with the *natrometer* its results would be merely approximative.

In the course of three years, more than 1000 specimens of salts and refined potashes have been analysed by us, an example of which we subjoin below.

COMPOSITION OF BEET-ROOT SALTS.

(3). MM. Gunguièz et Cie., Bucy-le-Long, near Soissons.

Specimens No. 1 and 2 may be considered as types of salts of good quality. No. 5 is one of the richest with

which we have met, and Nos. 3 and 4 are the poorest. The composition of the crude potashes varies extremely, as is self-evident, each constituent element occurring in different proportions in the various examples. We have been asked by some chemists why the composition of salts has been thus formularised, and how we could prove that they did not contain, say, for instance, chloride of sodium. Setting aside the established custom in all commercial refineries of combining the elements in the mode we have adopted, our answer is that refining itself proves that this formula points out the true composition of the salts. If the refining be well conducted, all the salts indicated by this formula will be obtained, and in almost exactly the same proportions.

Potashes Derived from the Grease of Wool.—Before terminating our account of salts, a few words may be added relative to the potashes derived from grease extracted from wool-washings. The potashes made from grease analysed by us were produced by M. Thery-Disière, who is at the head of an important manufactory at Verviers (Liège), and who was the first to use baths for the purpose of steeping wool, which was, formerly, always thrown into the river. Here is the composition of one of these potashes—

POTASH OF WOOL GREASE.

	I.	II.	III.
Moisture	2·83	1·20	1·05
Insoluble matter	11·98	5·28	11·19
Chloride of potassium ..	5·88	6·12	7·04
Sulphate of potash ..	2·48	3·03	3·33
Carbonate of potash ..	71·52	79·01	72·25
Carbonate of soda	4·96	5·15	5·14
Non-estimated and loss	0·35	0·21	5·14
	100·00	100·00	100·00

Potashes extracted from wool-grease are produced in several manufactories in France, and constitute an excellent product, rich in carbonate of potash; but an important progress in this branch of manufacture yet remains to be realised, viz., the diminution, or even complete removal, of insoluble matter without recourse to refining.

REFINED POTASHES.

Refining the Salts.—The salts are broken into fragments the size of an egg, and lixiviated in water. The lixivium should mark from 20° to 25° on the Beaumé areometer; it is passed into cauldrons, where, by successive evaporations, crystallisations, and solutions, the separation of the salts is effected.

In the first set of cauldrons, the lixiviate is evaporated until it marks 40° on the Beaumé areometer; at this density, most of the sulphate of potash is precipitated. The liquid is left to settle, and decanted into crystallising pans, where the greater part of the chloride of potassium crystallises when quite cold.

The mother liquor is evaporated in the second set of cauldrons until it marks 45°, during which process it precipitates carbonate of soda. After settling, the lixiviate is again passed into the crystallising pans, where, on cooling, a new deposition of chloride of potassium takes place. The lixivium is again heated in the third set of cauldrons, and rendered sufficiently concentrated to mark either 50, 51, 52, or 53 areometric degrees. Carbonate of soda is still deposited; the liquid in the crystallising pans, when cool, still precipitates chloride of potassium, and, when evaporated to dryness, yields commercial refined potash, generally containing from 78 to 82 per cent of carbonate of potash. In order to obtain potashes refined to a still higher standard, these are dissolved at 80°, and the solution evaporated to 61 or 63 areometric degrees. Carbonate of soda is deposited, and the liquid obtained, when evaporated and calcined, yields potashes containing from 88 to 94 per cent of carbonate of potash.

Sulphate of Potash.—It has been shown that the greater part of the sulphate of potash contained in the salts was deposited during the first evaporation of the lixivium. This salt, polluted in the first instance by the impurities of the lixivium, contains, besides the alkaline carbonates, chloride of potassium. By means of rakes, the salt is taken up as it precipitates, placed to drain in vessels of perforated sheet-iron, dissolved, and subjected to a fresh crystallisation. Commercial sulphate of potash is thus obtained.

Chloride of Potassium.—The chloride of potassium successively deposited during the different phases of evaporation of the lixivium is left to drain, and, when deprived of the liquid which moistens it, is saleable. After the second or third cooling, it is not, however, sufficiently pure to be introduced into trade, and must be collected and restored to the first set of cauldrons, there to be operated upon anew.

Carbonate of Soda.—The carbonate of soda produced by evaporation of the lixivium is purified, after desiccation, by means of successive solutions and crystallisations, repeated two or three times. The soda-salt thus obtained furnishes, after calcination, commercial white soda.

It is, of course, understood that these evaporations never produce salts in a state of complete purity, and that all products thus obtained are mingled more or less with other substances. Sulphate and chloride of potassium and carbonate of soda are manufactured by other processes than those we have described. On this subject a few words will be said when discussing more especially these different salts. We will at present confine ourselves to an examination of the composition of refined potash (carbonate of potash).

METHOD OF ANALYSIS AND COMPOSITION OF REFINED POTASH.

The analysis of refined potash is effected in a precisely similar manner to that of crude potash, except that it is more rapid, on account of the non-necessity of separating the insoluble substances, which occur in only the smallest proportions.

Twenty-five grms. of refined and pulverised potash are dissolved by decantation in a flask, and the obtained lixivium is diluted to the volume of 500 c.c. Decant 100 c.c. to obtain the standard, 100 c.c. to estimate the sulphate, 50 c.c. to determine the proportion of chlorine, and 10 c.c. to estimate the potassium, by means of bichloride of platinum. The moisture is estimated by heating the potash-salt to a red heat in a platinum crucible. The analytical results given below may be considered as representative types of the different qualities of

Substances estimated.	I.	II.	III.	IV.	V.	VI.	VII.	VIII.	IX.	X.

commercial refined potashes. As in the case of the beet-root salts, we give the names of the manufactories whence the specimens were obtained; and we here desire to thank those manufacturers who, while supplying all necessary information, have kindly authorised us to publish the composition of their products.

These results will show that commercial refined potashes contain from 69 to 93 per cent of carbonate of potash. It should be added that analyses Nos. 8 and 9 were performed upon carbonate of potassium from Stassfurt, according to the method of M. Leblanc.

(To be continued.)

PRELIMINARY NOTE ON

THE PRODUCTS OF THE DESTRUCTIVE DISTILLATION OF RESIN.

By THOMAS ANDERSON, M.D., F.R.S.E., F.C.S.,
Professor of Chemistry in the University of Glasgow.

I HAVE been engaged for several years in the investigation of the distillation products of resin. The subject having proved one of great extent and complexity, it was not my intention to have made any part of it public until it was more complete than it is at the present moment, but the recent appearance of a similar investigation by Mr. Tichborne* has induced me to alter this intention and to publish my results, especially as some of them differ from those which he has obtained.

When common colophony is distilled, the first product is a small quantity of a volatile oil, commonly known as "rosin spirit," consisting of some products of decomposition of the resin contaminated with a portion of the essential oil originally existing in the turpentine. When this is separated, an oil is obtained which becomes more and more viscid as the distillation proceeds, and shows a gradually increasing blue fluorescence as the temperature rises, and at last a small quantity of charcoal is left in the still. When this crude resin oil is rectified, the first product is a "rosin spirit," larger in quantity and somewhat different in smell from that obtained in the first distillation. This is followed by a mixture of thick oils of high boiling point, and the last product, if kept separate, acquires, on cooling, the consistency of soft butter, or rather of a mixture of oil and butter. When this is exposed to a freezing mixture and expressed, a solid crystalline substance is left on the cloth, which, when purified, proves to be the metanaphthaline or retisterene of Pelletier and Walter.

My investigations hitherto have been mainly confined to the spirit obtained in rectifying the crude resin oil. When this is submitted to a systematic fractionated distillation, it splits up into a variety of oils, and after seven or eight rectifications, fractions are obtained at all temperatures, from 70° C. up to 400°, the latter being of course portions of the less volatile oils which passed over at the first rectification.

The fractions boiling between 125° and 150° deposit a crystalline substance, which is obviously an oxidation product, and increases in quantity when the oil is preserved in partially filled bottles. This substance is Mr. Tichborne's colophonine. It is soluble in water, ether, and alcohol, and is deposited from the hot solutions in long needle-shaped crystals, which fuse at 106° and sublime easily at a higher temperature. Their smell is aromatic, and they have a warm and somewhat pungent taste. They were purified by expression, exposure to the air until the oil attached to them had evaporated, and then subliming repeatedly. The results of combustion were as follows:—

(I.) 0·425 gramme gave 1·004 CO_2 and 0·424 H_2O.
(II.) 0·2225 gramme gave 0·526 CO_2 and 0·225 H_2O.

* CHEMICAL NEWS, vol. xx., p. 38.

	I.	II.	Calculation.	
Carbon	64·43	64·47	64·61	C_7 84
Hydrogen	11·09	11·24	10·77	H_{14} 14
Oxygen			24·62	O_2 32
			100·00	130

This corresponds completely with the empirical formula $C_7H_{14}O_2$ which bears a simple relation to terebic acid, $C_7H_{10}O_4$. I have endeavoured, but as yet without success, to convert this substance into terebic acid by means of oxidising agents. By strong nitric acid it is converted into oxalic acid, with more dilute acid a resin is produced, but I have not obtained it in sufficient quantity to admit of any process of purification being applied to it. Not having analysed the crystals of this substance deposited from water, I failed to detect Mr. Tichborne's hydrate of colophonine, but the composition he gives for it is not altogether inconsistent with my formula, for a hydrate $C_7H_{14}O_2+H_2O$ would give—

Carbon	56·75
Hydrogen	10·81

The oils contained in resin spirit are very complex, and consist of a mixture of hydrocarbons, the investigation of which is still quite incomplete. The most volatile fraction, which was very small and boiled between 70° and 80°, contained a volatile acid, apparently acetic acid, which gave abundant white fumes with ammonia. After separation of this acid by washing with water and drying, the oil gave—

Carbon	84·62
Hydrogen	13·71

Though the oil obviously contains oxygen, these numbers approximate to the composition of an olefiant, and its vapour density was 3·257, agreeing sufficiently with 3·386, which is the theoretical number for heptylene. The oil is probably a mixture of this substance with some oxygenated product, but the quantity at my disposal did not permit of any process of separation being employed.

At the temperature of 107° a larger quantity of oil was obtained, also containing oxygen. It gave, on combustion—

	I.	II.
Carbon	85·90	86·44
Hydrogen	12·75	12·97
	98·65	99·41

in which the carbon agrees with that of an olefiant, although the hydrogen is deficient. As far as analysis is concerned, the oil appears to be homogeneous, for, on rectifying it and separating the first few drops and the last few drops of the distillate, they were found, on combustion, to give identical results. The action of reagents, however, leads to an opposite conclusion. When digested for some time at 220° with strong hydriodic acid, it is converted into a black oil heavier than water. This, after being washed with potash and dried, yielded on distillation two oils, one boiling at about 177°, which contains iodine, is partially decomposed by distillation, and for which no formula could be obtained, and a non-iodised oil, very viscous, with a green fluorescence, and boiling a 290°. On combustion, it gave the following results:—

	Experiment.	Calculation.	
Carbon	87·94	88·24	C_{10} 120
Hydrogen	12·19	17·76	H_{16} 16
	100·03	100·00	136

It is therefore a terpene apparently corresponding with the colophene or metaterpene of Berthelot.

Of the less volatile oils, I have as yet examined only one boiling at 157°, and another boiling at a higher temperature. The former is an oxygenated oil, with a specific gravity of 0·853. The results of its analyses in

the first instance approximated to those of terpinol, with which, however, it is only isomeric and not identical. But some results afterwards obtained lead me to suspect that it may be a product of hydration of a terpene existing in the crude oil. When treated with sulphuric acid, heat is evolved, and the oil, after being separated from the acid and purified by distillation, has exactly the smell and composition of terebene. The products at higher boiling points appear to be terpenes, but they give no solid hydrochlorates, and their separation presents difficulties which I have not hitherto been able to overcome.

I trust I may be able at some future period to throw further light on the constitution of these substances; my investigation of which must be considered for the present as entirely preliminary.

ON THE

ESTIMATION OF THE SO-CALLED PRECIPITATED PHOSPHATES IN MANURES,

AND THE

ESTIMATION OF SOLUBLE PHOSPHATES GENERALLY.

By FRANCIS SUTTON, F.C.S., Norwich.

THE difficulty presented by this subject has lately been discussed in this journal from two points of view, namely, that of the manure manufacturer and the professional analyst.

Anyone who knows anything of the matter must certainly feel, with the manufacturer, that it is a real grievance to have expended time and money in producing soluble phosphate which, owing to this reducing action, is valued at only about one-third the price it ought to sell for.

Again, on the other hand, the analyst is asked to say how much phosphate of lime soluble in water is present in a particular sample of manure, and his duty is plainly to treat such a sample with water only, and state the percentage of phosphate therein.

The manufacturer says, I believe the recently-reduced phosphate is quite as effectual in action as the soluble phosphate, because I am told by good authorities that, so soon as soluble phosphates come in contact with the soil, they are rendered insoluble, and, therefore, why should not my recently-precipitated phosphates be just as valuable as the soluble phosphates? The only reply that can be made to this is that the analyst, unless he can find a reliable process for estimating recently-reduced phosphates, must consider and value them solely as insoluble phosphates. It has been proposed to use citric acid, oxalic acid, or oxalate of ammonia for the purpose of rendering these phosphates soluble, in order that they may be estimated and valued at a higher price than ordinary insoluble phosphates.

If it can be shown that any of these reagents will affect such a material as Cambridge coprolite, and render it soluble in water, it is manifest that such aids cannot be depended upon for the purpose required.

This seems to have been pretty well settled by the experiments of Mr. Hughes; but the results obtained by him have been cavilled at by one of your correspondents ("Fair Play") as being conducted in an improper way. As I am situated in the heart of a large manure-consuming district, and continually estimating phosphates, it has occurred to me to extend these experiments somewhat further, and I think the result will show that no real dependance can possibly be placed upon any of the hitherto-suggested plans for determining these reduced phosphates.

The experiments were made upon two substances, namely, a mineral superphosphate which originally contained about 23 per cent of soluble phosphate (calculated as bone-earth), but which, at the time of the first experiment, yielded only between 17 and 18 per cent, together with about 10 per cent of insoluble; the other substance was raw Cambridge coprolite, containing about 56 per cent of insoluble phosphate of lime. All the determinations were made by the acetate of uranium process, in the presence of a slight excess of free acetic acid.

1. One grm. superphosphate, treated first with cold and afterwards with hot water, yielded 17·7 per cent soluble phosphate.

2. One grm. finely-ground coprolite, treated precisely in same manner (as might be expected), gave no soluble phosphate.

3. Residue of No. 1, boiled with 100 c.c. water and 4 c.c. strong acetic acid, yielded 2·3 per cent soluble phosphate.

4. One grm. coprolite, with same proportions of water and acetic acid, gave 4·8 per cent soluble.

5. One grm. of the superphosphate, heated with equal parts of acetic acid and water, gave 19·5 per cent soluble.

6. One grm. coprolite, treated in same manner, gave 9·9 per cent soluble.

7. One grm. coprolite, heated with 1 grm. citric acid and 100 c.c. water, gave 10·4 per cent soluble.

8. One grm. coprolite, with same quantities of tartaric acid and water, gave 10·8 per cent soluble.

9. One grm. of same superphosphate, digested in the cold with ½ litre of water for twelve hours, gave 14·8 per cent soluble.

10. One grm. of the same superphosphate, but some five or six weeks older, was put into a vessel with ½ a litre of water, and charged with 10 volumes of carbonic acid for five hours; the yield was 13·8 per cent soluble.

11. One grm. coprolite was treated precisely in same manner, and gave slight traces only of soluble phosphate.

12. 2·5 grms. same superphosphate, digested in the cold with 2·5 grms. oxalate of ammonia in ½ litre of water for twelve hours, gave 16·0 per cent soluble.

13. 2·5 grms. coprolite, digested in the cold with same weight of oxalate in ½ litre of water for twelve hours, gave no soluble phosphate.

14. 2·5 grms. superphosphate and 2·5 grms. oxalate of ammonia were mixed with ½ litre water, and heated on the water bath one hour; the yield was 17·1 per cent.

15. One grm. superphosphate, with 1 grm. oxalate, were mixed with 50 c.c. water, and digested half an hour on water-bath; the yield was 19·4 per cent soluble.

16. Same weights of both were mixed with 50 c.c. water, and digested in the cold twelve hours; the yield was 17·6 per cent soluble.

17. One grm. superphosphate, with 1 grm. oxalate, were mixed with 50 c.c. water, and boiled ten minutes; the yield was 22·6 per cent soluble.

18. One grm. coprolite, boiled for same time in 50 c.c. water and 1 grm. oxalate, gave 10·8 per cent soluble.

The results of these experiments are, in some respects, anomalous, but a little consideration will probably throw some light on the matter.

The superphosphate here examined contained considerable quantities both of iron and alumina; and it seems that it is only such phosphates that are, to any considerable extent, liable to this reduction. The true explanation of their action in this respect I cannot pretend to give, nor have I heard of any being given by others; it is, however, well known that raw phosphates containing these substances make very soft and pasty manures, which, before they can be rendered marketable, must be dried by the addition of some absorbing substance which, as it removes the constitutional water from the iron or alumina phosphates, converts them into some basic form which is not soluble in plain water. If it be the case that iron or alumina, or both, are at the bottom of this matter, this explains the slight effect which acetic acid has upon the residue of this particular superphosphate after exhaustion with water (see experiments 3 and 5); while the plain coprolite, containing only slight traces of iron or alumina, yields double the percentage of soluble phosphate under the same treatment in experiment 4, and about five times as much in experiment 6.

With regard to the effect which oxalate of ammonia has upon reduced phosphates, it appears that no very great increase of soluble phosphate is obtained by dilute solutions in the cold, nor upon coprolite; but when a boiling heat is used, and the solution concentrated, a considerable yield is obtained in the case of the reduced phosphates, and as much as 10·8 per cent from the coprolite.

It does, therefore, appear that, where a superphosphate contains the so-called reduced phosphates, their amount may pretty nearly be found by the use of oxalate of ammonia in a boiling solution. But it is quite another question whether the phosphates so recovered are as valuable as if they were soluble in water; at any rate, carbonic acid, under considerable pressure, has no more effect upon them than it has upon raw coprolite. The thing which does affect them, namely, oxalic acid, acts upon hard raw coprolite still more; and this does not favour the supposition that they are as valuable as if they had never been reduced.

Again, suppose a manufacturer chooses to mix off some tolerably pure form of insoluble phosphate with a superphosphate liable to reduction; the analyst who used the oxalate process for estimation would, probably, report several per cents of soluble phosphate in the manure which had never been in the soluble state at all, and the farmer would be asked to pay about three times as much for such phosphates as he might have bought them for in the form of coprolite.

Under such circumstances as these, it, therefore, seems that the duty of the analyst is plainly to state the absolute truth—namely, that such a sample of manure contains so much phosphate of lime soluble in water—and there leave it. I repeat that this is a hardship to the maker, in many cases; but I am not certain that it is necessary for him to incur this risk.

I would now say a word or two relative to the method of estimating soluble phosphates; the stigma which has been brought upon professional chemists in general by the fact that some well-known professional men invariably give high results, while others, also, invariably give low ones, is considerable, and ought, if possible, to be removed.

This discrepancy may, in most cases, be accounted for by the process adopted in determining the phosphates; and, in order to remedy this evil, I would recommend the universal use of one process only, granting that a good and reliable process can be found.

All chemists are aware of the good effect which has resulted from the adoption of this system in silver assaying by the wet method and others of like nature; and I see no reason why it should not be adopted in the matter of soluble phosphates. There may, of course, be a difference of opinion as to what process shall be adopted, but I know of none so reliable for manures of all descriptions (for soluble phosphates), as the uranium process by weight (fully described by me in this journal of February 4th and 18th, 1860). A very large number of analyses made in my laboratary since that time, and tested by every conceivable comparison, have brought the conviction that no other process is, at the same time, so short and so exact, and is quite available, without modification, in the presence of iron or alumina phosphates usually found in some samples of manure. An analysis can be begun and completed within three hours; and, of course, a series may be carried on at one and the same time, if a sufficient number of vessels are at hand. The objection against the process, on the ground of expense, amounts to nothing, since the whole of the uranium can be recovered again for repeated use.

To Melt Two Metallic Mixtures by Friction.—Melt, in one vessel, one part of mercury and two parts of bismuth; and in another one part of mercury and four of lead. When cold, they will be quite solid, but, by rubbing them against each other, they will soon melt, as if each had been rubbed separately against red-hot iron.—*American Artisan.*

DETECTION OF POTASH AND SODA BY BLOWPIPE VESICULATION.

THE following letter and list of experiments has been forwarded by Capt. W. A. Ross, R.A., to Professor Theodore von Richter, Head of the Royal College of Freiburg, and also to us for publication in the CHEMICAL NEWS:—

Simla, India, June 17th, 1869.

Dear Sir,—In accordance with the request contained in your letter of the 1st of January, 1868, to my address at Woolwich, to be informed of the result of my further labours in the matter of blowpipe vesiculation discovered by me, I have the pleasure now to communicate the following:—On arriving here in April, the weather being very warm and dry, and an aneroid barometer compensated for heat standing only at 22·80°, I made some borax vesicles of KOHO and CaCl, and other of the most deliquescent salts I had, none of which, to my surprise, either deliquesced or showed the least sign of crystallisation. They remained unchanged until the 8th of June, when very heavy rain fell the whole day and night. Next morning the potash vesicle had partly deliquesced, and the rest were covered with crystals. From this fact I ascertained that the vesicular crystallisations of borax discovered by me are all superposed, or formed from the hygrometric moisture of the air, and not pyrogenous, or formed from the hot borax on cooling, like those mentioned by Berzelius (pp. 64, 190, 214, &c., of the American Translation, Boston, 1845), Rose of Berlin, and other writers. As it appeared to me that the moist atmosphere could only act with uniformity on uniformly composed substances presented to it for crystallisation, I strove to attain something like uniformity by measuring 50 milligrammes of borax for each bead, taking up as near as possible an equal quantity in each case of the substance to be examined. I found this a troublesome process, and hit upon a far easier and equally exact method—by measuring the bead after it had cooled, by slipping over it a glass tube of the diameter of 5° on the lead measure, filing a shoulder on the top of the platinum wire holder to allow the tube to stand upright over the wire, and then seeing with the magnifying glass how far the sides of the bead (placed with the wire next the eye) were from touching the sides of the tube. I reflected, however, that borax, being a compound salt, could scarcely be expected to give uniform results chemically, either as regards crystallisation or any other operation, and connecting the fact in my mind that alkalies and alkaline earths always give a cloudiness to vesicles of borax in moist weather with the other facts—(1) that the "boron diamond" can only be attacked by the fused hydrates of the alkalies; and (2) that alkaline borates are freely soluble, while those of the other bases are either insoluble or very sparingly so—I determined to operate if possible on pure boracic acid. I was much pleased to find that substance easily blown into vesicles (having expected the contrary), as it is very viscid when the HO and air bubbles are expelled from it, and I found that its vesicles, being thinner than those of borax, invariably possessed a most brilliant iridescence. But the most useful feature to me was the fact of their clouding over a few seconds after formation, with a delicate blue white film upon which the iridescent colours, gleaming beneath, bestowed a beautiful opaline or mother-of-pearl lustre which I have called "opalescence." I immediately saw that as the borax vesicle is clear and the boracic acid one opaline, a valuable and sure means of detecting the presence of soda, at least in the proportion in which it enters into the composition of borax, is thus afforded, for that amount of soda in the subject of analysis would of course combine with the BO_3 forming a boracic acid (or clear) vesicle. I will not fatigue you with details of the experiments I made, 48 of which I have the pleasure to enclose. You will be able to draw just conclusions from them or others repeated far better than

I can possibly do, but I may venture to state that my object hitherto has been almost exclusively confined to a means of isolating, by this method, potash from soda, the blowpipe flame and oxide of nickel tests being, as you are aware, almost worthless, and that, by the wet analyses, a long, tedious, and difficult operation. Without troubling you with details (which will be found in the experiments), I ventured to conclude—

1st. That soda and fluor spar (CaF) interfere with the opalescence of BO_3 vesicles.

2nd. That potash does not interfere with it.

3rd. That chlorine increases it both as to quickness of appearance and intensity.

4th. That CO_2 causes it to appear after a time weakly, even in the presence of soda.

I regret I have no pure or caustic soda to operate with, nor can I obtain it nearer than Calcutta. Experiments 17 and 20 show that 10 to 13 c.c. of potash Alaunstein can be detected by this method in presence of 53Fl and 32 soda (in kryolite), and, on the other hand, experiment 48 shows that, without soda as a constituent, potash alone fails to neutralise the effect of CaF in preventing the opalescence of vesicles of boracic acid.

I have, as you will see, attempted scarcely anything but the two alkalies—the acids and metals, &c., remaining for future examination. It was easy enough to distinguish by this method between potash and soda in pure salts, but I found it more difficult when applied to traces of those alkalies in silicates; still, I discovered, as you will see, traces of potash by this means in the soda minerals, "albite, analcine, and labradorite," supplied me from Freiberg, while kryolite showed not a trace, and when artificially supplied with KO from Alaunstein, immediately showed a strong trace of that alkali.

Besides being (I hope) found to be most useful in detecting soda and potash in minerals, and of making BO_3 and CaF betray each other, these boracic acid vesicles form the most delicate hygrometers possible, clouding over with a rapidity proportional to the amount of moisture contained in the atmosphere. If the air is so very dry that even boracic acid vesicles take some time to opalesce, the addition of chlorine will make them still more sensitive, and if the air is very moist, that of CaF far less so, until absolute insensibility (or transparency) is attained. I regret that the departure to-day of the mail prevents my saying more at present on this interesting subject. Pray let me know what results your experiments on the subject give, and believe me, yours with great respect,

W. A. Ross.

EXPERIMENTS IN VESICULATION WITH BORACIC ACID, JUNE 13, 1869.
(Bar. 22·70; Ther. 82; Air, very dry).

1. BO_3 + KOHO.	Opalesced in four minutes.
2. BO_3 + $NaOCO_2$.	Remained quite clear for hours.
3. BO_3 + $KOCO_2$.	Opalesced in fifteen minutes.
4*a*. BO_3 + NaCl.—At first I took a large quantity of BO_3, and could not take enough Na from the NaCl to satisfy it, as the bead dropped off.	The BO_3 therefore apparently seized upon a part of the Cl (which came off in thick fumes) and the vesicle clouded over the moment it was taken from the flame.
4*b*. Tried NaCl again, in large quantity, with very little BO_3.	Fumes of Cl, when stopped vesicle made; remained quite clear ever since up to to-day (June 17).
5. BO_3 + MoS.—The native sulphide.	Clouded (not opalesced) in quarter of an hour; afterwards crystals formed exactly like leopards' spots.
6. Tried 4*a* and 1 near the flame of spirit lamp.	Opalescence vanished immediately, leaving a clear dry vesicle exactly like the volatilisation of the sublimate of arsenic from charcoal before the blowpipe.
7. Alaunstein.	Opalesced in fifteen minutes.
8. Kryolite.	Remained quite clear to date; vesicle much less fragile and iridescent than those of BO_3, and bead more fluid.
9. Adular.	Opalesced slightly in twenty minutes.
10. Albite.	Faint opalescence after quarter of an hour.
11. SiO_2 powdered.	The SiO_2 remained undissolved; the BO_3 opalesced strongly after quarter of an hour.
12. Vesiculated KOHO in borax; made a hole with pin at top, and breathed upon it.	Deliquesced rapidly and translucently on the edges of the hole, without having clouded over or opalesced in any way; crystals afterwards formed on edges of the hole.
13. Breathed upon 1 and 4*a* when freshly re-made.	Both rapidly opalesced, but when heated very gently near spirit lamp, frothed instead of vanishing.
14. Mixed 11 with a little kryolite.	Opalesced slightly.
15. Mixed ditto with NaCl, driving off the Cl well, as I did not think it had Na enough.	Remained quite clear to date (17th).
16. Analcim.	Very difficult to make; opalesced faintly in quarter of an hour.
17. Ditto, with CaF.	Remained quite clear to date.
18. Labradorite.	Opalesced pretty strongly in twenty minutes.
19. Ditto with CaF.	Remained quite clear to date.
20. Mixed 7 and 8.	Opalesced pretty strongly.
21. „ 7 with CaF.	Remained quite clear all night.
22. „ 9 „ „	„ „ „
23. „ 10 „ „	„ „ „
24. Re-made 12 and added BO_3.	Remained clear for twenty-five minutes.
25. Re-made 1 and added $NaOCO_2$.	Opalesced faintly in quarter of an hour.
26. Re-made 21, 22, and 23, and added KOHO to each in large quantity.	Remained quite clear to date.
27. Pure boracic acid.	Opalesced round platinum wire in thirty seconds.
28. Re-made 4*a* and 1 fresh.	Opalesced in a few seconds 4*a* quickest.
29. Re-made 20 and added $NaOCO_2$.	Remained quite clear to date.

30. Added BO_3 to 24.	Remained clear for twenty minutes.
31. Added $NaOCO_2$ to 25.	Opalesced very faintly in quarter of an hour at one end only.
32. Added more $NaOCO_2$ to ditto.	Remained quite clear to date.
33. Added much BO_3 to 30.	Bead very fluid; opalesced in quarter of an hour.
34. Re-made 27.	Opalesced slightly in one minute; all over in twenty minutes.
35. Added NaCl to much BO_3.	Began to opalesce in thirty seconds; completely opalesced in two and a half minutes.
36. Added more NaCl to ditto.	Remained quite clear.
37. BO_3 + CaCl to saturation.	No Cl disengaged; vesicle clouded mechanically with Ca.
38. BO_3 + very little CaCl.	Opalesced in one minute, but did not increase.
39. Pure boracic acid.	Opalesced slightly in half a minute; all over in five minutes.
40. Re-wetted 37 with geblase.	Bead opaque; vesicle opalesced in ten minutes.
41. BO_3 with slight trace CaF.	Opalesced in quarter of an hour.
42. The same with double CaF.	Remained quite clear to date.
43. BO_3 with trace CaF.	Opalesced in quarter of an hour.
44. Pure boracic acid.	Opalesced slightly in half a minute; all over in three minutes.
45. $NaOCO_2$ (sub-carbonate).	Opalesced slightly in ten minutes.
46. ,, (double quantity).	Opalesced considerably in quarter of an hour.
47. ,, (more $NaCO_3$).	Remained clear to date.
48. Added KOHO to 42.	,, ,, ,,

MISCELLANEOUS.

British Pharmaceutical Conference.—The meeting for the present year will be held during the third week in August, at Exeter, in the College Hall, under the Presidency of Mr. Daniel Hanbury, F.R.S. On Tuesday, the 17th, at 10 a.m., the President will deliver an address; the reading and discussion of papers on pharmaceutical subjects will then commence, be continued in the afternoon till 4.30, and be carried on during Wednesday; an adjournment from 12.30 till 2.0 taking place each day. On Thursday a complimentary entertainment to their visitors will be given by the chemists of Exeter. On Friday, the chemists of Torquay invite members to view some points of interest in the neighbourhood and partake of luncheon.

University of London.—The following are lists of the candidates who have passed the recent examinations in Arts and Science. *First B.Sc. Examination* (*Pass Examination*).—First Division. Edward Bibbins Aveling, University College; Walter W. Rouse Ball (First B.A.), University College; Henry Septimus Bott, Owens College; Frank Clowes, Royal College of Chemistry and Pr. st.; John William Elwes, King's College; Thomas Oliver Harding, B.A. University College; Marcus Manuel Hartog, University College; Charles William Hodson, Chester College; David Bridge Lees, B.A. Camb., Owens and Trinity College, Cambridge; Robert Routledge, Owens College. Second Division. Hampden Gurney Jameson, University College; Sidney Follett Osler, University College; Charles Rigg, Chester College; Robert Davies Roberts, University College.

The Metric System of Weights and Measures.—The second report of the Standards Commission has just been published, together with an appendix of detailed information. The Commissioners confine themselves in this report to the questions connected with the metric system, and with its adoption in the United Kingdom; and they consider the reasons for and against its introduction under two heads—namely, those which relate to the internal commercial transactions of the country; and those which relate to transactions with other countries. With regard to the former, they observe that there is at present no inconvenience arising from the discordance between the customary weights and measures, because, whatever difference may prevail as to the multiples in local use, the essential units—the yard, the pound, and the gallon—are everywhere the same; based upon standards which are constructed with the utmost skill and care, and supported by a system of inspection which, though chargeable with imperfections, is, on the whole, efficient. Moreover, the requirements of different trades need somewhat different bases. The yard is a very convenient length for draper's measures, but the foot is far more convenient for carpenter's measure. It has been remarked that the last, or coomb, the bushel, and the peck, are well suited for men's backs, arms, and hands; and also that the natural inclination of the mind to halve and quarter continually exhibits itself in the subdivision of almost every base. The metric system does not offer facilities either for the change of the adopted base, or for the continued binary subdivision; and any attempt to force it into use in shops and into workmen's operations and accounts would propably be felt as a needless grievance. At the same time the want of weights and measures on a decimal scale generally, or on the metric scale specifically, is not unfrequently felt by the manufacturing and trading classes, and more especially by men of science and by chemists and engineers of the highest class; and it appears hardly possible to satisfy this want except by the legal establishment of metric standards, and by the legal sanction of the use of metric weights and measures in shops and offices of conveyance. In order to prevent confusion, it would be necessary to provide that the metric weights and measures should have such form or other characteristics as would render it impossible to mistake them for those of the existing system; and in a future report the Commissioners promise to deal with the question of further simplification by the abolition of troy weight. Passing on to our transactions with foreign countries, the Commissioners remark upon the recent great increase in the amount of these transactions, and argue from it to the permissive adoption of the system which agrees with that of so many of our foreign trade correspondents, as well as to the giving the ordinary statistical publications relating to trade on the metric as well as on the imperial system. Attention is next called to the degree in which the introduction of a decimal system of coinage would assist in rendering the public familiar with the use of decimal weights and measures; and the report concludes by recommendations arranged under nine heads. These recommendations are, in substance, that metric standards under the French nomenclature should be legalised and provided, but that the use of the system should be entirely permissive, and not even in prospect compulsory; that regulations should be adopted to prevent confusion between the two classes of weights and measures; that Customs and other duties might be levied and the business of public departments conducted by either system; that mural standards of both systems should be exhibited in public places; and that the decimalisation of our system of coinage should be undertaken by the Government. At the same time it appears to the Commissioners to be essential that any measure for the introduction of the metric system should be proposed to Parliament by the Executive Government; and, considering that the Commission will shortly enter upon the questions referred to, those relating to the system of local inspection of weights and measures throughout the United Kingdom, its members are of

opinion that "it is expedient that no legislation should take place with respect to the metric system until the whole subject of the weights and measures of this kingdom be brought before Parliament in one Bill."

The British Association.—Great preparations are being made at Exeter for the reception of the British Association next week. A new hall has just been completed capable of holding 2000 persons. The new wing of the Albert Museum is also finished. Various excursions are organised; and altogether the association week is expected to be very successful. The President-elect, Professor Stokes, is to be the guest of Lord Devon, at Powderham, where there will be several other distinguished guests. Lady Rolle will likewise receive a number at Bicton. Lord Clifford will receive the Abbé Moigno. Sir Stafford Northcote will entertain, at Pynes, Lord Fortescue, Lord Stanley, M.P., Lord Houghton, Lord and Lady Colchester, Sir C. Trevelyan, Mr. Baring, and others. Sir Henry Ferguson Davie will have staying with him, at Creedy, Col. Sykes, M.P., Mr. D. Dalrymple, M.P., Professor Newton, Professor Lawson, &c. At Claremont, Sir John Bowring will entertain Professor Huxley and several distinguished foreigners. The order of proceedings starts with a general meeting of the council and committees of sections of the association on Wednesday, the 18th inst., when the committees and officers of the various sections will be appointed. On the same evening, the President, Professor Stokes, will deliver the inaugural address at the new Victoria Hall. On the following day, the presidents of the seven sections will deliver their addresses, and the reading of the papers will commence. A *soirée* will be held on Thursday evening in the Museum. On Friday evening, Professor Phillips, D.C.L., F.R.S., will lecture on Vesuvius. Saturday will be slack in the sections, as there are to be two excursions on that day—one to the extreme west, and the other to the extreme east of the county; but in the evening Professor Miller will deliver his lecture to the operative classes in the Victoria Hall. As it is intended for working men and their families, the price for admission is fixed at 2d., and it is fully expected that there will be very numerous applications for tickets. On Monday, the sectional meetings will be supplemented by a lecture on the sun, to be delivered in the Victoria Hall by Mr. Norman Lockyer. The sections will resume work on the Tuesday; and on Wednesday, the 26th, the British Association week in Exeter will terminate with the Mayor's luncheon at the Royal Public Rooms.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

In accordance with the generally expressed wishes of our friends and readers, we have effected arrangements to enable us to give, under the above heading, notices of EVERY CHEMICAL PAPER IN THE WORLD, *as soon as possible after publication. Whenever possible, these notices will appear in the form of carefully prepared, although necessarily brief, abstracts; as respects papers either too long or too abstruse to render condensation possible, their titles will be chronicled; and in all cases accurate reference will be made to the original publication. The two half-yearly volumes of the* CHEMICAL NEWS, *with their copious indices, will therefore be equivalent to an English edition of the "Jahresberichte," with the additional advantage of keeping the readers week by week on a level with the latest advances of science.*

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus des Séances de l'Académie des Sciences, vol. lxix., No. 4, July 26, 1869.

A very considerable portion of this number is again devoted to an apparently never-ending dispute about the Pascal, Newton, and Chasles-Le Verrier controversy. Among the papers we notice:—

Researches on the Products of Oxidation of the Principal Normal Alcohols.—MM. Pierre and Puchot.—The authors have used the well-known plan of acting with bichromate of potassa and sulphuric acid upon the alcohols submitted to experiment. They distinguish, among the products of this reaction, between the normal acid belonging specially to an individual alcohol, its aldehyde, and the compound ether, which are proper to each separate alcohol; for instance, with amylic alcohol, valerianate of amyl may be obtained; with butylic alcohol, butyrate of butyl may be produced. The authors describe, at great length, what precautions are in general required to be observed in experiments of this kind, and then specify the following particulars:—(1) The preparation of valerianate of amyl, $C_{10}H_9O_3,C_{10}H_{10}O$, by the oxidation of amylic alcohol; (2) the preparation of butyrate of butyl, $C_8H_7O_3,C_8H_9O$; (3) the preparation of propionate of propyl, $C_6H_5O_3,C_6H_7O$. These preparations are concisely described.

Proposed Plan of Protecting Iron Vessels against Rust and Corrosion.—MM. Dance and Bertin.—The plan proposed by these gentlemen for this purpose, is to convert the hull of the iron vessel into a galvanic battery by placing, inside the hull, pipes and tanks made of zinc and filled with sea-water, and connected, by means of bolts and rivets in metallic contact, with the outer side of the vessel. The authors of this paper also propose the use of strips of zinc on the iron plates of the vessel immersed in the water.

Correlation of the Unequal Visibility of Colours at Twilight, and their Unequal Photographic Activity in Full Daylight.—M. Keller.—The author observes that, after sunset, those colours which are the brightest when seen by daylight, become very dark—for instance, red, orange, and yellow; while blue, violet, and indigo, which are less bright when seen by daylight, become whitish (*blanchâtres*) in twilight. The author further observes that, in a photographic print, the first-named colours produce black, and the last-named grey. White light, producing all vibrations, is capable of exciting all colours; but, since, according to the researches of the Rev. Father Secchi, S.J., the light of the sky after sunset is especially rich in blue rays, it need not excite astonishment that the less refrangible rays should be, as it were, extinguished.

Action of Permanganate of Potassa upon Cinchonine.—MM Caventon and Willm.—The principal products of the reaction of a very cold solution of permanganate of potassa added, *guttatim*, to a cold solution of cinchonine, slightly acidified with sulphuric acid, are:—(1) An indifferent, neutral compound, which unites with bases as well as with acids, which has been named by the authors, *cinchoténine*; (2) an acid capable of being obtained in crystals, which is named *carboxycinchonic acid*; (3) a substance which reduces the tartrate of copper and potassa. In addition to these compounds, the authors state that they have discovered, by this reaction, a new alkaloid, which is made up according to the formula $C_{30}H_{26}N_2O$, and which is named *hydrocinchonine*. This base fuses at 268°, cinchonine fusing at 257°; the former base is insoluble in water, difficultly soluble in strong alcohol at ordinary temperature, and more readily so in boiling alcohol. Cinchonétine, $C_{18}H_{20}N_2O_2$, is a solid substance, soluble in boiling water. Carboxycinchonic acid, $C_{21}H_{14}N_2O_4$, is a solid substance, pretty readily soluble in water, and obtainable in crystalline state; it is a bibasic acid which forms with alkalies and baryta very soluble salts.

August 6, 1869.

Leaving, again, the purely mathematical and physico-mathematical papers, and also the voluminous papers on the controversy about the Newton, Galileo, Le Verrier, and Chasles papers and communications, we notice the following papers:—

Laws Governing the Solution of a Substance in Two Solvents.—MM. Berthelot and Jungfleisch.—This paper is not well suited for abstraction; but the subject it treats of may be stated in a few words, while we reserve the paper for more full treatment in our pages at a future time. All chemists know that it often happens that, in order to obtain from its solution, in water, for instance, they make use of ether, or other fluids not miscible with water, to extract therefrom any substance, *e.g.*, bromine or iodine, dissolved therein; the ether thus applied acts purely by its physical properties. The authors in this paper give, at length, the results of their researches on this subject which is very ingeniously treated.

Researches on Alloys.—M. Riche.—This paper is a continuation of a series of communications on this subject by the same author. While the hardening of steel has the effect of decreasing its density, as already long since stated by M. Caron, it was thought that this same effect was produced in bronze sonorous instruments, as, for instance, the Chinese gongs. The author finds that hardening and annealing are two operations the effect of which is totally different for steel and for bronze; whilst hardening has the effect of decreasing the density of the former, it increases that of the latter; annealing, on the other hand, increases the density of steel, and decreases the density of hardened bronze. Copper, repeatedly hardened and annealed, does not perceptibly vary in density.

A New Pyrometer.—M. Lamy.—The author proposes to use pure Iceland spar, basing the use of this substance, as a pyrometer, upon the law of dissociation.

Synthesis of Glucosides.—M. Schützenberger.—We reserve this paper for full translation in our columns.

Action of Anhydrous Sulphuric Acid upon Perchloride of Carbon.—M. Schützenberger.—When in perchloride of carbon, CCl_4, anhydrous sulphuric acid is dissolved, there is instantaneously observed a smell of phosgen gas, and when the solution is heated upon a water-bath, chloroxycarbonic gas is regularly given off. When this evolution of gas ceases, there remains in the retort a fuming liquid, which, on being submitted to distillation, yields, at about 75°, the excess of perchloride of carbon; next, the thermometer rises to 130°, and at that

temperature nearly the whole of the liquid distils off. The distillate is a colourless liquid, fuming in the air, and, on contact with water, instantly decomposed into hydrochloric and sulphuric acids; on being analysed, this liquid yields results leading to the formula, $S_2O_3Cl_2$, that is, an oxychloride of sulphur. The action of anhydrous sulphuric acid upon perchloride of carbon can, therefore, be represented by—

$$S_2O_6 + CCl_4 = S_2O_3Cl_2 + CCl_2O.$$

Gases Given Off by Fruit.—MM. Lechartier and Bellamy.—The authors prove, in this paper, that various kinds of fruit, after having been plucked from the trees—for instance, apples, cherries, gooseberries, and currants—begin to absorb oxygen and give off carbonic acid. The paper enters into lengthy quantitative details on this subject; as a proof that the quantity of carbonic acid given off by large quantities of fruit, say apples, for instance, stored up, may be considerable; suffice it to notice that five apples, weighing together 348 grms., yielded, from the 19th of January last up to the 15th of July last, 6648 c.c. of carbonic acid gas.

New Synthetical Method for the Preparation of Naphthalin-carboxylic Acid.—M. Eghis.—The author mixes monobromide of naphthaline, chloroxycarbonic ether, and sodium amalgam; and, after a complicated set of operations and purifications, obtains, as result, a solid substance, readily soluble in alcohol, ether, and boiling water, fusing at 160°, and yielding, on elementary organic analysis, results leading to the formula $C_{11}H_8O_2$. An identical substance was obtained by Prof. A. W. Hofmann, from cyanide of naphthaline derived from oxalate of naphthylamine; the body here in question was named by the last-named *savant*, menapthoxylic acid, or naphthalin-carboxylic acid.

Cosmos, July 31, 1869.

We quote from this paper a brief account of—

The Rio Vinagre.—This river has its source at a height of 3500 metres above sea level, near a very difficultly accessible spot of the volcano named the Puracé. The late Alexander von Humboldt first ascertained that the water of this river contains free sulphuric and hydrochloric acids. According to M. Boussingault, this river discharges into the Rio Cauca, wherein it falls from a height of 125 metres, during every twenty-four hours, 34,784 cubic metres of water, containing 37,611 kilos. of strong sulphuric acid, and 31,654 kilos. of concentrated hydrochloric acid. The Rio Cauca, after having received the waters of the first-named river, does not feed any fish for a distance of 18 kilometers of its seaward course. The volcano Puracé is not provided with a crater, as ordinarily met with on volcanoes, but its main outlet is a longitudinal split, 2 metres in length by 1 in width; it is covered at the top with a layer of very pure sulphur of about half a metre thick. There is at all times a strong escape of gases and vapours from the main outlet of this curious trachytic mountain, accompanied by a loud noise akin to that of the blowing off of the steam of several large high pressure steam-boilers. In the island of Java there are several rivulets and small lakes also containing free sulphuric and hydrochloric acids; while in one locality on the island of Sumatra, a lake is met with which contains free nitric acid. All these phenomena are caused by active volcanic action.

The American Journal of Science and Arts, No. 141, May, 1869.

We notice from this periodical the following original papers, omitting such as relate to astronomy, mathematics, and mechanical science:—

Atomic Volumes of the Elements.—M. Frank Wigglesworth Clarke, S.B.—This is a continuation of an essay on this subject from former numbers of this periodical. The author says, in his introduction to this part:—"In a recent paper in this journal I called attention to some remarkable relations which seem to exist between the atomic volumes of certain elements in the liquid condition. Since that time, I have found similar relations between the same elements in solid state, and also between the atomic volumes of some other solid elements, of which no liquid compounds are known. A few relations between the atomic volumes of different metals have been previously observed; chief of these, we find the equality of the atomic volumes of the metals of the iron group, the similar equality connecting the platinum metals, the equality between silver and gold, and that between molybdenum and tungsten. But, as far as I have been able to learn, nothing seems to have been done towards studying the more remarkable multiple relations which connect the members of certain natural groups together." The author next proceeds to the review of the alkaline metals, quoting the specific gravities as follows:—Lithium, 0·589; sodium, 0·972; potassium, 0·865; rubidium, 1·52. Upon dividing the atomic weights of the four metals, by these specific gravities, we get, as their atomic volumes, respectively, the numbers 11·9, 23·7, 45·1, and 56·2. It will be at once seen that the three highest of these values are very nearly multiples by whole numbers of the lowest. The author reviews, next, the oxygen group, oxygen, sulphur, selenium, and tellurium; after this, the nitrogen group, the carbon group, and metals. The very brief sketch given here may, perhaps, be followed by a more full and extended abstract in our journal afterwards.

On some Minerals from Newlin Township, Chester Co., Penn.—S. P. Sharples.—The first mineral described is *Diaspore*, containing, in 100 parts:—Silica, 43·56; alumina, 38·16; water, 5·64; potassa, 10·81. Specific gravity, 2·87. Colour varies from white to greenish or yellowish; it fuses before blowpipe-flame with extreme difficulty, forming a white enamel. *Lesleyite.*—Colour, white to reddish; hardness, about three; streak, white; before blowpipe flame, loses water; does not fuse with borax; does not dissolve in hydrochloric acid; is specifically heavier than quartz, its specific gravit being 3·203. It contains, in 100 parts:—Silica, 33·59; alumina, 55·41; potassa, 7·43; water, 4·30. *Pattersonite* contains in 100 parts:—Silica, 30·20; peroxide of iron, 14·88; alumina, 20·55; magnesia, 1·28; potassa, 11·35; water, 11·73.

Note upon the Origin of the Phosphatic Formation.—C. U. Shepard, sen.—The formation here alluded to is a very extensive one found in Southern Carolina. The paper is entirely of geological interest only.

On some Derivatives of Trichlormethyl-sulphon-Chlorid, $(CCl_3)SO_2Cl$.—M. O. Loew.—This paper will be given *in extenso* in our next number.

Notes on the Occurrence and Composition of the Nodular Phosphates of South Carolina.—C. U. Shepard, jun.—It appears that the specific gravity of this phosphatic mineral varies from 1·94 to 2·54; the quantity of water varies from 5·60 to 9·15; carbonic acid varies from 2·55 to 6·62; sulphuric acid, from 1·8 to 8·7; phosphoric acid, from 24·95 to 30·17, all in 100 parts. The mineral contains, besides lime, alumina, oxide of iron, magnesia; sand, varying from 4 to 15·7 per cent; and traces of chlorine, fluorine, and sodium. The author adds the analysis of the water of an artesian well, at Charlestown, S.C. This well is 1250 feet deep; the temperature of the water at the spout is 87° F. Specific gravity of the water, at 15°, is 1·0015; the amount of solid ingredients in the water=0·228 to 0·234 per cent. In 100 parts of solid ingredients are found:—Bicarbonate of soda, 52·749; chloride of sodium, 47·051; bicarbonate of lime, 0·0883; bicarbonate of magnesia, 0·01375; silica, 0·00102; phosphates of lime, iron, and alumina, 0·0004; organic matter, 0·0017. In 100 imperial gallons of this water at 15° are contained about 1¼ lbs. of bicarbonate of soda, and 1¼ lbs. of common salt.

Certain Phenomena of Transmitted and Diffused Light.—Carey Lea.

The Cohahuila (Mexico) Meteoric Irons of 1868.—Mr. J. Lawrence Smith.—It appears that the region of Mexico bordering on Texas has been most profusely furnished with these celestial visitors; six masses, weighing, respectively, 290, 430, 438, 550, 580, and 654 lbs., have been brought to the United States. They are irregular compact masses, without any evidence of stony minerals; they belong to the softer irons, not difficult to cut with a saw. A sample taken from one only of these masses has been as yet submitted to research. Specific gravity, 7·692. It contains, in 100 parts:—Iron, 92·95; nickel, 6·62; cobalt, 0·48; phosphorus, 0·02; copper, a very minute quantity.

On Atomic Ratio.—Mr. Josiah P. Cooke, jun.—This paper treats on the so-called oxygen ratio used by mineralogists, and is more a mineralogical than strictly chemical paper.

Formation of Sugar in the Liver.—Dr. George F. Barker.—A physiologico-chemical essay.

This number of the periodical contains, as usual, a copious amount of scientific intelligence, but, since this is chiefly a reproduction from European prints, or is otherwise of local interest only, we do not notice it, the more so as there is nothing therein contained of interest which has not already been noticed by us in our journal.

Annalen der Physik und Chemie, von Poggendorff, No. 6, 1869.

This periodical contains the following original papers:—

Cohesion Exhibited by Rock-Salt in Different Crystallographical Directions.—Dr. Sohncke.—The author of this paper gives an account of his experiments on the resistance exhibited by rock-salt to tractive forces, applied thereto in a similar manner as is done to wood, metallic wires, and other solids. The paper is, however, not well suitable for proper abstraction with due justice to the author's labour, and could not, moreover, be well understood without the reproduction of a large number of tables.

Description of a Photometrical Method of Measurement and Comparison of the Intensity of Coloured Light.—M. C. Vierordt.—A large-sized engraved plate accompanies this paper.

Isolating Intermediate Layer (Zwischenschicht) of a Condenser.—M. W. von Bezold.—A mathematico-physical essay.

Point of Solidification of the Component Portions of Fluid Mixtures.—C. Schultz.—The author proves, by quoting a large number of instances, that, in a mixture of solid bodies which are miscible in a fluid state, without thereby calling forth chemical reactions, a return to the fluid state, may, and actually does, take place at a temperature below the melting-point of the most easily melting substance. This fluidisation takes place more readily, and with a less amount of absorption of heat, when the temperature, at the time of making the mixture, is so high that one of the component parts thereof is already fluid, as, for instance, is the case when salts are dissolved in water, or in alcohol, and when amalgams are mixed with mercury. The author of this paper records a large number of substances he has experimented upon.

Freezing Point of Water containing Gases in Solution, and on the Regelation of Ice.—M. Schultz.—The author states that, as a general rule, the point of solidification of fluids is lowered by substances dissolved therein, and that gases dissolved in fluids exercise the same effects. The fusing point of pure acetic acid is 16°; this is lowered to 15·2° when a current of carbonic acid is transmitted through this acid. That hydrochloric acid gas and ammonia gas do lower the freezing temperature of the water they are dissolved in is a well-known fact; carbonic acid and sulphurous acid gas do the same; and the author found that nitrogen, oxygen, and hydrogen gases exert, when dissolved in water, the same effect. The author records

a series of experiments made by him with the view of ascertaining the effect of an increase of pressure brought to bear upon the absorption of various gases by water, and the lowering of the freezing point of that liquid in consequence thereof. By the phenomenon of regelation is understood that property exhibited by ice of freezing together to a solid mass, when pieces of that substance are pressed together at the temperature of 0°. After quoting the opinions of Messrs. Faraday, Forbes, Thomson, and Helmholtz on this subject, the author says—When we take it for granted that regelation is the formation of ice from water anew, we must bear in mind that only pure water, or water, at least, not saturated with air, is suitable for this purpose. The author has studied the influence divers gases exert upon this phenomenon, but the description of his experiments is too lengthy to admit of further quotation.

Fluids Enclosed in Minerals.—M. Vogelsang.—This paper is an appendix to a paper on the same subject published in a former number of this periodical. The chief result of the author's researches is the fact that fluid carbonic acid is far more generally met with enclosed in large masses in stone, and that the conditions under, or during which that condensation took place, are as yet only very scantily known.

Influence which Mechanical Changes Exert upon the Capability of Magnetical Rotation of some Substances.—M. R. Lütge.—This essay is entirely of a mathematico-physical nature, and there belong to it a series of engravings, which render the paper not well suitable for abstraction.

Application of a Steel Magnet, armed with a Wire Spiral, to the Dynamo-Electrical Machine.—Dr. Sinsteden.

Improved Arrangement of Leclanché's Element, and a New Self-Acting Commutator.—Dr. Sinsteden.

On Laxmannite, a New Mineral from Beresowsk.—M. Nordenskjöld.—While making some researches on minerals containing vanquelinite, met with in the large mineralogical museum at Stockholm, the author found a mineral containing a double salt of chromic and phosphoric acids, which mineral he has named laxmannite, in honour of the late Professor Laxmann, who, while making a journey through Siberia, in the year 1773, brought back to Sweden a great number of minerals from the former country and from the Ural mountains. Laxmannite has a specific gravity of 5·77; its colour is dark olive-green; on heating, it loses a very slight amount only of water, fuses before the blowpipe-flame, yielding a blackish-coloured bead. When treated before blowpipe-flame with boracic acid and iron wire, it exhibits the well-known reaction for phosphoric acid; while, on being fused with soda and saltpetre, it exhibits the reaction for chromic acid; it is soluble in nitric and hydrochloric acids, chloride of lead being separated thereby. The formula of this mineral is—

$$(CuO,\tfrac{1}{2}H_2)_3PO_5+3(PbO,CuO)_3CrO_3;$$

and it consists, in 100 parts, of:—Oxide of lead, 61·48; oxide of copper, 13·13; chromic acid, 16·57; phosphoric acid, 7·83; water, 0·99.

Behaviour of the Iodates and Periodates when Submitted to Heat, and the Formation of the latter from Iodides by means of Peroxides.—M. C. Rammelsberg.—The author first points out a very remarkable difference between the iodate of potassa and the iodate of soda; the former salt, when heated, yields oxygen and iodide of potassium; the latter salt crystallises, containing 8·33 per cent of water, which is driven off at 150°. Various experimenters have stated that this salt always loses iodine when heated; others, again, have denied this. The author finds that, unless the iodate of soda is, previous to being heated, mixed with carbonate of soda, iodine is always set free. As regards the periodates, the author has submitted a number of them to properly-defined higher temperatures, and found that periodate of potassa remains unchanged, even at 200°, but at 300° it is entirely changed into iodate of potassa. The periodate of silver changes, at 175°, into iodate of silver; normal periodate of ammonia detonates on being strongly heated, yielding iodine, nitrogen, oxygen, ammonia, and water. The author has devoted a large portion of this paper to a record of his experiments on the action of iodine upon baryta and the peroxide of barium. Curiously enough, these researches have brought to light the fact that pure baryta is by no means so readily obtained as one might feel inclined to imagine, even though the product of the ignition of nitrate of baryta contained only very minute traces of silica and alumina. The author found that there is about 3 per cent deficiency therein, for, instead of finding Ba 89·54 per cent, he found Ba 86·36 per cent, and even less; and he is inclined to assume the existence of a compound Ba_4O_5; on treating baryta with iodine at higher temperature, compounds were obtained consisting, in 100 parts, of:—Ba, 58·6, I, 32·0; Ba, 56·8, I, 34·1; Ba, 57·0, I, 33·8. These compounds all contain oxygen, and the author gives the formula $Ba_9I_2O_4$. Peroxide of barium behaves in a similar manner with iodine.

Formation and some of the Reactions of the Periodates.—M. Philipp.—This paper is a lengthy essay on this subject, and too full of formulæ to admit of useful abstraction.

On the Krähenberg Meteorite, fallen on the 5th of May, 1869.—M. vom Rath.—It appears that, on the date just alluded to, there fell, at a small village in the Bavarian palatinate, near to Deux-Ponts, a meteoric stone, accompanied by a strong detonation. The author describes this stone at length, and also describes his method of analysis of this stone. In 100 parts, it consists of:—Chromate of iron, 0·94; sulphur, 2·25; iron, 3·47; silica, 43·29; alumina, 0·63; magnesia, 25·32; lime, 2·01; protoxide of iron, 21·06; protoxide of manganese, a trace; soda, 1·03. The specific gravity of this stone is 3·4975 at 18°. The analysis just quoted has been made after a portion of the pulverised stone had been repeatedly treated by means of a magnet to extract metallic iron and nickel; the powder thus separated by the magnet was found to consist, in 100 parts, of—Iron, 84·7; nickel, 15·3. The weight of the entire meteorite was found to be about 30 lbs.

Bulletin Mensuel de la Société Chimique de Paris, July, 1869.

This periodical contains the *procès verbaux* of the meetings of this Society, held on the 7th and 21st of May last, from which we learn that M. Silva described—

Some Compounds of Isopropyl.—The valerianate of isopropyl boils at 142°; its specific gravity, at 0°, is 0·870; and its vapour density 5·04. The author has tried to prepare trisisopropylamine; he obtained, however, a liquid exhibiting a strongly alkaline reaction, which distils over between 80° and 120°, and which the author thinks is a mixture of di- and tris-isopropylamine. By making butyrate of silver act upon iodide of isopropyl, the author obtained the butyrate of isopropyl ether, $C_4H_7O_2C_3H_7$, boiling at 128°, under a pressure of 755 m.m. The specific gravity of this fluid, at 0°, is 0·8787; its vapour density, as found by experiment, is 4·730. By causing nascent hydrogen to act upon the monochlorhydrine of the amyl-glycol, the author has obtained a product very much resembling amylic alcohol, as was discovered by analysis.

Synthesis of Glucosides.—M. Schutzenberger has tried to effect this by boiling a solution of *saligénine sodée* in benzine with triacetic glucose, which is slightly soluble in that liquid; and, by evaporating the filtrate on a water-bath, a substance was obtained which is viscous at 100° and solid when cold. This compound answers the characters of the glucosides; it is split up into glucose and salicetine, yielding then, also, acetic acid. This glucose is, however, a modification of that substance known as glucosane; its reducing power is less strong than that of ordinary glucose. The residue insoluble in benzine is entirely soluble in water, with the exception of a small quantity of resinous matter; the aqueous solution yields to ether a crystallisable compound, which possesses all the characteristics, also, of a glucoside, but does not contain acetic acid; its composition is $3C_{14}H_{22}O_9,C_6H_9O_9$.

M. Vogt stated that, while treating the chlorobenzylsulphate and chlorotolylsulphate of potassium with fusing caustic potassa, he has obtained salicylic and cresotic acids.

The following original papers are contained in this number of the above-named periodical:—

Immediate Analysis of the Divers Varieties of Carbon.—M. Berthelot.—We published in full the contents of this paper some time ago.

Comparison between the Saline Constituents of the Grease of Sheep's Wool and the Human Perspiration.—M. S. Cloëz.—In this elaborate paper, the author first reviews the researches of M. Vanquelin and M. Chevreul on this subject; he then briefly refers to M. Evrard's patent, for extracting, from the grease of sheep's wool, carbonate of potassa, which process has been brought to perfection by MM. Maumené and Rogelet, and is carried on on the large scale with success. The two last-named gentlemen, having published some scientific researches on this matter, have come to the conclusion that pure grease of sheep's wool was devoid of soda or salts of this alkali. The author of this paper proves, by a series of analyses, that although in the grease of sheep's wool potassa salts prevail, the salts of soda are not altogether absent. As instances of the composition of the saline constituents of this material, we quote, out of the large number of analyses, a couple of instances:—Grease from sheep's wool taken from animals in pasturage near the sea contained saline matter, in 100 parts, composed of—Carbonate of potassa, 84·80; sulphate of soda, 4·65; chloride of sodium, 10·45. Another sample contained, in 100 parts—Carbonate of potassa, 87·27; sulphate of potassa, 3·59; sulphate of soda, 0·68; chloride of sodium, 8·27. The saline constituents of human perspiration the author found to contain:—Carbonate of potassa, 31·82; sulphate of potassa, 11·76; chloride of potassium, 16·02; chloride of sodium, 38·54.

Relative Proportion of Alkalies found in the Ash of Divers Plants.—M. Cloëz.—This paper is a valuable addition to the methods of ash analysis of plants; but the author chiefly desires to call attention to facts observed already by the late MM. Ingenhousz, Senebier, and Johnston—namely, that the same plants grown near the sea, and at remote distances therefrom, alter their saline constituents, so that, while growing near the sea, soda prevails, as a rule, over potassa, the reverse being the case while the same plant vegetates at a distance more or less remote from the sea; of this fact, some instances are given in this paper. The relation of the soda to the potassa of the ash of *Crambe maritima*, when grown near the sea, was as 960 to 1000; when grown at Paris, as 89 to 1000. The relation of soda to potassa in the ash of black mustard seed grown near the sea was as 200 to 1000, while when grown at Paris, it was as 96 to 1000.

Supersaturation and Dissolution.—M. Lecocq de Boisbaudran.—This paper is a critical review of a paper published in the *Comptes Rendus*, and is not well suited for abstraction.

On Nucitannic Acid.—Dr. Phipson.—The author says that he has discovered, in the epispermium of walnuts, a peculiar kind of tannin, to which he has given the name of nucitannic acid or nucitannin. It is soluble in water and in alcohol; is precipitated by subacetate of lead; while its most remarkable property is that, when boiled with dilute acids, it is split up into glucose, and a reddish-coloured substance, called by author *rothic acid*, since it has acid properties and is soluble in ammonia and alcohol. The nucitannic acid is accompanied by ellagic and gallic acids, which interfere, the author says, with the purifying of the nucitannic acid; about the latter, and about rothic acid, the author promises further communications when his researches shall be complete.

Chemisches Centralblatt, No. 26, June 30, 1869.

This number does not contain any original papers, and the whole of its contents have been noticed by us previously from the originals.

Moniteur Scientifique, No. 302, July 15, 1869.

This paper contains a very lengthy essay on—

Designolle's Gunpowder.—M. Jouglet.—The paper is evidently written with the view to bring, if possible, into general use a powder containing picrates, in addition to nitrate of potassa. The paper is too much an essay written for artillery purposes to render it peculiarly suitable for abstraction; but, incidentally, the author speaks of nitroglycerine, and, while on this subject, he positively asserts that nitroglycerine, even when well and carefully made, is spontaneously altered by keeping, becoming acid, and then disengaging gas. This the author asserts is the true clue to the fearful explosions now and then witnessed with this material; and he concludes that if it is to be used at all, it should be made on the spot where it is wanted, and only in such quantities as may be required for blasting during one, or at most two days before.

Among the specifications of French patents, we notice the patent granted to M. Collas, for the—

Application of Phosphate of Lime for Dyeing and Calico Printing.—The author calls attention to the fact that phosphate of lime yields, with various vegetable colours, lakes which are different from those obtained with alumina; that the oxides of copper and cobalt yield, with the freshly-precipitated phosphate of lime, blue-coloured lakes, which greatly surpass, in richness of colour, Thénard's and other blues. The principle of this patent has been long enough known, and, as well remarked by the editor of this paper, it is very questionable whether this matter should be subject to any patent at all.

New Kind of Heating Apparatus for Chemical Laboratories. M. E. Kopp.—This is a rather lengthy description of a complicated set of apparatus intended for heating the laboratory in winter, and, at the same time, supplying at all times a drying stove for filters, &c. The paper describes two kinds of apparatus, in one of which heated air, while in the other steam is applied. It does not, however, appear, from the description, that anything decidedly good is effected by these apparatus, which, from the complicity of construction, cannot but be very expensive; moreover, to be well and readily understood, this paper ought to have been accompanied by a woodcut.

Tinning by the Moist Way.—Dr. Hillier.—It is a well-known fact that, when it is desirable to cover metals, especially brass or copper, with a strongly-adhering coating of tin, this is usually effected by boiling the articles to be thus coated with an aqueous fluid, to which is added cream of tartar, crystallised protochloride of tin, and some lumps of pure metallic tin. The author states that, instead of this mixture, he uses, with very good success, a solution of 1 part of protochloride of tin in 10 parts of water, to which he next adds a solution of 2 parts of caustic soda in 20 parts of water; the mixture becomes turbid, but this does not affect the tinning operation, which is effected by heating the objects to be tinned in this fluid, care being taken, at the same time, to place in the liquid a piece of perforated block-tin plate, and to stir up the fluid during the tinning with a rod of zinc.

Annales des Mines, No. 2, 1869.

This periodical contains the following original papers:—

Some Peculiarities in the Working and Manufacture of Bessemer Steel in Styria and Carinthia.—M. Clérault.—The author of this paper states that, owing to the special advantages due to the excellent iron ores of the countries above named, the manufacture of steel, according to Bessemer's method, is effected with less cost, and yields better results, than is the case elsewhere. The paper is full of practical matters, especially as regards the manufacture of railway iron.

Certain Peculiarities of the Blast Furnaces of the Siegen District.—M. Douville.—The author of this short memoir describes the peculiarities of the blast furnaces established a few years ago in this district of Prussia, wherein, centuries since, iron-works have been in existence, but where only recently the use of coke has been substituted for that of wood. The author's paper is valuable chiefly to ironmasters.

Geological Description and Account of the Mineral Resources of the Canton de Vic Dessos.—M. Musey.—This is the third and concluding portion of a lengthy monograph exposing the mineral resources, and describing the geology, of that portion of the French Département de l'Ariège, which is contiguous to the republic of Andorra, a country wherein mineral wealth abounds. The paper is an excellent monograph on such a subject.

Journal fur Gasbeleuchtung, June, 1869.

This periodical contains an excellent monograph on photometers and their applications under the title of—

Photometrical Studies.—Dr. Rüdorff.—The author's memoir is too lengthy, and enters too deeply into mathematical details, to render it suitable for abstraction, but it is in every respect, an excellent essay on this subject, and duly applied to practical purposes also.

This number contains the first portion of the report of the annual meeting of German gas engineers, held this year at Cobourg. From this report, we learn that, when hydrate of lime is saturated with carbonic acid, it is yet, provided it be moist, capable of taking up sulphuretted hydrogen very energetically, without thereby simultaneously giving off again carbonic acid gas. One of the members of this Association explains, in a few words, that the removal of sulphur from the oxide of iron used in the purifiers may be advantageously effected by means of quicklime; but no particulars of this process are given.

Les Mondes, July 29, 1869.

We notice from this paper:—

The Champonnois Press.—The name of M. Champonnois as an indefatigable industrial genius, is well and very deservedly known to all acquainted with the manufacture of beet-root sugar especially. We learn, from a short notice in the above-named periodical, that the gentleman just named has succeeded in bring out a very greatly improved press for forcing the saccharine juice out of beet-root pulp so as to obtain a larger quantity of saccharine matter from a given weight of pulp, and also to bring the juice to a state of clearness (that is to say, absence of suspended matter) not hitherto obtained. Experiments with this kind of press, which is worked, moreover, with great economy of power, and yet with enormous force, may be witnessed at the works of MM. J. F. Cail and Co., Quai de Grenelle, Paris, where a large number of these presses have been made to order by beet-root sugar manufacturers, to be applied in the ensuing season.

The Academy of Exact Sciences at Madrid has proposed the following prizes to be distributed in 1871:—To discover the best method of making starch in Spain. Description to be given of the divers varieties of vines cultivated in certain parts of Spain, excepting always the provinces of Asturia, Pontevedro, Biscaya, and Castelloo de la Plana. Description to be made of the various rocks met with in one province, at least, of Spain; to indicate their *detritus*, and to point out how this *detritus* contributes to the formation of the agricultural soil in general, and in how far this soil is suitable to the cultivation of trees. The premiums for the approved memoirs are a gold medal and a sum of 1575 francs (£63). The memoirs (written in Spanish, Latin, or French) must be received by the Secretary of the Academy, on or before the 1st of May, 1871.

NOTES AND QUERIES.

Wood-Lice.—I should be very much obliged if any of your correspondents can inform me how to destroy wood-lice in beams, floors, and furniture. It should be something that would not injure or discolour the furniture.—WOOD PRESERVER.

Drying of Animal and Vegetable Substances.—Dr. Müller.—A large glass vessel, a tumbler for instance, is filled for about half its capacity with fused chloride of calcium, and over this a quantity of ether is poured; on the top of the glass vessel another suitable glass or porcelain vessel is placed containing the substance to be dried, and over these vessels, previously placed on a polished glass plate, a bell-jar is placed. The drying takes place in consequence of the fact that the chloride of calcium withdraws water continuously from the ether, and the vapour of the latter, in its turn, withdraws the water from the substances to be dried. It is stated that both animal and vegetable substances dried by this process retain their natural colour, and that animal substances, moreover, retain their elasticity and flexibility.—*Deutsche Ind. Zeitung.*

Dr. Gladstone's Experiments on Light.—Seeing in your report of Dr. Gladstone's Friday evening lecture at the Royal Institution, delivered April 24, 1868, and contained in your impression of June 5, 1868, that he has discovered that, in the case of liquids, $\frac{\mu-1}{d}$ is constant for all temperatures and for all mixtures, with some slight deviations, owing, apparently, to an undiscovered law, you will confer a great favour on me if you will give me the number.—ALEPH.

[Dr. Gladstone informs us that the fact that, in the case of liquids, $\frac{\mu-1}{d}$ is a constant for all temperatures and for mixtures, with some slight deviation, was discovered by Mr. Dale and himself several years ago, and has been verified by some of the German physicists. They (Dr. Gladstone and Mr. Dale) have, however, gone far beyond that now, showing that it is a constant (generally speaking) notwithstanding chemical combination. Dr. Gladstone sent a long paper founded on this to the Royal Society last month.—*Ed.* C. N.]

TO CORRESPONDENTS.

*** Vol. XIX. of THE CHEMICAL NEWS, containing a copious index, is now ready, price 11s. 4d., by post, 11s. 10d., handsomely bound in cloth, gold-lettered. The cases for binding may be obtained at our office, price 1s. 6d. Subscribers may have their copies bound for 2s. 6d. if sent to our office, or, if accompanied by a cloth case, for 1s. Subscribers wishing to complete their sets of volumes, are requested to apply to the publisher, who will give them information respecting scarce numbers and volumes. Vol. XX. commenced on July 2nd, and will be complete in twenty-six numbers.

ERRATUM.—In No. 506, p. 68, line 13 from top, *for* "condemning oleography" *read* "commending oleography."

THE CHEMICAL NEWS.

VOL. XX. No. 508.

BRITISH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

EXETER MEETING, AUGUST 18, 1869.

INAUGURAL ADDRESS OF THE PRESIDENT,

GEORGE GABRIEL STOKES, M.A., Sec. R.S.,
D.C.L., Oxon.; LL.D., Dublin;
Fellow of Pembroke College; and Lucasian Professor of Mathematics in the University of Cambridge.

My LORDS, LADIES, AND GENTLEMEN,—

As this is the first time that the British Association for the Advancement of Science has met in the city of Exeter, and it is probable that many now present have never attended a former meeting, I hope the older members of the Association will bear with me if I say a few words in explanation of the objects for which the Association was instituted. In the first place, then, it aims at fulfilling an office which is quite distinct from that of the various scientific societies which are established in different parts of the country. These, for the most part, have for their leading object to make the voluntary labours of isolated workers in science available to the scientific world generally, by receiving, discussing, and publishing the results which they may have obtained. The British Association, on the other hand, aims at giving *a more systematic direction* to scientific inquiry, and that in various ways.

Objects of the Association.—Scientific Reports.

In a rapidly progressing branch of science it is by no means easy to become acquainted with its actual state. The workers in it are scattered throughout the civilised world, and their results are published in a variety of Transactions and scientific periodicals, mixed with other scientific matter. To make oneself, without assistance, well acquainted with what has been done, it is requisite to have access to an extensive library, to be able to read with facility several modern languages, and to have leisure to hunt through the tables of contents, or at least the indices, of a number of serial works. Without such knowledge, there is always the risk that a scientific man may spend his strength in doing over again what has been done already; whereas, with better direction, the same expenditure of time and labour might have resulted in some substantial addition to our knowledge. With a view to meet this difficulty, the British Association has requested individuals who were more specially conversant with particular departments of science, to draw up reports on the present state of our knowledge in, or on the recent progress of, special branches; and the influence of the Association as a public body has been found sufficient to induce a number of scientific men to undertake the great labour of preparing such reports.

By thus ascertaining thoroughly what we already had, what we still wanted was made more clear; and, indeed, it was one special object of the reports I have mentioned to point out what were the more prominent desiderata in the various subjects to which they related. The Association was thus the better enabled to fulfil another of its functions, that of organising means for the prosecution of researches which require co-operation. When the want is within the compass of what can be accomplished by individuals, the demand may be left to create the supply; but it often happens that a research can hardly be carried out without co-operation. It may, for instance, require a combination of the most profound theoretical knowledge with the greatest experimental skill, or an extensive knowledge of very dissimilar branches of science; or, again, the work to be done, though all of one kind, may be of such an extent as to be beyond the power of any one man. In such cases, the limited power of the individual can only be supplemented by the principle of co-operation; and, accordingly, it becomes an important part of the business of the Association to organise committees for the prosecution of special researches. The researches thus undertaken, at the request of the Association, are published at length, along with the reports on the progress of science, in the first part of the annual volume.

Money Grants.

In close connection with the last, must be mentioned another mode in which the Association contributes to the progress of science. Many researches require not only time and thought, but pecuniary outlay; and it would seem hard that scientific men who give their time and labour gratuitously to carrying out such researches should be further obliged to incur an expenditure which they often can ill afford. The Association accordingly makes grants of money to individuals or committees for defraying the expenses of such researches. It appears, from the report which has just been published, that, reckoning up to the year 1867 inclusive, the sum of £29,312 4s. 1d. has been voted by the Association for various scientific objects. Deducting from this the sum of £23 16s., for the balances of grants not wholly expended, which were returned to the Association, we may say that £29,288 8s. 1d. has been expended in the manner indicated. When we remember that these grants were mostly of small amount, and do not include personal expenses, and that very many of the researches undertaken at the request of the Association do not involve money grants at all, we may form some idea of the amount of scientific activity which has been evoked under the auspices of the Association.

Recent Progress of Science.

In the address with which the business of the meeting is opened, it is usual for your President to give some account of the most recent progress of science. The task is by no means an easy one. Few, indeed, are familiar with science in all its branches; and even to one who was, the selection of topics, and the mode of treating them, would still present difficulties. I shall not attempt to give an account of the recent progress of science in general, but shall select, from those branches with which I am more familiar some examples of recent progress, which may, I hope, prove to be of pretty general interest. And even in this, I feel that I shall have to crave your indulgence; for it is hard to be intelligible to some without being wearisome to others.

Astronomy.

Among the various branches of physical science, astronomy occupies, in many respects, a foremost rank. The movements of the heavenly bodies must have occupied the attention and excited the interest of mankind from the earliest ages, and accordingly the first rudiments of the science are lost in the depths of antiquity. The grandeur of the subjects of contemplation which it presents to us have won for it especial favour, and its importance in relation to navigation has caused it to be supported by national resources. Newton's great discovery of universal gravitation raised it from the rank of a science of observation to that of one admitting of the most exact mathematical deduction; and the investigation of the consequences of this law, and the explanation thereby of the lunar and planetary disturbances, have afforded a field for the exercise of the highest mathematical powers on the

part of Newton and his successors. Gradually the apparent anomalies, as they might have been deemed, in the motions of the heavenly bodies, were shown to be necessary consequences of the one fundamental law; and at last, as the result of calculations of enormous labour, tables were constructed enabling the places of those bodies at any given time to be determined years beforehand with astonishing precision. A still more striking step was taken. When it had been shown, by careful calculation, that the apparent motion of the remotest of the planets then known to belong to our system could not be wholly explained on the theory of gravitation, by taking account of the disturbing powers of the other known planets, Adams, in our own country, and Le Verrier, in France, boldly reversed the problem, and, instead of determining the disturbing effect of a known planet, set themselves to inquire what must be the mass and orbit of an unknown planet which shall be capable of producing, by its disturbing force, the unexplained deviations in the position of Uranus from its calculated place. The result of this inquiry is too well known to require notice.

After these brilliant achievements, some may, perhaps, have been tempted to imagine that the field of astronomical research must have been well-nigh exhausted. Small perturbations, hitherto overlooked, might be determined, and astronomical tables thereby rendered still more exact. New asteroids might be discovered by the telescope. More accurate values of the constants with which we have to deal might be obtained. But no essential novelty of principle was to be looked for in the department of astronomy; for such we must go to younger and less mature branches of science.

Researches which have been carried on within the last few years, even the progress which has been made within the last twelve months, shows how short-sighted such an anticipation would have been; what an unexpected flood of light may sometimes be thrown over one science by its union with another; how conducive, accordingly, to the advancement of science may be an association like the present, in which not only are the workers at special sciences brought together in the Sectional Meetings, but in the General Meetings of the Association, and in the social intercourse, which, though of an informal character, is no unimportant part of our proceedings, the cultivators of different branches of science are brought together, and have an opportunity of enlarging their minds by contact with the minds of others, who have been used to trains of thought of a very different character from their own.

The Velocity of Light.

The science of astronomy is indebted to that of optics for the principles which regulate the construction of those optical instruments which are so essential to the astronomer. It repaid its debt by furnishing to optics a result which it is important we should keep in view in considering the nature of light. It is to astronomy that we are indebted for the first proof we obtained of the finite velocity of light, and for the first numerical determination of that enormous velocity. Astronomy, again, led, forty-four years later, to a second determination of that velocity in the remarkable phenomenon of aberration discovered by Bradley, a phenomenon presenting special points of interest in relation to the nature of light, and which has given rise to some discussion, extending even to the present day, so that the Astronomer Royal has not deemed it unworthy of investigation, laborious as he foresees the trial is likely to prove, to determine the constant of aberration by means of a telescope having its tube filled with water.

If, in respect of these phenomena, optics received much aid from astronomy, the latter science has been indebted to the former for information which could not otherwise have been obtained. The motions and the masses of the heavenly bodies are revealed to us more or less fully by astronomical observations; but we could not thus become acquainted with the chemical nature of these distant objects. Yet, by the application of the spectroscope to the scrutiny of the heavenly bodies, evidence has been obtained of the existence therein of various elements known to us by the chemical examination of the materials of which our own earth is composed; and not only so, but light is thrown on the state in which matter is there existing, which, in the case of nebulæ especially, led to the formation of new ideas respecting their constitution, and the rectification of astronomical speculations previously entertained. I shall not, however, dwell further on this part of the subject, which is now of some years' standing, and has been mentioned by more than one of your former presidents, but will pass on to newer researches in the same direction.

Proper Motion of the Fixed Stars.

We are accustomed to apply to the stars the epithet *fixed*. Night after night they are seen to have the same relative arrangement; and when their places are determined by careful measurement, and certain small corrections due to known causes are applied to the immediate results of observation, they are found to have the same relative distances. But when instead of days the observations extend over months or years, it is found that the fixity is not quite absolute. Defining as fixity invariability of position as estimated with reference to the stars as a whole, and comparing the position of any individual star with those of the stars in its neighbourhood, we find that some of the stars exhibit "proper motions," show, that is, a progressive change of angular position as seen from the earth, or rather as they would be seen from the sun, which we may take for the mean annual place of the earth. This indicates linear motion in a direction transverse to the line joining the sun with the star. But since our sun is merely a star, a line drawn from the star exhibiting proper motion to our sun is, as regards the former, merely a line drawn to a star taken at random, and therefore there is no reason why the star's motion should be, except accidentally, in a direction perpendicular to the line joining the star with our sun. We must conclude that the stars, including our own sun, or some of them at least, are moving in various directions in space, and that it is merely the transversal component of the whole motion, or rather of the motion relatively to our sun, that is revealed to us by a change in the star's apparent place.

How then shall we determine whether any particular star is approaching to or receding from our sun? It is clear that astronomy alone is powerless to aid us here, since such a motion would be unaccompanied by change of angular position. Here the science of optics comes to our aid in a remarkable manner.

The pitch of a musical note depends, as we know, on the number of vibrations which reach the ear in a given time, such as a second. Suppose, now, that a body, such as a bell, which is vibrating a given number of times per second, is at the same time moving from the observer, the air being calm. Since the successive pulses of sound travel all with the velocity of sound, but diverge from different centres, namely, the successive points in the bell's path at which the bell was when those pulses were first excited, it is evident that the sound-waves will be somewhat more spread out on the side from which the bell is moving, and more crowded together on the side towards which it is moving, than if the bell had been at rest. Consequently the number of vibrations per second which reach the ear of an observer situated in the former of these directions will be somewhat smaller, and the number which reach an observer situated in the opposite direction somewhat greater, than if the bell had been at rest. Hence to the former the pitch will be somewhat lower, and to the latter somewhat higher, than the natural pitch of the bell. And the same thing will happen if the observer be in motion instead of the bell, or if both be in motion; in fact, the effect depends only on the *relative* motion of the observer and the bell in the direction of a line joining the two—in other words, on the velocity of re-

cession or approach of the observer and the bell. The effect may be perceived in standing by a railway when a train in which the steam-whistle is sounding passes by at full speed, or better still, if the observer be seated in a train which is simultaneously moving in the opposite direction.

The present state of optical science is such as to furnish us with evidence of a force which is perfectly overwhelming, that light consists of a tremor or vibratory movement propagated in an elastic medium filling the planetary and stellar spaces, a medium which thus fulfils for light an office similar to that of air for sound. In this theory, to difference of periodic time corresponds difference of refrangibility. Suppose that we were in possession of a source of light capable, like the bell in the analogous case of sound, of exciting in the æther supposed at rest vibrations of a definite period, corresponding, therefore, to light of a definite refrangibility. Then, just as in the case of sound, if the source of light and the observer were receding from or approaching to each other with a velocity which was not insensibly small compared with the velocity of light, an appreciable lowering or elevation of refrangibility would be produced, which would be capable of detection by means of a spectroscope of high dispersive power.

Alteration of the Refrangibility of a Ray of Light.

The velocity of light is so enormous, about 185,000 miles per second, that it can readily be imagined that any motion which we can experimentally produce in a source of light is as rest in comparison. But the earth in its orbit round the sun moves at the rate of about 18 miles per second; and in the motions of stars approaching to or receding from our sun we might expect to meet with velocities comparable with this. The orbital velocity of the earth is, it is true, only about the one ten-thousandth part of the velocity of light. Still the effect of such a velocity on the refrangibility of light, which admits of being easily calculated, proves not to be so insensibly small as to elude all chance of detection, provided only the observations are conducted with extreme delicacy.

But how shall we find in such distant objects as the stars an analogue of the bell which we have assumed in the illustration drawn from sound? What evidence can we ever obtain, even if an examination of their light should present us with rays of definite refrangibility, of the existence in those remote bodies of ponderable matter vibrating in known periods not identical with those corresponding to the refrangibilities of the definite rays which we observe? The answer to this question will involve a reference, which I will endeavour to make as brief as I can, to the splendid researches of Professor Kirchhoff. The exact coincidence of certain dark lines in the solar spectrum with bright lines in certain artificial sources of light had previously been in one or two instances observed; but it is to Kirchhoff we owe the inference from an extension of Prevost's theory of exchanges, that a glowing medium which emits bright light of any particular refrangibility *necessarily* (at that temperature at least) acts as an absorbing medium, extinguishing light of the same refrangibility. In saying this it is but just to mention that, in relation to radiant heat (from whence the transition to light is easy), Kirchhoff was preceded, though unconsciously, by our own countryman, Mr. Balfour Stewart. The inference which Kirchhoff drew from Prevost's theory thus extended led him to make a careful comparison of the places of the dark lines of the solar spectrum with those of bright lines produced by the incandescent gas or vapour of known elements; and the coincidences were in many cases so remarkable as to establish almost to a certainty the existence of several of the known elements in the solar atmosphere, producing by their absorbing action the dark lines coinciding with the bright lines observed. Among other elements may be mentioned in particular hydrogen, the spectrum of which, when traversed by an electric discharge, shows a bright line or band exactly coinciding with the dark line C, and another with the line F.

Mr. Huggins's Researches on Sirius—Determination of Radial Proper Motion.

Now Mr. Huggins found that several of the stars show in their spectra dark lines coinciding in position with C and F; and what strengthens the belief that this coincidence, or apparent coincidence, is not merely fortuitous, but is due to a common cause, is that the two lines are found associated together, both present or both absent; and Kirchhoff's theory suggests that the common cause is the existence of hydrogen in the atmospheres of the sun and certain stars, and its exercise of an absorbing action on the light emitted from beneath.

Now, by careful and repeated observations with a telescope furnished with a spectroscope of high dispersive power, Mr. Huggins found that the F line, the one selected for observation, in the spectrum of Sirius did not exactly coincide with the corresponding bright line of a hydrogen spark, which latter agrees in position with the solar F, but was a *little* less refrangible, while preserving the same general appearance. What conclusion, then, are we to draw from the result? Surely it would be most unreasonable to attribute the dark lines in the spectra of the sun and of Sirius to distinct causes, and to regard their almost exact coincidence as purely fortuitous, when we have in proper motion a *vera causa* to account for a minute difference. And if, as Kirchhoff's labours render almost certain, the dark solar line depends on the existence of hydrogen in the atmosphere of our sun, we are led to infer that that element, with which the chemist working in his laboratory is so familiar, exists and is subject to the same physical laws in that distant star, so distant, that, judging by the most probable value of its annual parallax, light which would go seven times round our earth in one second would take fourteen years to travel from the star. What a grand conception of the unity of plan pervading the universe do such conclusions present to our minds!

Assuming, then, that the small difference of refrangibility observed between the solar F and that of Sirius is due to proper motion, Mr. Huggins concludes from his measures of the minute difference of position that at the time of the observation, Sirius was receding from the earth at the rate of 41·4 miles per second. A part of this was due to the motion of the earth in its orbit; and on deducting the orbital velocity of the earth, resolved in the direction of a line drawn from the star, there remained 29·4 miles per second as the velocity with which Sirius and our sun are mutually receding from each other. Considering the minuteness of the quantity on which the result depends, it is satisfactory to find that Mr. Huggins's results as to the motion of Sirius have been confirmed by the observations of Father Secchi made at Rome with a different instrument.

The determination of radial proper motion in this way is still in its infancy. It is worthy of note that, unlike the detection of transversal proper motion by change of angular position, it is equally applicable to stars at all distances, provided they are bright enough to render the observations possible. It is conceivable that the results of these observations may one day lead to a determination of the motion of the solar system in space, which is more trustworthy than that which has been deduced from changes of position, as being founded on a broader induction, and not confined to conclusions derived from the star in our neighbourhood. Should even the solar system and the nearer stars be drifting along, as Sir John Herschel suggests, with an approximately common motion, like motes in a sunbeam, it is conceivable that the circumstance might thus be capable of detection. To what wide speculations are we led as to the possible progress of our knowledge when we put together what has been accomplished in different branches of science

Spectrum Observations of the Solar Eclipse.

I turn now to another recent application of spectral analysis. The phenomenon of a total solar eclipse is described by those who have seen it as one of the most imposing that can be witnessed. The rarity of its occurrence and the shortness of its duration afford, however, opportunity for only a hasty study of the phenomena which may then present themselves. Among these, one of the most remarkable, seen indeed before, but first brought prominently into notice by the observers who watched the eclipse of July 7, 1842, consists in a series of mountain-like or cloud-like luminous objects seen outside the dark disk of the moon. These have been seen in subsequent total eclipses, and more specially studied, by means of photography, by Mr. Warren De La Rue in the eclipse of June 18, 1860. The result of the various observations, and especially the study, which could be made at leisure, of the photographs obtained by Mr. De La Rue, proved conclusively that these appendages belong to the sun, not to the moon. The photographs proved further their light to be remarkable for actinic power. Since that time the method of spectral analysis has been elaborated; and it seemed likely that additional information bearing on the nature of these objects might be obtained by the application of the spectroscope. Accordingly various expeditions were equipped for the purpose of observing the total solar eclipse which was to happen on August 17, 1868. In our own country an equatorially mounted telescope, provided with a spectroscope, was procured for the purpose by the Royal Society, which was entrusted to Lieut. (now Captain) Herschel, who was going out to India, one of the countries crossed by the line of the central shadow. Another expedition was organised by the Royal Astronomical Society, under the auspices of Major Tennant, who was foremost in pressing on the attention of scientific men the importance of availing themselves of the opportunity.

Shortly before the conclusion of the meeting of the Association at Norwich last year, the first results of the observations were made known to the meeting through the agency of the electric telegraph. In a telegram sent by M. Janssen to the President of the Royal Society, it was announced that the spectrum of the prominences was very remarkable, showing bright lines, while that of the corona showed none. Brief as the message necessarily was, one point was settled. The prominences could not be clouds in the strict sense of the term, shining either by virtue of their own heat, or by light reflected from below. They must consist of incandescent matter in the *gaseous* form. It appeared, from the more detailed accounts received by post from the various observers, and put together at leisure, that, except in the immediate neighbourhood of the sun, the light of the prominences consisted mainly of three bright lines, of which two coincided with C and F, and the intermediate one nearly, but, as subsequent researches showed, not exactly with D. The bright lines coinciding with C and F indicate the presence of glowing hydrogen. Several of the other lines were identified with those which would be produced by the incandescent vapour of certain other elements.

This is precious information to have gathered during the brief interval of the total phase, and required, on the part of the observers, self-denial in withdrawing the eye from the imposing spectacle of the surrounding scenery, and coolness in proceeding steadily with some definite part of the inquiry, when so many questions crowded for solution, and the fruits of months of preparation were to be reaped in three or four minutes or lost altogether, especially when, as too often happened, the observations were provokingly interrupted by flying clouds.

But, valuable as these observations were, it is obvious that we should have had long to wait before we could have become acquainted with the usual behaviour of these objects, and their possible relation to changes which may be going on at the surface of the sun, if we had been dependent on the rare and brief phenomenon of a total solar eclipse for gathering information respecting them. But, how, the question might be asked, shall we ever be able so to subdue the overpowering glare of our great luminary, and the dazzling illumination which it produces in our atmosphere when we look nearly in its direction, as to perceive objects which are comparatively so faint? Here, again, the science of optics comes in aid of astronomy.

Spectral Examination of the Eclipse Prominences.

When a line of light—such as a narrow slit held in front of a luminous object—is viewed through a prism, the light is ordinarily spread out into a coloured band, the length of which may be increased at pleasure by substituting two or more prisms for the single prism. As the total quantity of light is not thereby increased, it is obvious that the intensity of the light of the coloured band will go on decreasing as the length increases. Such is the case with ordinary sources of light—like the flame of a candle, or the sky, which give a continuous spectrum, or one generally continuous, though interrupted by dark bands. But, if the light from the source be homogeneous, consisting, that is, of light of one degree of refrangibility only, the image of the slit will be merely deviated by the prisms, not widened out into a band, and not consequently reduced in intensity by the dispersion. And, if the source of light emit light of both kinds, it will be easily understood that the images of the slit corresponding to light of any definite refrangibilities which the mixture may contain will stand out, by their superior intensity, on the weaker ground of the continuous spectrum.

Preparations for observations of the kind had long been in progress in the hands of our countryman Mr. Lockyer. His first attempts were unsuccessful; but, undismayed by failure, he ordered the construction of a new spectroscope of superior power, in which he was aided by a grant from the sum placed annually by Parliament at the disposal of the Royal Society for scientific purposes. The execution of this instrument was delayed by what proved to be the last illness of the eminent optician to whom it was entrusted (the late Mr. Cooke); but, when at last the instrument was placed in his hands, Mr. Lockyer was not long in discovering the object of his two years' search. On the 20th of October last year, in examining the space immediately surrounding the edge of the solar disk, he obtained evidence, by the occurrence of a bright line in the spectrum, that his slit was on the image of one of those prominences the nature of which had so long been an enigma. It further appeared, from an observation made on November 5th (as, indeed, might be expected from the photographs of Mr. De La Rue, and the descriptions of those who had observed total solar eclipses), that the prominences were merely elevated portions of an extensive luminous stratum of the same general character, which, now that the necessity of the interposition of the moon was dispensed with, could be traced completely round the sun. Notices of this discovery were received from the author by the Royal Society on October 21st and November 3rd, and the former was almost immediately published in No. 105 of the "Proceedings." These were shortly afterwards followed by a fuller paper on the same subject.

Meanwhile, the same thing had been independently observed in another part of the world. After having observed the remarkable spectrum of the prominences during the total eclipse, it occurred to M. Janssen that the same method might allow the prominences to be detected at any time; and, on trial, he succeeded in detecting them the very day after the eclipse. The results of his observations were sent by post, and were received shortly after the account of Mr. Lockyer's discovery had been communicated by Mr. De La Rue to the French Academy.

In the way hitherto described, a prominence is not seen as a whole, but the observer knows when its image is intercepted by the slit; and, by varying a little the position of the slit, a series of sections of the prominence

are obtained, by putting which together the form of the prominence is deduced. Shortly after Mr. Lockyer's communication of his discovery, Mr. Huggins, who had been independently engaged in the attempt to render the prominences visible by the aid of the spectroscope, succeeded in seeing a prominence as a whole by somewhat widening the slit, and using a red glass to diminish the glare of the light admitted by the slit, the prominence being seen by means of the c line in the red. Mr. Lockyer had a design for seeing the prominences as a whole by giving the slit a rapid motion of small extent; but this proved to be superfluous, and they are now habitually seen with their actual forms. Nor is our power of observing them restricted to those which are so situated that they are seen by projection outside the sun's limb; such is the power of the spectroscopic method of observation that it has enabled Mr. Lockyer and others to observe them right on the disk of the sun—an important step for connecting them with other solar phenomena.

One of the most striking results of the habitual study of these prominences is the evidence they afford of the stupendous changes which are going on in the central body of our system. Prominences, the heights of which are to be measured by thousands and tens of thousands of miles, appear and disappear in the course of some minutes. And a study of certain minute changes of position in the bright line F, which receive a simple and natural explanation by referring them to proper motion in the glowing gas by which that line is produced, and which we see no other way of accounting for, have led Mr. Lockyer to conclude that the gas in question is sometimes travelling with velocities comparable with that of the earth in its orbit. Moreover, these exhibitions of intense action are frequently found to be intimately connected with the spots, and can hardly fail to throw light on the disputed question of their formation. Nor are chemical composition and proper motion the only physical conditions of the gas which are accessible to spectral analysis. By comparing the breadth of the bright bands (for, though narrow, they are not mere lines) seen in the prominences with those observed in the spectrum of hydrogen rendered incandescent under different physical conditions, Dr. Frankland and Mr. Lockyer have deduced conclusions respecting the pressure to which the gas is subject in the neighbourhood of the sun. I am happy to say that Mr. Lockyer has consented to deliver a discourse during our meeting, in which the whole subject will doubtless be fully explained.

The Great Southern Telescope.

I have dwelt, perhaps, too long on this topic, and I cannot help fearing that I may have been tedious to the many scientific men to whom the subject is already perfectly familiar; yet the contemplations which it opens out to us are so exalted, and the proof which it affords of what can be accomplished by the union of different branches of science is so striking, that I hope I may be pardoned for occupying your time. I cannot, however, leave the subject of astronomy without congratulating the Association on the accomplishment of an object which originated with it, and in the promotion of which it formerly took an active part. It was at the meeting of the Association at Birmingham in 1849, under the presidency of the Rev. Dr. Robinson, that a resolution was passed for making an application to Her Majesty's Government to establish a reflector of not less than 3 feet aperture at the Cape of Good Hope, and to make such additions to the staff of that observatory as might be necessary for its effectual working. This resolution met with the hearty concurrence of the President of the Council of the Royal Society, who suggested that the precise locality in the Southern Hemisphere where the telescope should be erected had best be left an open question. This modification having been adopted by your Council, the application was presented to Earl Russell, then First Lord of the Treasury, by representatives of both bodies early in 1850. A reply was received from Government to the effect that, though they agreed with the Association as to the interest which attached itself to the inquiry, yet there was so much difficulty attending the arrangements that they were not prepared to take any steps without much further inquiry. This reply was considered so far favourable as not to forbid the hope of success if the application were renewed on a suitable opportunity. The subject was again brought before the Association, by Colonel (now General Sir Edward) Sabine, in his opening address as President at the Belfast meeting in 1852. The result was that the matter was again brought before Government by a Committee of the British Association acting in conjunction with a Committee of the Royal Society, by means of an application made to the Earl of Aberdeen. By this time the country was engaged in the Russian war, in consequence of which it was replied, no funds could then be spared; but a promise was given that, when the crisis then impending was past, the matter should be taken up—a promise which the retirement from office and subsequent death of Lord Aberdeen rendered of no avail.

But, though failing in its immediate object, the action of the British Association in this matter has not remained fruitless. A few years later, the subject was warmly taken up at Melbourne, and, after preliminary correspondence between the Board of Visitors of the Melbourne Observatory and the President and Council of the Royal Society, and the appointment by the latter body of a committee to consider and report on the subject, in April, 1864, a proposition was made to the Colonial Legislature for a grant of £5000 for the construction of a telescope, and was acceded to. Not to weary you with details, I will merely say that the telescope has been constructed by Mr. Grubb, of Dublin, and is now erected at Melbourne, and in the hands of Mr. Le Sueur, who has been appointed to use it. It is a reflector of 4 feet aperture, of the Cassegrain construction, equatorially mounted, and provided with a clock-movement. Before its shipment, it was inspected in Dublin by the committee appointed by the Royal Society to consider the best mode of carrying out the object for which the vote was made by the Melbourne Legislature; and the committee speak in the highest terms of its contrivance and execution. We may expect before long to get a first instalment of the results obtained by a scrutiny of the southern heavens with an instrument far more powerful than any that has hitherto been applied to them—results which will, at the same time, add to our existing knowledge, and redound to the honour of the colony by whose liberality this long-cherished object has at last been effected.

(To be continued.)

Section B.

ADDRESS
TO THE
CHEMICAL SECTION.

AUGUST 19, 1869.

By Dr. DEBUS, F.R.S., President.

I BELIEVE it has been the custom with many of my predecessors in this office to place before the members of the British Association a Report of the progress of Chemistry during the year preceding their election. In attempting to follow their example, I soon found that it would be impossible for me, without making too great a demand upon your time, to give even a bare outline of the more important chemical work done during the year. A science, the report of whose yearly advances fills about 1000 large octavo pages, cannot, by any powers of mine, have its progress chronicled in an address of half an hour's duration. The best course open to me under such ci-

is to direct your attention to the ideas which at present guide chemists in their researches, to place in a clear light the objects they are striving to attain, and to indicate the direction of scientific thought of our time. To do this is by no means an easy task; for the more manifold and diversified the objects of a science become—the more numerous and extensive its relations with other branches of knowledge, the more difficult it becomes to draw a picture of its actual condition.

It is always an excellent recommendation to a theory or hypothesis when, amongst the cultivators of the science to which it pertains, very little difference of opinion exists as regards its admissibility and scientific value. This is, in a high degree, the case with regard to the atomic theory. The vast majority of chemists, I believe, accept this theory as the most suitable exponent of the fundamental truths of their science; and certainly, if the quality of the tree may be judged by its fruit, there is no other view which furnishes a clearer image to our minds of the chemical constitution of bodies, and, at the same time, conducts to the discovery of so many important facts and relations. By Dalton's profound hypothesis, all bodies are supposed to be composed of atoms of infinitely small dimensions. But these atoms are supposed not to be single; two or more of them are held together by certain forces, and thus constitute what is called a molecule. One atom of carbon, one atom of calcium, and three atoms of oxygen, joined together by the force called chemical affinity, constitute a molecule of carbonate of lime. Vast numbers of such molecules, bound to each other by the force of cohesion, form a visible piece of chalk. If a chemist wishes to examine a body, his first endeavour is to ascertain of what sort of atoms the body is formed. This is a mere matter of experiment. He next determines how many of such atoms are contained in each molecule of the body, and, finally, he ascertains how these atoms are arranged, or, more correctly, combined within the molecule; for it is quite clear that a substance like saltpetre, which contains one atom of nitrogen, one of potassium, and three of oxygen, may have these atoms arranged in very different manners, and still have the same composition. We might assume the potassium and nitrogen in more intimate union, nearer to each other than they are to oxygen, or we might consider nitrogen and oxygen more closely packed together, and, so to speak, attached as a whole to the potassium; in both cases, saltpetre would have in each molecule the same number of atoms, and the weight of the molecule would be the same. The three determinations just mentioned are of fundamental importance to the chemist; not that such inquiries are the only ones which interest him, for we shall, in the sequel, notice others of almost equal importance.

Nor must it be supposed that questions of this nature are of quite a modern date; for Leucippus, 500 B.C., appears to have sought to explain the nature of things, by the assumption that they are formed by the union of small particles, which latter received the name of atoms from Epicurus. It is true the notion of atoms, as conceived by the Grecian philosophers, is not quite the same as ours, but their speculations contain our notions pretty much in the same way as the acorn contains the oak-tree.

The determination of the quality of the atoms in a molecule, or the analysis of the latter, has not undergone many changes during the last few years; and the same may be said about the finding of the relative weight of a molecule, or the determination of the number of atoms which are contained in it. With regard to the latter point, however, it may be mentioned that Avogadro's hypothesis, according to which equal volumes of gaseous substances, measured at the same temperature and pressure, contain the same number of molecules, guides us chiefly in assigning to each molecule its relative weight and its number of atoms; this hypothesis has won more and more the confidence of chemists, and it is now admitted to hold good in nearly all well-examined cases.

Our views relative to the combinations of atoms in molecules, and our methods of ascertaining this arrangement, have, however, undergone great alterations, and received great additions, during the last ten or fifteen years. To a consideration of these changes I will now, for a short time, invite your attention. Since our modern views, however, originated, in a great measure, from the study of organic bodies, and since the majority of chemists now devote their time and labour thereto, I shall confine my remarks principally to the organic branch of the subject.

Eighteen years ago, Prof. Williamson read before the members of this Association a remarkable paper, which contained the germ of our modern chemical views, and was the cause of many discoveries. He proposed to regard three large classes of bodies, acids, bases, and salts from the same point of view, and to compare their chemical properties with those of one single elected substance. For this term of comparison he chose water. Now water is composed of three atoms—two of hydrogen and one of oxygen. Williamson showed that all oxygen acids—all oxygen bases, and the salts resulting from a combination of the two—can, like water, be considered to be composed of three parts, or radicals, two of the radicals playing the part of the hydrogen atoms in water, and the third that of the atom of oxygen, thus:—

$\left.\begin{matrix}H\\H\end{matrix}\right\}O$	$\left.\begin{matrix}K\\H\end{matrix}\right\}O$	$\left.\begin{matrix}NO\\H\end{matrix}\right\}O$	$\left.\begin{matrix}NO\\K\end{matrix}\right\}O$
Water.	Potassic hydrate.	Hydric nitrite.	Potassic nitrite.

Potassic hydrate is water which has one of its atoms of hydrogen replaced by an atom of potassium; hydric nitrite is water which has one atom of hydrogen replaced by nitric oxide; and potassic nitrite is water with one of its hydrogen atoms replaced by nitric oxide, and the other by potassium. This speculation, as every chemist knows, is well supported by experiments; it embraces three large classes of bodies which, till then, had been considered as distinct. M. Gerhardt, in 1853, extended Williamson's views, by distinguishing two other types of molecular structure, represented, respectively, by hydrogen and ammonia, and succeeded, by help of the radical theory, in arranging the majority of the then known substances under one or the other of the three types already mentioned.

Like every theory which is in harmony with experience, the above considerations led to results of unexpected importance; for it soon became apparent that the radicals which thus replace hydrogen in water are not all of the same chemical value. If we place together the formulæ of hydric nitrite and carbonic acid—

$\left.\begin{matrix}NO\\H\end{matrix}\right\}O$	$CO\}O$
Hydric nitrite.	Carbonic acid.

we perceive, at once, that the atomic group NO has replaced one atom of hydrogen in one molecule of water, and carbonic oxide, CO, two atoms of hydrogen in one molecule of water. Nitric oxide (NO) is, therefore, said to be equivalent to one atom of hydrogen, and carbonic oxide (CO) equivalent to two atoms of hydrogen. The radical of phosphoric acid [PO] is found to be equivalent to three atoms of hydrogen. Professor Odling was one of the first to observe this difference in the equivalence of atoms, and groups of atoms, or compound radicals, as they are termed, a difference which he marks, as shown in the following examples:—

Radicals.

Equivalent to one atom of hydrogen.		Equivalent to two atoms of hydrogen.	
Nitric oxide	$(NO)'$	Carbonic oxide	$[CO]''$
Methyl	$(CH_3)'$	Methylene	$[CH_2]''$
Ethyl	$(C_2H_5)'$	Ethylene	$[C_2H_4]''$

The notion of equivalence enabled Professor Kekule to form most interesting speculations on the constitution of organic bodies, and to explain the relation between composition and equivalence of such radicals as methyl, CH_3,

ethyl, C_2H_5, methylene, CH_2, ethylene, C_2H_4, and acetylene, C_2H_2.

If from one molecule of marsh gas, CH_4, one atom of hydrogen is abstracted, the residue, CH_3, called methyl, can combine with an atom of hydrogen again, and produce the original marsh-gas molecule. But methyl, instead of combining with an atom of hydrogen, can unite with an atom of chlorine, or an atom of bromine, that is to say, the place of the atom of hydrogen can be taken by an atom of chlorine or bromine. Methyl being thus equivalent to an atom of hydrogen, is said to be monovalent. If from a molecule of marsh-gas two atoms of hydrogen are removed, the residue, CH_2, called methylene, can again unite with two atoms of hydrogen, or, instead of hydrogen, two atoms of chlorine or bromine, and from the compounds CH_4, $CHCl_2$, CH_2, Br_2 respectively. Methylene, therefore, being equivalent to two atoms of hydrogen, is termed divalent. The radical CH, left after the abstraction of three atoms of hydrogen from marsh-gas, is able to re-produce with three atoms of hydrogen one molecule of marsh-gas, or to combine with three atoms of chlorine, and form chloroform, $CHCl_3$. The residue, CH, is thus trivalent or equivalent to three atoms of hydrogen. In the same manner carbon is found to be tetravalent or equivalent to four atoms of hydrogen. But carbon, formen [CH], methylene, CH_2, methyl, CH_3, not only combine with hydrogen, chlorine, or other elements according to their equivalence, but also amongst themselves, and thus produce the so-called hydrocarbons, native as well as artificial. Methyl combines with methyl and produces dimethyl, or better known as ethylic hydride, $CH_3+CH_3=C_2H_6$; methylene combines with methylene, and forms ethylene, $CH_2+CH_2=C_2H_4$. Methylene is divalent, and methyl monavalent; therefore methylene combines with two equivalents of methyl and forms propylic hydride, C_3H_8, $CH_2+2CH_3=C_3H_8$. Six equivalents of formen are supposed to be contained in benzol $[C_6H_6]$, $6CH=C_6H_6$.

What has been said of marsh-gas also applies to ammonia and water. Ammonia, NH_3, minus one atom of hydrogen, forms the monovalent radical, NH_2, minus two atoms of hydrogen, the divalent radical, NH, and nitrogen itself trivalent, that is to say, it can replace three atoms of hydrogen in compounds, or can combine with three atoms of hydrogen. Water minus one atom of hydrogen produces the monovalent radical hydroxyl, HO, and water without both atoms of hydrogen gives us divalent oxygen. These radicals, NH_2, NH, N, HO, and O, can combine with each other, and with methyl, methylene, formen, and carbon respectively in different proportions. Thus methyl, methylene, and hydroxyl are contained in common alcohol. The union of methyl, carbon, oxygen, and hydroxyl gives acetic acid, $C_2H_4O_2$,

$$CH_3+C+O+HO=C_2H_4O_2.$$

Glycocoll is considered as a combination of methylene amidogen $[NH_2]$, carbon, oxygen, and hydroxyl:—

$$CH_2+NH_2+C+O+HO=C_2H_5NO_2=\text{glycocoll.}$$

The radicals C, CH, CH_2, CH_3, HO, O, N, NH, NH_2, and CO are considered to form the proximate constituents of the most important organic compounds. It often happens that, from the union of the same radicals, two or more bodies of the same composition, but differing from one another in properties, result. Glycocoll, as well as glycolamide, contain the radicals methylene, hydroxyl, carbonic oxide, and amidogen, NH_2. In such cases the nature of the compound depends on the arrangement of the radicals, as may be seen by the following formulæ:—

$$CH_2.NH_2.CO.HO = C_2H_5NO_2 = \text{glycocoll,}$$
$$CH_2.HO.CO.NH_2 = C_2H_5NO_2 = \text{glycolamide.}$$

Now, the great problem with whose solutions scientific chemists are occupied is *to determine, first, what sort of radicals of the above nature are contained in a given organic body, and, second, how these radicals are grouped amongst each other.*

There are several ways of solving this problem. The molecule may be built up by placing the radicals which are supposed to exist in it under suitable conditions in contact. Two molecules of iodopropionic acid placed together with metallic silver will lose their iodine, and the residues of the two molecules remain united. A new acid, called adipic acid, is thus formed.

$$\left.\begin{matrix}\text{Iodopropionic}\\ \text{acid}\end{matrix}\right\}\begin{matrix}CO.HO\\ CH_2\\ CH_2I\end{matrix} + Ag = 2AgI + \left\{\begin{matrix}COHO\\ CH_2\\ CH_2\\ CH_2\\ CH_2\\ COHO\end{matrix}\right. = \text{adipic acid.}$$
$$\left.\begin{matrix}\text{Iodopropionic}\\ \text{acid}\end{matrix}\right\}\begin{matrix}CH_2I\\ CH_2\\ COHO\end{matrix}$$

We know, therefore, the radicals of adipic acid and their arrangement if we possess the same knowledge with regard to iodopropionic acid.

The above elegant synthesis has lately been performed by Professor Wislicenus of Zurich. M. Berthelot has now succeeded in producing representatives of the principal classes of hydrocarbons from the elements of carbon and hydrogen, and Messrs. Bauer and Versow of Vienna have prepared from amylene, C_5H_{10}, a compound, $C_{10}H_{16}$, which appears to be identical with terebene, a body closely allied to turpentine.

Another way to determine the proximate constituents of molecules is to take the little structures to pieces, and to form a judgment of their constitution from the radicals which thus can be extracted. This plan has been adopted by Mr. Chapman, and described by him at one of our former meetings.

The more common and more reliable method for the determination of the grouping of atoms in molecules is, however, the replacement of one or more of them by atoms of another kind, and the careful examination of the properties of the bodies thus formed. M. Gautier has recently obtained a new substance of the same composition as acetonitrile, which he calls methcarbylamine. According to their formation, acetonitrile, as well as methcarbylamine, can be considered as combinations of cyanogen and methyl $=CH_3CN$. The two bodies, however, do not possess the same properties. If they are heated with potassic hydrate and water, methcarbylamine produces formic acid and methylia, whereas the same reagents cause acetonitrile to form acetic acid and ammonia. Thus—

$$\underbrace{C_2H_3N}_{\text{Acetonitrile.}} + \underbrace{2H_2O}_{\text{Water.}} = \underbrace{C_2H_4O_2}_{\text{Acetic Acid.}} + NH_3$$

$$\underbrace{C_2H_3N}_{\text{Methcarbylamine.}} + 2H_2O = \underbrace{CH_2O_2}_{\text{Formic Acid.}} + \underbrace{N\left\{\begin{matrix}CH_3\\ H_2\end{matrix}\right.}_{\text{Methylia.}}$$

In the first case, the radical methyl remains after the decomposition in union with carbon, and in the second case in combination with nitrogen. Accordingly, it is supposed that the same arrangement prevails in the undecomposed molecules, and with this supposition all the other properties of methcarbylamine and acetonitrile agree. In symbols these relations are expressed as follows:—

$$N\left\{\begin{matrix}C''\\ CH_3\end{matrix}\right. = \text{methcarbylamine.}$$
$$N\left\{\begin{matrix}\\ C_2H_3\end{matrix}\right. = \text{acetonitrile.}$$

This case of isomerism is most interesting, inasmuch as it furnishes a most instructive lesson on the grouping of atoms. The homologous bodies of methcarbylamine in the ethyl and propyl series have also been obtained.

Isomerism, indeed, has received much attention during the last year, and a great many interesting discoveries have resulted. Of these, one more example may be mentioned. We know two compounds of the formula CN_2H_4O—the one is ammonic cyanate, and the other urea. Until recently, only one corresponding sulphur-compound, ammonic sulphocyanate, was known. Professor Reynolds has succeeded in obtaining the true sulphur-urea, a body isomeric to ammonic sulphocyanate.

Thus every year produces results which improve our conceptions of the atomic and molecular constitution of

bodies. And, as our knowledge improves, new questions suggest themselves, and our power over the elements increases. It has already become possible to prepare, in the laboratory, bodies of a very complex character, and which, a few years ago, were only found in the bodies of animals or plants.

Alizarine, the beautiful compound of the madder root, has been obtained, by artificial means, in the course of the year, by MM. Liebermann and Græbe. Results of such a nature render it highly probable that, at no distant period, it will be in our power to render nearly all, if not all, the substances found in plants and animals. Here I must not be misunderstood. Organic structures, such as muscular fibre, or the leaves of a tree, the science of chemistry is incapable of producing; but molecules like those found in a leaf, or in the stem of a tree, will, no doubt, one day be manufactured from their elements.

I must not conclude this address without reference to two or three papers of great importance.

Professor Bunsen, of Heidelberg, has published a paper on the washing of precipitates. Every one acquainted with practical chemistry knows how much time is often lost in waiting for a liquid to pass through a filter. Bunsen found the rate of filtration nearly proportional to the difference between the pressures on the upper and lower surfaces of the liquid. If, accordingly, the funnel be fixed air-tight, by means of a perforated cork, to the neck of a bottle, and the air exhausted in the bottle, the liquid will run faster through the filter in proportion to the diminution of the pressure in the bottle. Comparative experiments, some made according to the old, and others according to the new method, showed that the filtration, washing, and drying of the precipitate, which took seven hours by the old plan, could be performed, by filtration into an exhausted bottle, in thirteen minutes. But a saving of time is not the only advantage of the improved method of collecting and washing precipitates. A more perfect washing, with less water than is required by the common way of proceeding, is by no means the least recommendation of Bunsen's ingenious method.

A very important paper has been published by Professor Liebig, on the improvement of the nourishing qualities of bread. Certain quantities of phosphates and other salts form necessary ingredients of wholesome food. Now, it is well known that most of these salts, which are naturally in wheat, remain with the husk. Liebig proposes to add salts, of a nature similar to those remaining in the husk, to the flour, and, at the same time, to substitute, for the carbonic acid developed by fermentation, gas liberated from iodic carbonate. The bread prepared according to Liebig's recommendation is said to be of excellent quality, and to exceed bread made by the common plan in value.

Mr. Graham, of Her Majesty's Mint, has continued his researches on the absorption of hydrogen by palladium. Palladium appears to be able to absorb more than 900 times its volume of hydrogen, and to form a combination which consists of nearly equal equivalents of the two elements. Hydrogenium, as Mr. Graham calls the combined hydrogen, acts in this case like a metal, and thus the opinion held by some scientific men, that hydrogen constitutes the vapour of a metal, receives confirmation. The specific gravity of hydrogenium, as contained in the alloy, was found to be 1·95. These experiments are remarkable in more than one respect. The palladium which absorbs and combines with the hydrogen, does not change its state of aggregation, but remains solid, and expands, as if it had been heated. The nodules of the palladium have, consequently, changed their relative positions, and combined with hydrogen, whilst the continuity of the metal remained intact.

The last paper to which I have to draw your attention, is to the beautiful paper by Professor Tyndall, on a new method of decomposing gaseous substances by means of light. Tyndall's experiments bring us face to face with the motions of atoms of molecules, and the relation of these motions to chemical decomposition. They will, no doubt, at some future time, furnish valuable materials to chemical dynamics.

ON THE

METHODS OF ANALYSIS

AND THE

COMPOSITION OF VARIOUS CHEMICAL MANUFACTURING PRODUCTS.

By M. GASTON TISSANDIER.

(Continued from p. 76.)

Chlorides of Potassium.

Commercial chlorides of potassium, or muriates of potash, contain sulphates, and frequently alkaline carbonates also; in certain cases a more or less considerable proportion of chloride of sodium is also found in them.

Method of Analysis.—Weigh 25 grammes of the muriate of potash to be tested, and dissolve them in a beaker; filter the solution to separate the insoluble matters, which usually occur only in very small proportion, and dilute it with water to the volume of ½ a litre.

Alkalimetric Standard.—This does not generally exceed 1° or 2°; for obtaining it, decant 100 c.c., corresponding to 5 grammes: ascertaining previously that the solution is alkaline, for it is possible that the muriate may not contain any alkaline carbonates.

Sulphuric Acid.—The sulphuric acid is estimated in 100 c.c. (5 grammes) by means of chloride of barium.

Chlorine.—The estimation of the chlorine is of great importance, and should be rigorously exact: take 10 c.c. of the filtered liquid tared to ½ a litre, and determine the amount of chlorine by means of a standard silver liquid. For greater exactness, it is a good plan to verify this estimation by directly weighing the chloride of silver precipitated in another experiment. Measure 10 c.c. (0·50 gr.) of the solution of muriate, and transfer them by means of a pipette into a beaker holding 500 c.c.; add a large quantity of boiling water, acidulate it with pure nitric acid, and precipitate the chlorine by a slight excess of nitrate of silver. The estimation previously made by means of the standard solution allows the quantity of nitrate of silver required to be calculated, so that the excess may not be great. The precipitate is well stirred with a glass rod, and the warm liquid settles so well that it is possible to wash the precipitate of chloride of silver by decantation with boiling water. When the washing water is not clouded on the addition of a drop of chlorhydric acid, it is thrown on a small filter, left to drain, and dried at 100°.

The desiccated precipitate is detached from the filter, which is calcined in a small tared porcelain capsule, and when the paper is burnt, the chloride of silver precipitate must be added and partially melted; it is then cooled, and the capsule weighed together with the chloride of silver; the weight of the precipitate is thus obtained by difference. The chloride of silver adheres closely to the capsule. In order to remove it, throw the whole into a glass, and place on it a piece of zinc, sulphuric acid, and water; the chloride of silver, partially reduced, will then separate from the capsule.

Potassium.—The estimation of potassium is effected in the same way as in the case of crude salts (see Chemical News, vol. xx., p. 73), by means of bichloride of platinum, working upon 10 c.c. (0·50 grms.)

Water.—The proportion of water is ascertained by heating, in a platinum crucible, a given weight of the muriate to be tested. A closed tube is still better, as it

allows the loss from projections arising from the deflagration of the salt to be more easily avoided.

Calculation of the Analysis.—Part of the estimated potassium is combined with the sulphuric acid contained in the sulphate. If the excess of potassium is sufficient to combine with the whole of the chlorine, the latter is transformed into chloride of potassium; if not, the quantity of chlorine necessary to form chloride of potassium with the remaining potassium is calculated, and the excess of chlorine reckoned as chloride of sodium.

Composition of Commercial Muriates.

		M. Paisant, jun., at Pont-l'Abbé (Finisterre).	

Chloride of potassium is obtained, as has been shown, from the beet-root salts; it is also extracted in abundant quantities from the ash of seaweed. The newly-discovered deposit at Stassfurt yields considerable quantities; and large kidney-shaped pieces of pure chloride of potassium have been found in abundance in the midst of that vast salt mass. We have repeatedly analysed this natural chloride of potassium (called by the Germans sylvin), and have never discovered more than 1-10th of foreign matter. Every sample which we examined contained from 80 to 99 per cent of chloride of potassium. This is a highly important fact; and it is well known that the influence of the exportation of the Stassfurt products is already making itself felt in the manufacture of potashes.

(To be continued).

The Laboratory of the London Institution.—We understand that Professor Wanklyn has recently been elected a corresponding member of the Munich Academy of Science.

NOTICES OF BOOKS.

Exeter Change, for the British Lions. Edited by Snug the Joiner. London: B. Pardon and Son, Paternoster Row. 1869.

The British Association for the Advancement of Science meets this year, as all the world knows, at Exeter. Exeter Change, as all the world—specially the younger portion of it—does *not* know, was once one of the sights of London; for therein were housed the British Lions which had whilom dwelt in the Tower of London, and, symbolising the sovereignty of this realm, had been considered necessary appurtenances of Royalty. "Exeter Change," says the editor of the pamphlet before us, "has disappeared, and the ground hallowed by memories of the caged lions; and the solitary beadle is now occupied by the Gaiety Theatre. Need I add that my title-page is deeply significant. You British Lions have now an Exeter Change productive of gaiety."

"Exeter Change" is not a satire; it has nothing of the lampoon about it; the sarcastic Roman Pasquino would scarcely allow it to be called a pasquinade; there is nothing in it the least bitter or spiteful, nothing that smacks of the *Tomahawk*, or *Queen's Messenger*. The mention of an individual is generally accompanied by his laudation, or, if the reverse, the censure is no more than the most harmless "chaff." What, then, shall we call it? A parody? Scarcely. A squib? By no means. A burlesque? This is nearer the mark; particularly if we may trace the word through the Italian *burlesco*, and the Low Latin *burleschus*, to the classical *burra*, as Mr. Donald tells us; but Ainsworth is silent about *burra*, and approaches it no more nearly than *burra*, which signifies "the hinder part of a plough," and is scarcely appropriate. What, then, remains to us? A travesty? That will do better. "Exeter Change" is a sort of travesty; or, if the reader pleases, he may find in it just a *soupçon* of several of the above forms of composition.

Having defined our work, let us look more closely into it. In the "Prologue," the editor greets the various presidents of sections and learned bodies of the British Association, and states the object and aim of his work. This is followed by a "History of the Association," written in the exact and somewhat prosaic style of certain students of the Buckle School. Then comes the "Wail of the Mathematician," a poem in imitation of "Locksley Hall," which is clever, and shall speak for itself—albeit in a somewhat *staccato* manner. The mathematician here describes the progress of his courtship:—

"Once about the beach we wandered, spooning in a way sublime,
While the dreary tales of Science were reserved for future time;

When geologists before us on contorted strata prosed,
We were sure to find a seaweed in a place not much exposed."

. . . . . .

"At the time when Dr. Hooker the Darwinian standard raised;
At the time when sharp Miss Becker got herself unduly praised;
At the time when Father Secchi fraternised with prelates grave;
Then it was that I discovered I was simply Kitty's slave."

Determining to discard this fickle Kitty, the mathematician tries to find some strong-minded woman—

"Iron-visaged, tall, snd skinny, she the bluest of the blues,
Shall with potent mathematics my domestic life suffuse.
Dingy black shall be her costume: pins shall take the place of hooks:
And her hair, close-cropped, shall startle followers of fashion books."

The poem is followed by a long article on "The Development Hypothesis," a travesty of some recent animadversions of the German anti-Darwinites. "On some Recent Spectral Observations" follows this. Herein a man is supposed to fall asleep in his library, and to see a vision of the various authors of the books around him, and to hold a short conversation with them: the following extract is taken from the concluding portions:—

"But there now arose such a clamour that I could not hear myself speak. Albertus Magnus *would* keep striking Avicenna with a crozier; Cardinal Bellarmine threw his hat at Galileo; Abelard tripped up William of Champeaux; the pretty little Heloise flirted with Peter of Cluny; while a host of Plenists, headed by Father Linus, were having a set fight with a host of Vacuists, headed by Robert Boyle."

Next we have "Mercurius Rex"—a chemical ode. Recitative and air, with accompaniments of Maëlzel's metronome, contrabassos in F in altissimo, Helmholtz's double syren, and the tibia pastorale.

In the next article—"On the Alcoholic Compound termed Punch," by John T—nd—ll, LL.D., F.R.S.—we have a capital imitation of the style of a certain eminent lecturer and physicist. Let us content ourselves with the last two paragraphs—

"Experiment has proved that the juice of three or four lemons, and three-quarters of a pound of loaf-sugar dissolved in about three pints of boiling water, give saporous waves which strike the palate at such intervals that the thrilling acidity of the lemon-juice and the cloying sweetness of the sugar are no longer distinguishable. We have, in fact, a harmony of saporific notes. The pitch, however, is too low, and to heighten it, we infuse in the boiling water the fragrant yellow rind of one lemon. Here we might pause, if the soul of man craved no higher result than lemonade. But to obtain the culminating saporosity of punch, we must dash into the bowl, at least, a pint of rum and nearly the same volume of brandy. The molecules of alcohol, sugar, and citric acid collide, and an entirely new series of vibrations are produced—tremors to which the dullest palate is attuned.

"In Punch, then, we have rhythm within rhythm, and all that philosophy can do is to take kindly to its subtle harmonies. It will depend in some measure upon previous habits, whether the punch when mixed will be taken in excess or in moderation. It may become a dangerous ally of gravity and bring a sentient being to the gutter. But, on the other hand, it may become the potent inner stimulus of a noble outward life."

The remainder of the pamphlet is filled with shorter articles:—An "Alphabet for Young Associates;" "Rejected Addresses," giving a list of certain supposititious papers rejected by different Sections;" Advice "To the Dyspeptic Members of the Association," containing a *menu* in which we notice "Goujon sauté en l'eau froide;" "Poulet pansu;" "Porc à la trichine;" "Xéres de Hamburg nouveau et brûlant;" and "Vin d'Oporto des environs de Spital-fields."

"Eozöon Canadense: a lay of Chivalry from Section C" is a poem of twenty-one stanzas; "What will they do with it?" an account of a meeting in the Albert Hall of Arts and Sciences" in 1872, when a grand difficulty has arisen as to what use the Hall shall be applied to, and various *savants* express their various opinions. Then we have a letter from Francis Bacon, headed "Elysian Fields, August 15th, 1869," in which, in the quaint English of the early part of the seventeenth century, Bacon refers to his treatise "Nova Atlantis," and shows that he therein shadowed forth such an Association of the learned as we now have in the British Association for the Advancement of Science.

Altogether, "Exeter Change" is very readable. There is not much wit in it, but it is pleasant and lively, and never gross or coarse, nor do we detect any *doubles entendres*, too often the vehicle for raillery and sarcasm, and sometimes for what is worse. It is evidently the work of young writers; and it is equally evident that the matter has been struck off rapidly, without much elaboration, and this we consider an advantage, for, by the means, we get fresh, budding ideas, in the place of garish and dressed-up piracies. We wish Snug the Joiner, and his colleagues, Peter Quince and Nick Bottom, every success; and we commend their trim little work, not alone to members of the Association, but to their scientific *confréres* who have not journeyed to Exeter.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

In accordance with the generally expressed wishes of our friends and readers, we have effected arrangements to enable us to give, under the above heading, notices of EVERY CHEMICAL PAPER IN THE WORLD, *as soon as possible after publication. Whenever possible, these notices will appear in the form of carefully prepared, although necessarily brief, abstracts; as respects papers either too long or too abstruse to render condensation possible, their titles will be chronicled; and in all cases accurate reference will be made to the original publication. The two half-yearly volumes of the* CHEMICAL NEWS, *with their copious indices, will therefore be equivalent to an English edition of the "Jahresberichte," with the additional advantage of keeping the readers week by week on a level with the latest advances of science.*

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

The Journal of the Franklin Institute, June, 1869.

A large portion of this excellent periodical is devoted to engineering facts. Among the original communications relating to chemistry we find:—

Sugar and Starch from Sweet Potatoes.—M. H. Bartol presented, at the last meeting of this Institute, samples of sugar and starch, and the following analysis made in November last, from the juice of North Carolina sweet potatoes (per cent):—Sugar, 10·50; starch, 6·00; various salts, 1·17; gum, &c., 0·33; water, 82·00. By the use of powerful presses, 90 per cent of the weight of the potato can be obtained in juice; the density of this juice is 10° Beaumé=1·075 sp. gr. These potatoes, the author says, will yield 6·18 per cent of sugar and 5 per cent of starch; but, by improved culture, as evidenced in Europe in the instance of beet-root, this quantity may be largely increased.

Tin in Missouri.—M. Williams.—This gentleman, in a note addressed to the editor of the above periodical, states that the granitic rocks of south-east Missouri are all more or less charged with stannic acid, so that there is a fair prospect of obtaining tin ore in quantity in that country.

The larger number of papers of this number relate to engineering and astronomy, rather than to chemistry or sciences allied therewith

American Journal of Pharmacy, July, 1869.

This periodical contains a very large amount of excellent matter, but most of it belongs too strictly to pharmacy to be suited for our pages We abstract the following papers:—

Bicarbonate of Ammonia as a Pharmaceutical Preparation.—W. Procter, jun.—The author begins by stating that he has used this salt as an antacid, instead of bicarbonate of soda, above which it is preferable, owing, also, to its somewhat stimulating powers. As to the formation of this salt, the author says—It is well known to druggists that considerable quantities of this salt are formed on the sides of casks in which carbonate of ammonia is imported, and other portions are derived from the accidental or careless exposure of the sesqui-carbonate of ammonia, whereby an equivalent of mono-carbonate is lost. It has been usual to reserve the salt thus obtained for forming acetate, nitrate, or other ammoniacal salts; but it is rarely used medicinally on its own merits. If it were sufficiently abundant or

could be prepared cheaply by a direct process, it would form the best yeast powder that can be offered, since it contains a larger portion of carbonic acid than any of the alkaline bicarbonates except that of lithia, which is, of course, unsuited to this use. Bicarbonate of ammonia in its purest state is a white salt, isomorphous with bicarbonate of potassa, and possesses the same crystalline form; its composition is expressed by the formula $NH_4O_2CO_2.HO$; its taste is saline, with a slight ammoniacal impression, and is slowly volatile when exposed, and gradually evaporates with a slight odour of ammonia; it is soluble in eight parts of water at 60° F., and its aqueous solution exhibits an alkaline reaction with syrup of violets; it is decomposed by the heat of boiling water, giving off carbonic acid; it is nearly insoluble in strong alcohol, but soluble in 60 parts of dilute alcohol; it is readily prepared on the small scale, by dissolving out the mono-carbonate from the powdered sublimed sesqui-carbonate (which consists of one equivalent of each salt) by means of alcohol of 85 per cent, in which the bicarbonate is almost insoluble. When a saturated solution of sesqui-carbonate of ammonia in water is saturated with CO_2, a quantity of the bicarbonate separates in crystals, owing to its less solubility.

Sweet Quinine.—W. Procter, jun.—It appears that, under this name, there has been thrown into commerce, by M. F. Stearns (U.S.), an article which, according to a statement made in the manufacturer's circular, appeared to be quinine associated with liquorice sugar. The author of this paper very properly states that the article in question, having been submitted by him to chemical tests, does not contain any quinine at all, but mainly cinchonine, precipitated from the sulphate, dried and triturated with an impure glycyrrhizin prepared from liquorice root. The tastelessness of "sweet quinine" is due to the very difficult solubility of cinchonine, which requires nearly 4000 parts of cold water; with acid or alcoholic fluids, which salify and dissolve it, its bitterness becomes apparent.

The remainder of the papers of this excellent periodical are not suited for abstraction in our pages, for the reason already given.

Bayerisches Industrie und Gewerbeblatt, June, 1869.

This number contains, besides a large collection of official communications, among which is a well-digested and arranged law for limited liability companies, the following original papers:—

Utilisation of the Waste Products of Soda and Bleaching Powder Manufacture.—M. Züngerle.—The contents of this paper are, in some form or other, known to our readers, as this subject has been fully treated of in our columns. This paper does not teach us anything new, and therefore we quote nothing more from it than this—that, in Germany, the manufacture of sulphur from soda waste, and of peroxide of manganese containing 60 per cent, is carried out largely, and with success.

Use of the Miesbach Coal as Fuel at the Salt-work of Hall, in the Tyrol.—M. Hailer.—This paper is chiefly of local importance but it may be noticed that the coal here alluded to, while containing 18·6 per cent of ash, and being chiefly small coal, containing, on an average, 52 per cent of carbon, is yet successfully applied to heat the salt-pans, at almost nominal cost, since the furnace is so arranged as to get the most heat from the fuel.

Jet-Black China Varnish.—M. Marx.—Under the above name is sold a varnish for boots and shoes, which, according to the author's analytical researches, chiefly consists of an alcoholic solution of shellac. According to the author, an excellent imitation of the original may be made by dissolving 10 grms. of shellac, and 5 grms. of turpentine, in 40 grms. of strong methylated spirits, in which fluid should be previously dissolved 1 grm. of extract of logwood, with some neutral chromate of potassa and sulphate of indigo. The varnish is to be kept in well-stoppered bottles.

Parisian Copying Ink.—M. Marx.—To make this, take 30 grms. of extract of logwood, and 7·5 grms. of crystallised carbonate of soda; boil this with 240 grms. of water, and add, while vigorously stirring, 30 grms. of glycerine. When the fluid has become cold, dissolve in it 1 grm of neutral chromate of potassa, and add, lastly, 7·5 grms. of gum arabic, previously made into a thick mucilage with water. The paper upon which it is desired to transfer a copy need not be moistened if this ink is used.

Mixture for Producing "Japanese Lightning."—M. Marx.—Anhydrous saltpetre (nitrate of potassa), 33·3 parts; charcoal from lime-tree wood, 58·3; flowers of sulphur, 8·4. As to the name of Japanese lightning, it means the same as the Japanese matches Prof. A. W. Hofmann spoke about a couple of years ago, at a meeting of the Chemical Society.

Zeitschrift für Chemie, von Beilstein, No. 13, 1869.

This number contains only one original paper, the great bulk being abstracts from various periodicals written and published in English, French, Italian, and German languages. The original paper alluded to is on—

Hæmatoxyline and Hæmateine.—Dr. Tabensky.—The author states that, since MM. Erdmann and Hesse had discovered that hæmatoxyline reduces solutions of silver and becomes coloured red by the action of direct sunlight, he was induced by Prof. von Babo to make some experiments in order to discover whether the alcoholic extract of logwood might not be very serviceable in photography. For this purpose the author prepared hæmatoxyline in pure state according to Erdmann's method, taking care to re-crystallise the substance repeatedly from an alcoholic solution. Next, two glass plates, properly prepared, were exposed, in a photographic apparatus, to light, and afterwards one of these plates was treated, as usual, with pyrogallic acid, the other with a solution of hæmatoxyline. The success of the latter operation left nothing to be desired, and the further experiments of the author leave no doubt whatever that hæmatoxyline may be advantageously applied in photography. The quantities best suited for this solution are as follows:—Hæmatoxyline, 0·5 grm.; distilled water, 80 grms.; 22 grms. of acetic acid of 33° strength; and a small quantity of glycerin. The method of preparation of hæmateine has been altered and improved by the author of this paper in the following manner:—By means of an aspirator, air is drawn through a bottle filled, for one-third of its capacity, with liquid ammonia; and the current of air thus charged with ammonia is made to pass slowly over and through hæmatoxyline suspended in water; but care is to be taken that the glass tube through which the air charged with ammonia strikes should only just dip very slightly under the surface of the water; by this means, excess of ammonia is excluded, and the formation of amorphous brown substances is prevented. By this method, from 10 to 12 grms. of hæmatoxyline are changed, within three hours, into hæmateine, yielding a magnificently purple-coloured solution, which is precipitated by bisulphite of ammonia when cold; but, on heating, this precipitate becomes re-dissolved. Hæmatoxyline is, according to M. Hesse, composed of $C_{32}H_{14}O_{12}+2HO$; hæmateine is $C_{32}H_9O_9+HO$. The former substance is a very weak acid, rather difficultly soluble in water, but very readily in an aqueous solution of borax; it is best and easiest prepared from the extract of logwood met with in commerce.

On Dichloraldehyde.—M. E. Paterno.—This paper, being taken from an Italian periodical which does not come to England, is therefore abstracted. The author states that he treated dichloraldehyde with chloride of phosphorus, with the view thus to obtain the chloride $CHCl_2—CHCl_2$; but this was not the result of the reaction between the two substances just named: a product was obtained which boils at 250°, and which, on being submitted to elementary organic analysis, gave results leading to the formula $C_4H_4Cl_6O$. The constitution of this substance is apparently that of an ethyliden-oxychloride, the composition of which is to be indicated by either of the two following formulæ:—

$$CHCl_2—CH_2—O—CCl_2—CHCl_2,$$

or by—

$$CHCl_2—CHCl—O—CHCl—CHCl_2.$$

The substance, $C_4H_4Cl_6O$, is a somewhat coloured oil, heavier than water, soluble in alcohol and ether, boiling at 250°, and giving off very irritating acid fumes; on being mixed with an alcoholic solution of caustic potassa, a very violent reaction ensues, and, on addition of water, an aromatic-smelling oil is separated, which boils at 196°, and has the formula $C_4H_4Cl_4O$. This substance combines readily with bromine, forming a solid crystalline substance fusing at 60°, and having for its formula $C_4H_3Cl_4Br_4O$. Dichloraldehyde is not readily oxidised; when its vapour, mixed with air, is passed through a tube containing spongy platinum, no perceptible change ensues; mixed with its own bulk of red fuming nitric acid, a very energetic reaction sets in; when this has somewhat subsided, and the excess of nitric has been expelled by evaporation, and the residue is submitted to distillation and rectification, dichloracetic acid is obtained, which boils at about 195°, and yields, when distilled with a mixture of concentrated sulphuric acid and alcohol of 90 per cent, pure dichloracetic ether boiling at 155°.

Crystallised Digitaline.—M. Nativelle.—This alkaloid is obtained in crystalline state in the following manner:—100 parts, by weight, of coarsely-powdered *herba digitalis* is mixed with a solution of 25 parts of acetate of lead in 100 parts of water, left standing for twelve hours, and then exhausted with water; the residue is treated with alcohol of 50° until the solution thereof is free from any taste. The solution thus obtained is treated with a solution (aqueous) of four parts of acetate of lead, and filtered. To this filtrate is next added a solution of two parts of phosphate of soda, again filtered, and the alcohol removed by distillation on a water-bath. It will be observed that, in the residue of the distillation, there are suspended, in the aqueous fluid, small crystals, surrounded by a yellowish-coloured, very bitter-tasted substance. The residue of the distillation is concentrated, by evaporation on a water-bath to about ten parts, next filtered, washed with cold water, the precipitate dried by pressing it between folds of filtering paper, dissolved in about twice its weight of alcohol of 60 per cent, and put by in a cool place. While thus standing, two different sets of crystals are separated—first, those of an inactive substance; next, after some days, yellowish-coloured crystals of digitaline. After these have been fully formed, the mother liquor is run off, and the crystalline mass is taken up with alcohol of 80 per cent, while, at the same time, some animal charcoal is added. The solution, having been filtered and left to evaporate, is treated with pure chloroform, and strongly shaken up with it; the digitaline only is dissolved. On distilling off the chloroform, a somewhat coloured digitaline is obtained, which is further purified by repeated treatment with alcohol and animal charcoal. The crystalline digitaline is a neutral, non-nitrogenous, inodourous substance, of very bitter taste, readily soluble in chloroform, while one part of this digitaline requires twelve parts of alcohol of 90 per cent for its solution at the ordinary temperature; it is slightly more soluble in boiling alcohol, but far less soluble in absolute alcohol and in pure ether, and, practically, entirely insoluble in water at any temperature. Sulphuric acid dissolves this substance, yielding a greenish-coloured solution, which, on contact of vapours of bromine, becomes *groseille* red coloured; but addition of water restores the original green colour. Hydrochloric acid, also, dissolves digitaline, exhibiting, likewise, a green solution, from which water precipitates a resinous matter. The result of the elementary organic analysis of digitaline led to the formula $C_{28}H_{40}O_{14}$. The other crystalline substance above mentioned is insoluble in chloroform, soluble in alcohol;

crystallises in colourless needle-shaped crystals which are devoid of taste, neutral to test-papers, free from nitrogen, less soluble in alcohol than digitaline, and practically insoluble in water and ether. With sulphuric acid, this substance yields a *groseille* red coloured solution, which turns yellow on addition of water; nitric acid dissolves this substance to a colourless fluid, while hydrochloric acid is hardly capable of dissolving it at all. There is no elementary organic analysis as yet made of this substance, but it has been ascertained to be free from nitrogen.

Polytechnisches Journal von Dingler, first number for July, 1869.

This number contains the following original papers:—

On Stoves suitably constructed to Burn Coal as Fuel for Heating Rooms in Dwelling-Houses.—M. W. Hobbach.—The author describes, at length, an excellently arranged stove, by the use of which economy of fuel and proper supply of fresh air to the room are secured. A stove of medium size is so arranged that with from 15 to 20 lbs. of coal, a room of 12,000 cubic feet capacity is kept heated to 16° Réaumur (=20° C., and 68° F.) for from eight to twelve hours. The construction of this stove could not be well understood without the reproduction of the engravings accompanying the original.

Chemical Composition of Native Chrome Iron Ore.—M. Clouet.—After referring to the kinds of rock wherein this ore occurs, the author states that all varieties of chrome iron ore which have been hitherto analysed exhibit a constant and definite chemical composition. As instances, he quotes the following analysis:—$FeOCr_2O_3$, Russian ore, as, also, Smyrna and Norway (Drontheim); $2FeO,Cr_2O_3$, Ile à Vaches, St. Domingo; $2FeO,3Cr_2O_3$, Russia (another district); $4FeO,5Cr_2O_3$, the Banat (Alt-Orsowa); $8FeO,5Cr_2O_3$, India; $6FeO,5Cr_2O_3$, California; $3FeO,2Cr_2O_3$, Australia. A sample of pure crystalline octahedrical ore from the Ile à Vaches was found by the author to consist, in 100 parts, of—Oxide of chromium, 51·53; protoxide of iron, 48·46. Formula, $2FeO,Cr_2O_3$. The author enters, at great length, into particulars about the analysis of chrome iron ores; but, since any good treatise on analytical chemistry may be consulted on this subject, we do not notice this part of his paper here any further.

Manufacture of Hyposulphite of Soda from Soda Waste.—M. Schaftner.—This paper is entirely a lengthy description of a manufacturing process on the large scale. The main facts are—that, to the soda waste, sulphate of soda is added; and, after this mixture has been exposed for some time to the influence of the air, it is lixiviated with water. Sulphur is obtained as a by-product.

Contribution to our Knowledge of the Relation of Carbon to Oxygen.—Dr. Richters.—This paper is far too lengthy for any useful abstraction. The chief point thoroughly elucidated by the author is the oxidation of coal, charcoal, and coke at comparatively low temperatures.

On Balata.—M. Sperlich.—Balata is the inspissated milk-juice of the *Sapota muelleri*, a tree met with in large numbers in the three Guianas. Balata appears to hold a middle place between caoutchouc and gutta-percha. The author obtained the raw material, and, after having first treated it with boiling acidulated water, next with absolute alcohol, he dried the substance, and next dissolved it, with the aid of gentle heat, in sulphide of carbon. After removing that fluid by distillation, the balata was repeatedly boiled with a mixture of ether and alcohol, well dried and submitted to elementary analysis, yielding, in 100 parts, 88·49 of carbon and 11·37 of hydrogen, and, therefore, pretty nearly the composition of purified gutta-percha, which gives 87·91 of carbon, and 11·94 of hydrogen.

Use of Maize (Indian Corn) for Distillation of Spirits in Hungary.—Dr. Schultze.—This paper is chiefly written for distillers. The use of maize is a good idea. Curiously enough, experience appears to have taught that this grain requires, after having been ground to meal, to be steeped for about twenty-four hours in water containing sulphurous acid gas in solution. The next operation is the boiling of the meal, after which it is, when sufficiently cool, mixed with green barley malt. The quantity of spirits obtained from this material is large, and the quality good.

Alloys for Bells.—M. Lichtenberger.—It appears that for some time there have been met, in the trade in Germany, clock-bells of excellent and loud silvery tone; the author of this paper was induced, therefore, to analyse—(1) the metal the bell of a large-sized house-clock is made of, (2) a smaller bell, (3) bells for horse-harness, and (4) an ordinary small yellow-metal bell; the results are as follows:—

	No. 1.	No. 2.	No. 3.	No. 4.
Copper	83·22	83·09	84·50	79·90
Tin	16·76	16·80	15·42	20·03

The Nos. 1 to 3 are from the same manufactory.

New Method of Bleaching Feathers.—M. Duflot.—This process is an entirely newly-discovered one, whereby the feathers of ostriches and other birds may be bleached, even if these feathers are naturally black or dark grey-coloured. The feathers are placed for from three to four hours in a tepid dilute solution of bichromate of potassa, to which, cautiously, some nitric acid has been added. After this lapse of time, the feathers will be found to have assumed a greenish hue, owing to the oxide of chromium precipitated on the substance; in order to remove this, the feathers are placed in a dilute solution of sulphurous acid in water, whereby the feathers become perfectly white and bleached. Care is to be taken that the solution of bichromate be not made too strong, and, especially, that not too much nitric acid be used, which would cause an irremovable yellow colour.

Annales du Génie Civil, July, 1869.

This number does not contain any papers or communications relative to chemistry, but we learn from it the—

Abolition of Patents for Inventions in the Netherlands.—A law has been made cancelling the old patent law of 1817; and, though all existing patents remain in force, no new ones are to be any more granted from and after the 1st day of August, 1869.

Moniteur Scientifique, August 1, 1869.

This number contains the following original papers:—

On the Cooling Down of the Sun.—M. Lecoq.—This is a very lengthy, and rather speculative treatise on a subject partly belonging to astronomy and partly to physical geography. The author deserves great credit for the lucid manner of his exposition; but we cannot enter into details on this matter, however interesting it may be.

Quantity of Heat Developed in Interrupted Electric and Galvanic Currents.—MM. Jamin and Roger.—A purely mathematico-physical paper.

On Toluol and the Alkaloid it Yields.—M. Rosenstiehl.—The greater part of the contents of this paper have been previously published, and have been quoted by us from another periodical: but we translate the last few lines of this publication for the practical value therein contained:—"Toluol is a unique and peculiar hydrocarbon, which, on being treated with nitric acid, yields, simultaneously, two nitro-derivatives (the manufacturer who desires to obtain alkaloids, in order to prepare therewith colouring matters, should take care to produce as little crystallised nitrotoluol as possible). The isomerism manifested after the action of nitric acid is maintained in its coloured derivatives. Although the two toluidines differ, as regards their chemical properties, they yield colouring matters the physical properties of which are identical. The fact of the existence of isomerism of the artificial colouring substances explains the large number of varied blue and violet matters obtained from fuchsine; this may lead to the discovery of a large number of isomers of one and the same colour; and this subject I intend to take up, experimentally, within a short time.

Fusible Alloys.—M. Stewart mixes 7·5 parts of bismuth, 4 of lead, 1·5 of tin, and 2 of cadmium, and thus produces an alloy fusing at 66°. We quote hereunder the composition of divers fusible alloys, respectively, so made that the quantity of bismuth of each is the same:—

	Newton's Alloy.	D'Arcet's Alloy.	Pelouze's Alloy.	Wood's Alloy.
Bismuth	600	600	600	600
Lead	375	300	360	320
Tin	225	300	240	160
Cadmium	—	—	—	120
	1200	1200	1200	1200

All these alloys fuse below 100°.

Under the title of—

What is Going on in Germany, we find in this periodical an excellent account briefly summarising the history, progress, and present state of the Prussian universities. The most ancient of these is that of Griefswald, founded in the year 1456; the youngest is Bonn, founded in 1818. Leaving the Austrian dominions altogether out of the question, Germany, that is to say, the North German Confederation and the Southern Independent German States, contain together 19 universities, with 773 ordinary, and 340 extraordinary professors, and 342 repetitors, and, collectively, frequented by an average of 14,383 students. Some of these institutions have large revenues; foremost among these is Tübingen, Wurtemberg, with an annual revenue of 100,000 florins (about £10,000). All of these universities are under government control, and the expenses are met by regular grants made with great liberality. The population of this portion of Germany amounts to about 36,000,000, and the area, in German geographical square miles, amounts to about 10,000.

NOTES AND QUERIES.

Yeast.—The essential cause of the difference of beer-yeast and the so-called German yeast, is due—1st, to the materials submitted to fermentation; 2nd, to the mode of conducting that process. The so-called German yeast is chiefly made at Schiedam, and owes its origin and qualities to the large quantity of raw (that is to say, unmalted) grain, chiefly rye, used for making Hollands. More correctly speaking, the starch of the grain, after having been converted into sugar by the aid of a comparatively small quantity of barley-malt, is suffered to undergo alcoholic fermentation. This fermentation proceeds far more slowly than the fermentation of the wort of malt intended for beer; and it is the slowness of this process, the use of raw grain, and the peculiar mode of setting up the fermentation, which constitute the essential difference of the yeast. After it leaves the distilleries, the yeast is carefully washed with very cold and pure water, and often, though not always, mixed with some very finely-ground starch; and, next, strongly pressed into stout canvas bags, and sent off to Paris, Berlin, Vienna, and elsewhere. If beer-yeast were washed, it would, perhaps, keep a longer time, but never so long as the yeast just alluded to, owing to the fact that the formation of beer-yeast takes place more tumultuously. German yeast has been made perfectly dry over sulphuric acid *in vacuo*, and in that state it may be kept, in well-closed bottles or tin canisters, in a dry and cool place, for any length of time, and has been sent, in good condition, even to Batavia and Calcutta.

THE CHEMICAL NEWS.

Vol. XX. No. 509.

BRITISH ASSOCIATION
FOR THE
ADVANCEMENT OF SCIENCE.

Exeter Meeting, August 18, 1869.

INAUGURAL ADDRESS OF THE PRESIDENT,

George Gabriel Stokes, M.A., Sec. R.S.,
D.C.L., Oxon.; LL.D., Dublin;
Fellow of Pembroke College; and Lucasian Professor of Mathematics in the University of Cambridge.

(Concluded from p. 89).

Researches on Gun-Cotton.

As I have mentioned an application to the Government on the part of the Association which was not successful, it is but right to say that such is not generally the result: I will refer to one instance. At the Cambridge meeting of the Association, in 1862, a committee, consisting of representatives of the Mechanical and Chemical Sections, was appointed for the purpose of investigating the application of gun-cotton to warlike purposes. At the Newcastle meeting, in the following year, this committee presented their report. It was felt that a complete study of the subject demanded appliances which could be obtained only from our military resources; and at the Newcastle meeting a resolution was passed recommending the appointment of a royal commission. This recommendation was adopted, and, in 1864, a commission was appointed, which was requested to report on the application of gun-cotton to civil as well as to naval and military purposes. The committee gave in their report last year, and that report, together with a more recent return relative to the application of gun-cotton to mining and quarrying operations, has just been printed for the House of Commons.

A substance of such comparatively recent introduction cannot be fairly compared with an explosive in the use of which we have the experience of centuries. Yet, even with our present experience, there are some purposes for which gun-cotton can advantageously replace gunpowder, while its manufacture and storage can be effected with comparative safety, since it is in a wet state during the process of manufacture, and is not at all injured by being kept permanently in water, but merely requires to be dried for use. Even should it be required to store it in the dry state, it is doubtful whether, with the precautions indicated by the chemical investigations of Mr. Abel, any greater risk is incurred than in the case of gunpowder. In the blasting of hard rocks it is found to be highly efficient; while the remarkable results recently obtained by Mr. Abel leave no doubt of its value for explosions such as are frequently required in warfare. General Hay speaks highly of the promise of its value for small arms; but many more experiments are required, especially as a change in the arm and mode of ignition require a change in the construction of the cartridge. In heavy ordnance, the due control of the rapidity of combustion of the substance is a matter of greater difficulty; and, though considerable progress has been made, much remains to be done before the three conditions of safety to the gun, high velocity of projection, and uniformity of result, are satisfactorily combined.

Deep Sea Soundings.

By the kindness of Dr. Carpenter, I am enabled to mention to you the latest results obtained in an expedition which could not have been undertaken without the aid of Government—an aid which was freely given. Last year, Dr. Carpenter and Professor Wyville Thomson represented to the President and Council of the Royal Society the great importance to zoology and palæontology of obtaining soundings from great depths in the ocean, and suggested to them to use their influence with the Admiralty to induce them to place a gun-boat, or other suitable vessel, at the disposal of those gentlemen, and any other naturalists who might be willing to accompany them, for the purpose of carrying on a systematic course of deep-sea dredging for a month or six weeks. This application was forwarded to the Admiralty with the warm support of the President and Council, and was readily acceded to. The operations were a good deal impeded by rough weather, but, nevertheless, important results were obtained. Dredging was successfully accomplished at a depth of 650 fathoms; and the existence was established of a varied and abundant submarine fauna, at depths which had generally been supposed to be either azoic or occupied by animals of a very low type; and the character of the fauna and of the mud brought up was such as to point to a chalk formation actually going on.

It seemed desirable to carry the soundings to still greater depths, and to examine more fully the changes of temperature which had been met with in the descent. Another application was accordingly made to the Admiralty, in the present year, and was no less readily acceded to than the former; and a larger vessel than that used last year is now on her cruise. I am informed by Dr. Carpenter that dredging has been successfully carried down to more than 2400 fathoms (nearly the height of Mont Blanc), and that animal life has been found, even at that depth, in considerable *variety*, though its *amount* and *kind* are obviously influenced by the reduction of temperature to Arctic coldness. A very careful series of temperature soundings has been taken, showing, on the same spot, a continuous descent of temperature with the depth, at first more rapid, afterward pretty uniform. Thermometers protected from pressure by a plan described by Dr. Miller were found to maintain their character at the great depths reached, the difference between them and the best ordinary thermometers used in the same sounding being exactly conformable to the pressure corresponding with each depth, as determined by the experiments previously made in smaller depths. All the observations hitherto made go to confirm the idea of a general interchange of polar and equatorial water, the former occupying the lowest depths, the latter forming a superficial stratum of 700 or 800 fathoms. The analyses of the water brought up indicate a large proportion of carbonic acid in the gases of the deep waters, and a general diffusion of organic matter.

The Faraday Memorial.

I must turn, for a few moments, to another application recently made to Government, which has not been successful. The application I have in view was made, not by the British Association or other scientific societies in their corporate capacity, but by a body composed of the Presidents of the British Association, and of the Royal and other leading scientific societies; and its object was, not the promotion of science directly, but the recognition of pre-eminent scientific merit. In the history of science, few names, indeed, hold so prominent a place as that of Faraday. The perfect novelty of principle, and recondite nature of many of his great discoveries, are such as to bear the impress of genius of the highest order, and to form an epoch in the advance of science; and, while his scientific labours excited the admiration of men of science throughout the world, his singularly genial disposition, and modest, unassuming character, won for him the love of those who had the happiness of numbering him among their personal friends. At a meeting of the presidents of

the scientific societies to which I have alluded, it was resolved to erect a marble statue in memory of Faraday. He was a man of whom England may well be proud, and it was thought that it would be a graceful recognition of his merits if the monument were erected at the public expense. The present Chancellor of the Exchequer, however, did not think it right that the recognition of scientific merit, however eminent, should fall on the taxation of the country, though, even in a pecuniary point of view, the country has received so much benefit from the labours of scientific men. The carrying out of the resolution being thus left to private exertion, a public meeting, presided over by H.R.H. the Prince of Wales, was held in the Royal Institution, an establishment which has the honour of being identified with Faraday's scientific career. At this meeting a committee was formed to carry out the object, and a subscription list commenced. By permission of the secretaries of this association, an office has been opened in the Reception Room, where those members of the association who may be desirous of taking part in the movement will have every facility afforded them.

Recent Discoveries in Chemistry.

In chemistry, I do not believe that any great step has been made within the last year; but perhaps there is no science in which an earnest worker is so sure of being rewarded by making some substantial acquisition to our knowledge, though it may not be of the nature of one of those grand discoveries which from time to time stamp their impress on different branches of science. I may be permitted to refer to one or two discoveries which are exceedingly curious, and some of which may prove of considerable practical importance.

Turacine.

The turaco or plantain-eater of the Cape of Good Hope is celebrated for its beautiful plumage. A portion of the wings is of a fine red colour. This red colouring-matter has been investigated by Professor Church, who finds it to contain nearly six per cent of copper, which cannot be distinguished by the ordinary tests, nor removed from the colouring-matter without destroying it. The colouring-matter is, in fact, a natural organic compound, of which copper is one of the essential constituents. Traces of this metal had previously been found in animals—for example, in oysters, to the cost of those who partook of them. But, in these cases, the presence of the copper was merely accidental; thus oysters that lived near the mouths of streams which came down from copper mines assimilated a portion of the copper salt, without apparently its doing them either good or harm. But, in the turaco, the existence of the red colouring-matter which belongs to their normal plumage is dependent upon copper, which, obtained in minute quantities with the food, is stored up in this strange manner in the system of the animal. Thus, in the very same feather, partly red and partly black, copper was found in abundance in the red parts, but none, or only the merest trace, in the black.

This example warns us against taking too utilitarian a view of the plan of creation. Here we have a chemical substance elaborated which is perfectly unique in its nature, and contains a metal the salts of which are ordinarily regarded as poisonous to animals; and the sole purpose to which, so far as we know, it is subservient in the animal economy is one of pure decoration. Thus, a pair of fine birds which were kept in captivity lost their fine red colour in the course of a few days, in consequence of washing in the water which was left them to drink, the red colouring-matter, which is soluble in water, being thus washed out; but, except as to the loss of their beauty, it does not appear that the birds were the worse for it.

Artificial Alizarine.

A large part of the calicos which are produced in this country in such enormous quantities are sent out into the market in the printed form. Although other substances are employed, the place which madder occupies among dye-stuffs with the calico-printer is compared by Mr. Schunck to that which iron occupies among metals with the engineer. It appears, from the public returns, that upwards of 10,000 tons of madder are imported annually into the United Kingdom. The colours which madder yields to mordanted cloth are due to two substances, alizarine and purpurine, derived from the root. Of these, alizarine is deemed the most important, as producing faster colours and yielding finer violets. In studying the transformations of alizarine under the action of chemical reagents, MM. Græbe and Liebermann were led to connect it with anthracene, one of the coal-tar series of bodies, and to devise a mode of forming it artificially. The discovery is still too recent to allow us to judge of the cost with which it can be obtained by artificial formation, which must decide the question of its commercial employment. But, assuming it to be thus obtained at a sufficiently cheap rate, what a remarkable example does the discovery afford of the way in which the philosopher, quietly working in his laboratory, may obtain results which revolutionise the industry of nations! To the calico-printer, indeed, it may make no very important difference, whether he continues to use madder, or replaces it by the artificial substance; but what a sweeping change is made in the madder-growing interest! What hundreds of acres, hitherto employed in madder cultivation, are set free for the production of human food, or of some other substance useful to man! Such changes can hardly be made without temporary inconvenience to those who are interested in the branches of industry affected; but we must not, on that account, attempt to stay the progress of discovery, which is conducive to the general weal.

Apomorphia.

Another example of the way in which practical applications unexpectedly turn up when science is pursued for its own sake, is afforded by a result recently obtained by Dr. Matthiessen, in his investigation of the constitution of the opium bases. He found that, by the action of hydrochloric acid on morphia, a new base was produced, which, as to composition, differed from the former merely by the removal of one equivalent of water. But the physiological action of the new base was utterly different from that of the original one. While morphia is a powerful narcotic, the use of which is apt to be followed by subsequent depression, the new base was found to be free from narcotic properties, but to be a powerful emetic, the action of which was unattended by injurious after-effects. It seems likely to become a valuable remedial agent.

In relation to mechanism, this year is remarkable as being the centenary of the great invention of our countryman, James Watt. It was in the year 1769 that he took out his patent involving the invention of separate condensation, which is justly regarded as forming the birth of the steam-engine. Little could even his inventive mind have foreseen the magnitude of the gift he was conferring on mankind in general, and on his own country more particularly. In these days of steamers, power-looms, and railways, it requires no small effort to place ourselves, in imagination, in the condition we should be in without the steam-engine. It needs no formal celebration to remind Britons of what they owe to Watt. Of him, truly it may be said "*si monumentum requiras, circumspice.*"

The Relations between Physical and Biological Sciences.

With reference to those branches of science in which we are more or less concerned with the phenomena of life, my own studies give me no right to address you. I regret this the less because my predecessor, and my probable successor in the presidential chair are both of well-known eminence in this department. But I hope I may be permitted, as a physicist, and viewing the question from the physical side, to express to you my views as to the relation which the physical bear to the biological sciences.

No other physical science has been brought to such

perfection as mechanics; and in mechanics we have long been familiar with the idea of the perfect generality of its laws, of their applicability to bodies organic as well as inorganic, living as well as dead. Thus, in a railway collision, when a train is suddenly arrested, the passengers are thrown forward, by virtue of the inertia of their bodies, precisely according to the laws which regulate the motion of dead matter. So trite has the idea become, that the reference to it may seem childish; but, from mechanics, let us pass on to chemistry, and the case will be found by no means so clear. When chemists ceased to be content with the mere ultimate analysis of organic substances, and set themselves to study their proximate constituents, a great number of definite chemical compounds were obtained which could not be formed artificially. I do not know what may have been the usual opinion at that time among chemists as to their mode of formation. Probably it may have been imagined that chemical affinities were indeed concerned in their formation, but controlled and modified by an assumed vital force. But, as the science progressed, many of these organic substances were formed artificially, in some cases from other and perfectly distinct organic substances, in other cases actually from their elements. This statement must, indeed, be accepted with one qualification. It was stated several years ago, by M. Pasteur, and I believe the statement still remains true, that no substance, the solution of which possesses the property of rotating the plane of polarisation of polarised light, had been formed artificially from substances not possessing that property. Now several of the natural substances which are deemed to have been produced artificially are active, in the sense of rotating the plane of polarisation; and, therefore, in these cases, the inactive artificial substances cannot be absolutely identical with the natural ones. But the inactivity of the artificial substance is readily explained on the supposition that the artificial substance bears to the natural the same relation as racemic acid bears to tartaric—that it is, so to speak, a mixture of the natural substance with its image in a mirror. And when we remember by what a peculiar and troublesome process M. Pasteur succeeded in separating racemic acid into the right-handed and left-handed tartaric acids, it will be at once understood how easily the fact, if it be a fact, of the existence in, the natural substance, of a mixture of two substances, one right-handed and the other left-handed, but otherwise identical, may have escaped detection. This is a curious point, to the clearing up of which it is desirable that chemists should direct their attention. Waiving, then, the difference of activity or inactivity, which, as we have seen, admits of a simple physical explanation, though the correctness of that explanation remains to be investigated, we may say that, at the present time, a considerable number of what used to be regarded as essentially natural organic substances have been formed in the laboratory. That being the case, it seems most reasonable to suppose that, in the plant or animal from which those organic substances were obtained, they were formed by the play of ordinary chemical affinity, not necessarily nor probably by the same series of reactions by which they were formed in the laboratory, where a high temperature is commonly employed, but still by chemical reactions of some kind, under the agency, in many cases of light, an agency sometimes employed by the chemist in his laboratory. And, since the boundary line between the natural substances which have and those which have not been formed artificially, is one which, so far as we know, simply depends upon the amount of our knowledge, and is continually changing as new processes are discovered, we are led to extend the same reasoning to the various chemical substances of which organic structures are made up.

But do the laws of chemical affinity, to which, as I have endeavoured to infer, living beings, whether vegetable or animal, are in absolute subjection, together with those of capillary attraction, of diffusion, and so forth, account for the formation of an organic structure, as distinguished from the elaboration of the chemical substances of which it is composed? No more, it seems to me, than the laws of motion account for the union of oxygen and hydrogen to form water, though the ponderable matter so uniting is subject to the laws of motion during the act of union just as well as before and after. In the various processes of crystallisation, of precipitation, and so forth, which we witness in dead matter, I cannot see the faintest shadow of an approach to the formation of an organic structure, still less to the wonderful series of changes which are concerned in the growth and perpetuation of even the lowliest plant. Admitting, to the full, as highly probable, though not completely demonstrated, the applicability to living beings of the laws which have been ascertained with reference to dead matter, I feel constrained, at the same time, to admit the existence of a mysterious *something* lying beyond—a something, *sui generis*, which I regard, not as balancing and suspending the ordinary physical laws, but as working with them and through them to the attainment of a designed end.

What this *something*, which we call life, may be, is a profound mystery. We know not how many links in the chain of secondary causation may yet remain behind; we know not how few. It would be presumptuous, indeed, to assume, in any case, that we had already reached the last link, and to charge with irreverence a fellow worker who attempted to push his investigations yet one step further back. On the other hand, if a thick darkness enshrouds all beyond, we have no right to assume it to be impossible that we should have reached even the last link of the chain; a stage where further progress is unattainable, and we can only refer the highest law at which we stopped to the fiat of an Almighty Power. To assume the contrary as a matter of necessity, is, practically, to remove the First Cause of all to an infinite distance from us. The boundary, however, between what is clearly known and what is veiled in impenetrable darkness, is not ordinarily thus sharply defined. Between the two there lies a misty region, in which loom the ill-discerned forms of links of the chain which are yet beyond us. But the general principle is not effected thereby. Let us fearlessly trace the dependence of link on link as far as it may be given us to trace it; but let us take heed that, in thus studying second causes, we forget not the First Cause, nor shut our eyes to the wonderful proofs of design which, in the study of organised beings especially, meet us at every turn.

Truth we know must be self-consistent, nor can one truth contradict another, even though the two may have been arrived at by totally different processes—in the one case, suppose, obtained by sound scientific investigation, in the other case taken on trust from duly authenticated witnesses. Misinterpretations, of course, there may be on the one side or on the other, causing apparent contradictions. Every mathematician knows that in his private work he will occasionally, by two different trains of reasoning, arrive at discordant conclusions. He is at once aware that there must be a slip somewhere, and sets himself to detect and correct it. When conclusions rest on probable evidence, the reconciling of apparent contradictions is not so simple and certain. It requires the exercise of a calm, unbiassed judgment, capable of looking at both sides of the question; and oftentimes we have long to suspend our decision, and seek for further evidence. None need fear the effect of scientific enquiry carried on in an honest, truth-loving, humble spirit, which makes us no less ready frankly to avow our ignorance of what we cannot explain, than to accept conclusions based on sound evidence. The slow but sure path of induction is open to us. Let us frame hypotheses if we will: most useful are they when kept in their proper place, as stimulating inquiry. Let us seek to confront them with observation and experiment, thereby confirming or upsetting them, as the result may prove; but let us beware of placing them prematurely in the rank of ascertained truths, and building further conclusions on them, as if they were.

When, from the phenomena of life, we pass on to those of mind, we enter a region still more profoundly mysterious. We can readily imagine that we *may* here be dealing with phenomena altogether transcending those of mere life, in some such way as those of life transcend, as I have endeavoured to infer, those of chemistry and molecular attractions, or as the laws of chemical affinity, in their turn, transcend those of mere mechanics. Science can be expected to do but little to aid us here, since the instrument of research is itself the object of investigation. It can but enlighten us as to the depth of our ignorance, and lead us to look to a higher aid for that which most neatly concerns our well-being.

PRELIMINARY REPORT OF THE COMMITTEE APPOINTED FOR THE

DETERMINATION OF THE GASES EXISTING IN SOLUTION IN WELL WATERS.*

By DR. E. FRANKLAND, F.R.S., and HERBERT McLEOD, F.C.S.

In consequence of the investigation being far from complete, this report must be considered as merely a preliminary one; a more detailed account of the results obtained and the inferences to be drawn from them must be postponed till a future occasion.

The apparatus employed in these and other experiments was described at the last meeting of the Chemical Society, and will shortly be published in the *Journal*.†

In collecting the waters, it is, of course, of the greatest importance that they should be prevented from coming in contact with the air, otherwise, serious errors might be produced in the determination of the gases dissolved. In order to avoid these errors, the tap delivering the water from the pumps is connected, by means of a caoutchouc tube, with a tubulure at the bottom of a tin cylinder, about 10 inches high, and 7 in diameter. The water is turned on, and allowed to flow over the edge of the vessel; thus only the surface of the water is exposed to the action of the air, and the liquid at the lower part of the vessel is protected by the upward current and continual overflow.

The bottles used for collecting the waters hold a little more than 100 c.c., and a separate quantity is used for each experiment. Into each bottle a piece of glass tube bent in the form of a U is introduced; one end of the tube is sealed, and, in the closed limb, a bubble of air is confined by mercury, which fills the open limb and the bend. In the collection of each water, four of these bottles are lowered, by means of pieces of string, into the tin vessel while the water is flowing over its edge. After being filled, each bottle is carefully examined, and, if any bubbles of gas adhere to the sides, they must be removed. The bottles are then again lowered into the vessel, and the temperature observed. A syphon is now passed to the bottom of one of the bottles, and, after it has drawn two or three hundred cubic centimetres of water through the bottle, it is placed into the second. The first bottle is now raised, and, while its neck is still under the water, a slightly-greased stopper is put into the neck, and carefully pressed down. This force compresses the air contained in the glass tube, and, if the pressure is sufficient, it prevents the escape of gas from the water—a precaution which, in some cases, is very necessary. The syphon is then transferred from the second into the third bottle, and the second is closed and removed. When the four bottles have been filled, the stoppers are covered with ground caps. The caps are next filled with mercury, through small holes at their tops, which are afterwards closed with glass stoppers.

The gases should be removed from the waters as soon after collection as possible. In the following cases, the greatest length of time which was allowed to elapse between these operations was five days; but usually the removal of the gases was effected the day after the collection.

	I. Rain-water.	II. Water from cistern of Royal College of Chemistry, supplied by Grand Junction Company.	III. Water from well, in chalk, 367 ft. deep, at Messrs. Barclay and Perkins's Brewery, Southwark.	IV. Water from well not down to chalk, in course of construction, 143½ ft. deep, at Messrs. Barclay and Perkins's Brewery, Southwark.	V. Water from chalk well at Worthing.	VI. Water from surface well to face of the chalk, 27—30 ft. deep, at Mr. Hill's Brewery, Deal. In the town. Influenced by the tide.	VII. Water from chalk well 115 ft. deep, Waterworks, Deal, surrounded by cultivated fields. Not influenced by tide.	VIII. Water from Waterworks, Deal, drawn from main about a mile from the reservoir.
Temperature at time of collection (° C.) ..	15·5	14·8	12·1	12	(?)	11·9	14·8	17·2
Mean of..	2 expts.	2 expts.	2 expts.	4 expts.	2 expts.	2 expts.	2 expts.	2 expts.
Volumes of gases in 100 volumes of water. Nitrogen ..	1·382	1·397	2·030	1·973	1·552	1·704	1·548	2·241
Oxygen ..	0·673	0·620	0·029	0·018	0·446	0·023	0·580	0·796
Carbonic anhydride	0·135	4·239	5·765	3·814	5·452	10·252	5·055	4·413
Total ..	2·190	6·256	7·824	5·805	7·450	11·979	7·183	7·450
Solubility of nitrogen in 100 volumes of distilled water (Bunsen) ..	1·468 at 15·5°	1·478 at 15°	1·549 at 12°	1·549 at 12°	—	1·549 at 12°	1·478 at 15°	1·441 at 17°

The experimental results, of which the above numbers are the means, were tolerably concordant. The greatest differences between the results of different experiments are the following:—In water No. IV., experiment 3 gave 0·140 parts more nitrogen than experiment 2; in water No. VII., the oxygen obtained in the second experiment was 0·045 in excess of the quantity obtained in the first; in water No. III., the second experiment gave 0·760 parts more carbonic anhydride than the other. Since this last was done, the mode of collection and removal of the gases have been improved.

With so few results as have been obtained up to the present, it will be impossible to do more than point out the small quantity of oxygen in the waters from deep wells as compared with those from shallow ones, and with rain and river waters. The quantity of nitrogen is also very remarkable as being, in all the cases, except the river and rain waters, in excess of the amount absorbable by distilled water. To show this, there is introduced into the foregoing table numbers from Bunsen's gasometry, indicating the quantities of nitrogen absorbable by 100 volumes of

* Read before the British Association, Exeter meeting, Section B.

† See CHEMICAL NEWS, vol. xx., p. 20.

distilled water at the temperatures which are nearest to those at which the waters were collected. The reasons of this apparent anomaly will be investigated during the course of the ensuing year, and it is hoped that, by the next meeting of the Association, a much larger amount of information will have been obtained. The prosecution of the experiments has been much hindered by the necessity of perfecting the apparatus for the removal of the gases and the means of collection, so that it was not until after the commencement of July that any systematic work could be commenced.

REPORT ON THE CHEMICAL NATURE OF CAST-IRON.*

By Messrs. F. A. ABEL, F.R.S., D. FORBES, F.R.S., and A. MATTHIESSEN, F.R.S.

THE Committee have to report that, during the past year, some material progress has been made in this research. They entrusted the preparation of pure iron to Dr. Matthiessen, who carried out this part of the investigation in conjunction with M. Prus-Szczepanowski. From a series of experiments, which are detailed in the Appendix, pure iron appeared to be obtainable in considerable quantities; and we hope, if the Committee be re-appointed, that next year a great deal of valuable information will be obtained on the chemical nature and physical properties of pure iron and its alloys. The iron obtained by the process described in the Appendix is almost absolutely pure, containing only a minute trace of sulphur. According to an analysis made by Professor Abel, the iron contained, in 100 parts, only 0·00025 parts of sulphur. In another analysis, the amount of sulphur found by M. Prus-Szczepanowski amounted to 0·0007 per cent. Phosphorus and silicon were carefully tested for by both analysts, and found to be entirely absent. The amount of substance taken for each analysis was about 30 grammes.

APPENDIX.

ON THE PREPARATION OF PURE IRON.

By A. MATTHIESSEN, F.R.S., and S. PRUS-SZCZEPANOWSKI.

AFTER numerous trials, the general outline of which was given in the report of last year, the following method was found to yield nearly absolutely pure iron, in quantities sufficient for the purpose of this research. Pure dried ferrous sulphate, and pure dried sodium sulphate, are mixed in nearly equal proportions, and introduced gradually into a red-hot platinum crucible. The mass is kept in fusion until the evolution of sulphurous acid gas ceases. The crucible is then allowed to cool, and the fused mass extracted with water. If the heat be properly regulated, the whole of the iron is left as a very fine crystalline oxide. This oxide is thoroughly washed, by decantation, to remove every trace of the sodium sulphate, and, after being dried, is reduced, by hydrogen, in a platinum crucible; the spongy iron thus obtained is then pressed into solid buttons, and melted in lime crucibles with the oxyhydrogen blowpipe.

Before proceeding further, it will be as well to mention the precautions observed in obtaining the raw material in the purest state. The commercial pure ferrous sulphate was freed from every trace of copper by leading sulphuretted hydrogen through the warm acetic acid solution. After filtration, the ferrous sulphate was twice re-crystallised, and dried, first in a water-bath, then in an air-bath. The commercial crystallised sodium sulphate was re-crystallised several times, to get rid of the last trace of chloride of sodium, and then heated on a water-bath to melt the crystals. As is well-known, anhydrous sodium sulphate separates out from this solution, which was scooped out from time to time, dried on an air-bath, and powdered. The purification of the sodium sulphate from chloride of sodium was found to be necessary, owing to the fact that when fusions were made with sodium sulphate containing that salt, the resulting oxide of iron always contained platinum. The hydrogen used for the reduction of the iron, as well as for the blowpipe, was prepared by the action of sulphuric acid on zinc, and purified by leading the gas through two wash bottles—the first containing nitrate of silver and strong nitric acid, and the second caustic soda and acetate of lead—both bottles being half filled with pieces of pumice-stone. The oxygen was prepared by heating a mixture of chlorate of potassium with 15 to 20 per cent of black oxide of manganese, and washed by leading through caustic soda. All connections were made of glass, lead, or pure india-rubber tubing.

The fusion took place in a large platinum crucible (the contents of which are rather more than ½ a litre), enclosed in the usual manner in a clay crucible. The dimensions were such, therefore, that about a kilo. and a half of the mixture could be fused at each operation. After fusion, the crucible is allowed to cool; it is then boiled out with distilled water, and the accumulated product of 6 to 8 fusions washed by decantation with boiling distilled water. The crystalline oxide settles very quickly, and thus allows of a very rapid and thorough washing. The washing was in every case continued several times after the wash waters ceased to give any turbidity with barium nitrate. It is worthy of mention that the above process to prepare pure oxide from the mixture of mixed sulphates yields the purest oxide we as yet obtained. The reduction of the oxide thus formed was made in a covered platinum crucible, heated by means of a large Bunsen burner. The hydrogen was introduced by means of a platinum tube, reaching through the cover to the bottom of the crucible. The gas, purified as described above, and dried by chloride of calcium, was always kept slightly in excess, a constant stream of gas being obtained by not using the generator, but two large gas-holders joined together, the contents of each being about 600 litres (20 cubic feet); two other gas-holders of similar capacity being used for the storage of the oxygen, the one being used to collect the gas from the retort, the other to contain the gas purified by passing it through a strong solution of caustic soda.

The resulting spongy iron was pressed into solid buttons, by means of a strong coining press and a diamond mortar, the cylinder of which being about 70 m.m. in height, the iron, when pressed, forms a cylinder of about 15 m.m. in height, and weighs about 20 grammes. The melting of the compressed iron took place in lime crucibles, the lime having been previously burnt, slacked, and re-burnt, thus forming a fine, impalpable powder, which was compressed in the crucible mould.

The best method of fusion was found to be as follows:—The lime crucible was placed in a slanting position on a piece of lime. One of the oxyhydrogen blowpipes used in the process played on the outside of the crucible whilst the flame of the other was directed inside. When white-hot, a cylinder of the compressed iron was thrown into it. It quickly melts, but at the expense of a large quantity of the iron which is oxidised. The amount lost by the oxidation varies between 25 to 50 per cent. In order to obtain a good solid button of melted iron, it is necessary to cool it in an atmosphere of hydrogen, which is easily obtained simply by turning off the oxygen from the blowpipe playing inside the crucible. The button thus obtained weighs about 15 grammes. On analysis, it was found that the buttons were free from sulphur, phosphorus, silicon, and calcium.

The preparation on a large scale of the pure ferrous sulphate and sodium sulphate was kindly undertaken for

* Read before the British Association, Exeter Meeting, Section B.

only 81·98 p.c. of metallic zinc. A specimen of what is sold as pure powdered zinc gave hydrogen corresponding to only 69·22 per cent of zinc.

With nickel and cobalt, the same process is applicable, and has been used for determining their atomic weights. The results have been communicated to the Chemical Society, and will be published in the *Journal* of the Society.*

The following results have been obtained with different specimens of iron:—

Dr. Matthiessen gave me what he believed to be a specimen of pure iron; it gave—

1st expt., 3·571 p.c. H, corresponds to 100·00 p.c. iron.
2nd „ 3·568 „ „ 99·93 „

Steel piano-wire (No. 10) gave—

1st expt., 3·444 p.c. H, corresponds to 96·45 p.c. iron.
2nd „ 3·445 „ „ 96·49 „

Some of the same wire was dissolved, and the amount of iron estimated by Penny's process.

1st. expt. gave 97·8 p.c. iron.
2nd „ 98·2 „

Mean.

Hydrogen process, 96·47. Penny's process, 98·00

This gives a suppression of hydrogen corresponding to 1·53 per cent of iron.

Cast-iron filings gave—

1st expt., 3·375 p.c. H, corresponds to 94·50 p.c. iron.
2nd „ 3·366 „ „ 94·27 „

When tested by Penny's process, the filings were found to contain 97·0 per cent of iron; this gives a suppression of hydrogen corresponding to 2·62 per cent of iron.

A specimen of grey crystalline pig-iron gave, when dissolved, a volume of hydrogen corresponding to only 89·04 per cent of iron.

A piece of magnesium ribbon evolved an amount of hydrogen corresponding to 99·18 per cent of metal.

The foregoing results will serve simply to indicate the kind of results which have been obtained by this form of volumetric analysis.

ON JARGONIA.†

By H. C. SORBY, F.R.S.

I HEREWITH send, for exhibition at the Chemical Section, what I believe to be nearly pure zirconia, and jargonia prepared by a modified combination of the methods described by Mr. David Forbes and myself. You will notice, at once, that the zirconia is perfectly white, whereas the jargonia is of a clear straw-colour. This exactly corresponds with the difference between the opaque borax blowpipe-beads heated to redness, as described in my paper in the *Proceedings of the Royal Society*, and I am strongly inclined to believe that it is a characteristic peculiarity. At first, I thought it might be due to the presence of a small quantity of iron, since zirconia, containing a little of the peroxide, is of a similar yellow colour. When, however, that is digested in sulphide of ammonium, it quickly turns to a deep green colour; whereas this yellow jargonia does not turn at all green. Subsequent experiments may show that the colour is due to some other substance; but, taking all the facts now known into consideration, it seems extremely probable that, after ignition, jargonia is of a clear straw-colour, paler than that of tungstic acid, but deeper than that of ceroso-ceric oxide.

* See CHEMICAL NEWS, vol. xx., p. 20.

† Extract from a letter to Mr. Crookes, read before the Chemical Section of the British Association, Exeter meeting.

MISCELLANEOUS.

British Association for the Advancement of Science.—The following is a complete list of the papers which were brought before Section B (Chemical Science) at the Exeter Meeting:—

Herbert McLeod.—*Report on the Determination of the Gases Existing in Solution in Well Waters.*
A. Matthiessen.—*Report of the Committee on the Chemical Nature of Cast-Iron.*
M. Jacobi.—*On Electrolytic Iron.*
J. Moffat.—*On the Phosphorescence of the Sea and Ozone in Connection with Atmospheric Conditions.*
J. Moffat.—*On the Oxidation of Phosphorus and the quantity of Phosphoric Acid Excreted by the Kidneys in Connection with Atmospheric Conditions.*
C. Tomlinson.—*On a Remarkable Structural Appearance in Phosphorus.*
B. H. Paul.—*Report on Treatment and Utilisation of Sewage.*
F. Braby.—*On Extraction of Ammonia from Gas Liquor.*
Stevenson Macadam.—*On the Economic Distillation of Gas from Cannel Coal.*
Walter Weldon.—*On the Manufacture of Chlorine by means of Perpetually Regenerated Manganite of Calcium.*
T. L. Phipson.—*On some New Substances Extracted from the Walnut.*
T. L. Phipson.—*On the Solubility of Lead and Copper in Pure and Impure Water.*
W. J. Russell.—*On the Measurement of Gases as a Branch of Volumetric Analysis.*
C. Tomlinson.—*On the supposed Action of Light on Combustion.*
Crace Calvert.—*On the Amount of Soluble and Insoluble Phosphates in Wheat Seed.*
H. Sorby.—*On Jargonia.*
S. Williams.—*On the Action of Phosphoric-chloride on Hydric-Sulphate.*
J. Dewar and G. Cranston.—*On Some Reactions of Chloro-Sulphuric Acid.*
A. Matthiessen and C. R. A. Wright.—*On the Action of Hydrochloric Acid on Morphia and Codeia.*
T. Andrews.—*On the Absorption Bands of Bile.*
M. Janssen.—*Methode Spectrale pour la recherche des Composés du Sodium.*
M. Janssen.—*Sur le Spectre de la Vapeur d'Eau.*
W. C. Roberts.—*On a specimen of Obsidian from Java.*
W. D. Michell.—*Are Flint Instruments of the First Stone Age Found in the Drift?*
E. C. C. Stanford.—*A Chemical Method of Treating the Excreta of Towns.*
H. Bamber.—*On the Water Supplies to Plymouth, Devonport, and Exeter.*
P. Spence.—*On the Production of Higher Temperatures by Steam of 212° Fahrenheit.*
A. Oppenheim.—*On Bromo-iodide of Mercury.*
A. Oppenheim.—*On Benzoe-sulphuric Acid.*
Professor Jellett.—*On a Method of Determining with Accuracy the Ratio of the Rotating Powers of Cane Sugar and Inverted Sugar.*
Dr. Fritsche.—*Notes on Structural Change in Block Tin.*—Communicated by W. C. Roberts.
H. Cooke.—*On the Registration of Atmospheric Ozone in the Bombay Presidency, and the Chief Causes which Influence its Appreciable Amount in the Atmosphere.*
J. Lowthian Bell.—*On the Decomposition of Carbonic Oxide by Spongy Iron.*

Report of the Committee for Recommending Increased Facilities for Scientific Investigations.—The following is the report of the "Committee for Recommending Increased Facilities for Scientific Investigations:"—Your committee, having sought the council of many of the most eminent men of science of the United King-

dom upon these questions, so far as it was found practicable to do so, and having carefully deliberated thereon, have arrived at the following conclusions:—I. That the provision now existing in the United Kingdom of Great Britain and Ireland is far from sufficient for the vigorous prosecution of physical research. II. It is universally admitted that scientific investigation is productive of enormous advantages to the community at large; but these advantages cannot be duly reaped without largely extending and systematising physical research. Though of opinion that greatly increased facilities are undoubtedly required, your committee do not consider it expedient that they should attempt to define categorically how these facilities should be provided for the following reason:—Any scheme of scientific extension should be based on a full and accurate knowledge of the amount of aid now given to science, of the sources from which that aid is derived, and of the functions performed by individuals and institutions receiving such aid. Your committee have found it impossible, with the means and powers at their command, to acquire this knowledge. A formal inquiry, including the inspection of records to which your committee have not access, and the examination of witnesses whom they are not empowered to summon, alone can elicit the information that is required, and, as the whole question of the relation of the state to science, at present in a very unsettled and unsatisfactory position, is involved, they urge that a royal commission alone is competent to deal with the subject. Your committee hold that this inquiry is of a character sufficiently important to the nation, and sufficiently wide in its scope, to demand the use of the most ample and most powerful machinery that can be brought to bear upon it. Your committee therefore submit, as the substance of their report, the recommendation that the full influence of the British Association for the Advancement of Science should at once be exerted to obtain the appointment of a royal commission, to consider—(1). The character and value of existing institutions and facilities for scientific investigation, and the amount of time and money devoted to such purposes. (2). What modifications or augmentations of the means and facilities that are at present available for the maintenance and extension of science are requisite; and (3). In what manner these can be best supplied.

Place of Meeting for Next Year.—At the meeting of the General Committee, on Monday last, it was decided that the meeting next year should be held in Liverpool, under the presidency of Professor Huxley, F.R.S., &c.

Death of M. Leiber.—We regret to learn the sudden demise of M. Leiber, the founder of the *Moniteur de la Photographie*, and the *Encyclopédie Photographique*, one of the kindest and most intelligent of the scientific publishers of Paris. His establishment, the Librairie Centrale des Sciences, in the Rue de Seine, has, for the last fifteen or twenty years, been the daily resort of the most eminent men of science; and his extensive knowledge of the older chemical and physical opuscules (memoirs, papers, notes, reprints, &c.) published in France, Germany, England, and America, caused him to be frequently consulted by literary men and authors of scientific works. His loss will be keenly felt by a very large portion of the enlightened Parisian public. Among the foreign works issued by him in French, we may notice the excellent little treatise on "Electricity," by Sir William Snow Harris, and De Filippi's charming "Letters to my Daughter on Terrestrial Creation."

Molybdenum and Chromium.—These metals can, according to Loughlin, be easily prepared as follows:—A mixture of one part of pure molybdic acid and one and a half of cyanide of potassium is placed in a porcelain crucible, and the lid luted on; this is placed in a large crucible, and the interstices having been packed with animal charcoal, the entire arrangement is exposed to a strong white heat for twelve hours; when cold the inner crucible is found lined with a white silver-like metal not acted upon by hydrochloric acid, but readily dissolved by nitric acid, and having a specific gravity of 8·56. By substituting oxide of chromium for molybdic acid metallic chromium is obtained.—*Engineer.*

CHEMICAL NOTICES FROM FOREIGN SOURCES.

In accordance with the generally expressed wishes of our friends and readers, we have effected arrangements to enable us to give, under the above heading, notices of EVERY CHEMICAL PAPER IN THE WORLD, *as soon as possible after publication. Whenever possible, these notices will appear in the form of carefully prepared, although necessarily brief, abstracts; as respects papers either too long or too abstruse to render condensation possible, their titles will be chronicled; and in all cases accurate reference will be made to the original publication. The two half-yearly volumes of the* CHEMICAL NEWS, *with their copious indices, will therefore be equivalent to an English edition of the "Jahresberichte," with the additional advantage of keeping the readers week by week on a level with the latest advances of science.*

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus des Séances de l'Académie des Sciences, vol. lxix., No. 6, August 9, 1869.

This number contains the following papers and communications:—

Evaporation of Water by Plants.—M. Dehérain.—The author states—(1) the evaporation of water from the leaves of plants is a function entirely different from the evaporation of the same fluid from a not living (inert) surface, since the evaporation from leaves of plants is not interrupted by the state of saturation of the atmosphere; (2) this evaporation is especially due to the action of light; (3) those rays of light which are most effectual in aiding the decomposition of carbonic acid by the leaves are also those which chiefly assist the evaporation of water therefrom.

Non-Poisonousness of Coralline.—M. Guyot.—This paper contains the results of an exhaustive series of experiments by which it is fully proved that coralline, neither when taken internally even in large doses nor also when brought directly into the blood, is a poison, and that its use in dyeing is not dangerous, provided, at the same time, poisonous substances are avoided.

Some Phenomena of Decomposition Produced by Sunlight.—M. Morren.—The author, while repeating some of Professor Tyndall's experiments, but applying, instead of electric light, the bright sunlight of Marseilles's clear sky, has discovered that several inorganic substances are decomposed when a ray of sunlight is made to pass through them; among these sulphurous acid gas is enumerated, this gas being decomposed into oxygen and vapour of sulphur. This phenomenon is caused, according to the author, by a peculiar dissociation called into play by the vibratory motion of the light, which has the effect of breaking up the chemical combination; by means of spectrum analysis the author has discovered that the activity of the light in this aspect depends partly upon its colour, and partly upon the refringence and the nature of the decomposed substance. The author has also found that a thin layer of sulphate of quinine of no more than 4 or 5 m.m. thickness entirely arrests the chemical rays, as if it were a thick yellow-coloured piece of glass. The author states that the chemical effects of highly-heated platinum—for instance, the decomposition of water by that metal, are due to the accumulation of more and more refringent rays.

On the Laws which Rule the Part any Substance Plays between Two Solvents.—M. Berthelot.—This paper is, on account of the abstruseness of the subject treated of, and also because of the algebraic mode of treatment, not very well suited for abstraction with due justice to the author and the subject.

Heat Developed by the Combustion of Coal.—MM. Scheurer-Kestner and Meunier.—This paper is a continuation of a former paper on the same subject by the same authors. The coals treated are those from the Creuzot and some Belgium coals; as an instance of the composition in 100 parts of the former we quote the analysis of a sample designated anthracitic by the authors:—Water, 1·76; carbon, 87·36; hydrogen, 3·47: ash, 3·63; oxygen and nitrogen, 3·75, Belgian coal from Denain, in 100 parts—water, 1·14; carbon, 77·68; hydrogen, 4·10; oxygen and nitrogen, 10·73; ash, 6·35. The observed quantity of heat of combustion of the first-mentioned sample amounts to 9409 units; that of the last mentioned sample amounts to 9085 units.

Succinate, Benzoate, Nitrite, and Nitrate of Isopropyl.—M. R. Silva.—The succinate of isopropyl is a liquid exhibiting an agreeable but very peculiar smell; insoluble in water, soluble in alcohol and ether, inflammable at a higher temperature, boils at 228°, its specific gravity at 0° is 1·009 and at 18° 0·997. Benzoate of isopropyl is also a liquid exhibiting a very pleasant smell; insoluble in water, but soluble in alcohol and ether; boils at 218°, its specific gravity at 0° is 1·054, at 25° 1·013. Nitrite of isopropyl is an inflammable, slightly yellow-coloured, liquid, boiling at 45°; specific gravity at 0° 0·856, and at 25° 0·844. Nitrate of isopropyl is a colourless, very inflammable liquid, boiling between 101° and 102°; specific gravity at 0° 1·054, at 19° 1·036; its vapour detonates violently when strongly heated.

Transport of Artificially-Made Ice.—M. Toselli states that a solid block of ice weighing 23 kiloe., and made in 18 minutes by a process invented by him, has been sent from Paris to Algeria, and received there without more than a very trifling loss by melting during this long journey in hot summer weather.

A large number of papers and communications in this number again refer to the Newton-Pascal and Chasles Leverrier controversy.

of a rather complicated process from parachloronitrotoluol, exhibits an oily strongly refractive liquid, the odour of which is akin to that of toluidine; its specific gravity at 18° is 1·175; boils at 236°; combines readily with hydrochloric, sulphuric, and nitric acids, forming therewith solid crystalline compounds. The authors states that this communication is only preliminary, and that their researches on this subject are not yet quite finished.

On Bismuth Silver.—M. Kayser.—When molten bismuth begins to solidify, the well-known phenomenon of the expulsion of a portion of the yet fluid metal from the interior of the partly fluid mass is observed in consequence of the fact that the solidified metal is specifically lighter than the molten and fluid metal; admixture of other metals, while impeding the crystallisation of the bismuth, also impede its expansion on cooling, but all metals do not act in this respect alike, for the addition of about 10 per cent of lead to bismuth entirely prevents its expansion. An alloy of silver and bismuth behaves in a different manner. The author, while working with silver on the large scale, accidentally obtained an alloy of the former metal and bismuth consisting, in 100 parts, of Bi, 56·1; Ag, 43·5. Upon the surface of this alloy were observed a large number of spherical particles of bismuth, measuring from 5 to 10 millimetres diameter, and consisting, in 100 parts, of Bi, 97·6; Ag, 2·355. While the operation of cupellation was being continued and the quantity of silver rose to 60, 70, and 80 per cent, the globules of bismuth expelled contained invariably 2·5 per cent of silver.

On Crystallised Phosphoric Acid.—M. Krämer.—When an aqueous solution of phosphoric acid, the specific gravity of which has been ascertained, and which solution consequently contains a known quantity of water, is so concentrated by evaporation that the remaining acid exactly corresponds to the formula H_3PO_4, this solution, on cooling, solidifies, yielding beautifully prismatic crystals of pure phosphoric acid.

On the Stilben Series.—MM. Limpricht and Schwaner state that the insinuation made against their researches on this subject, and especially the statement made by M. Grimaux, that his communication, on this subject made in 1867 in the *Bulletin de la Société Chimique de Paris*, has been made improper use of by the authors of the paper on the above subject, recently published in this German periodical, is altogether erroneous; they vindicate their rights and priority in this notice.

A Base Homologous with Kyanæthin.—M. Bayer.—In a rather lengthy paper, the author states that he has discovered a substance which he calls kyanmethin, consisting, in 100 parts, of—Carbon, 58·50; hydrogen, 7·35; nitrogen, 34·15; formula, $C_6H_9N_3$. This substance is a crystalline solid, readily soluble in water, less readily so in alcohol and ether, fuses at about 180°, sublimes without being decomposed, forming thereby finely white-coloured needle-shaped crystals; its vapour is very irritating and excites coughing; its taste is bitter and very like that of quinine. This base combines with acids, forming readily crystallisable salts. This base is a product, among others, of the action of sodium upon aceto-nitrile. The hydrochlorate of this base is composed according to the formula $C_6H_9N_3HCl$.

Cosmos, August 7, 1869.

This number contains, among a great mass of useful information not suitable for abstraction in our columns, a paper on the—

Ripening of Grapes by Cutting away part of the Leaves.—M. J. Comté.—At a meeting of the Agricultural Society of Agen, the author called attention to a chemico-physiological fact of great importance. It appears to have been an old custom, and is yet so, to pull off from the vines, especially in the Southern parts of France, a large quantity of leaves, especially close to where the fruit is placed on the stems, so as to allow full sunlight to fall on the grapes, which, in consequence thereof, soon get an amber-yellow colour, and appear to be rather over-ripe. The author condemns this custom; and, while citing, among the older authorities on this subject, MM. Rosier and Chaptal, he states that, as regards the grapes, the presence of the leaves, as arranged by nature, is absolutely necessary to them for perfecting their maturity, which means for converting into grape sugar a portion of the acids present in the unripe grapes in large quantity. The carbonisation (by which word the author understands the addition of carbon to the acids) is effected by the leaves, through which the vegetable juice passes, for the purpose of becoming deoxidised. Fully ripe grapes should exhibit an agreeable green colour; grapes taken from the vine before they were ripe do not reach maturity at all, as other fruit does, but remain as they were. Taking away the leaves, therefore, does not ripen, or speed the ripening of the fruit, but only alters its colour to a shade of yellow, which genuinely ripe grown grapes never present. The taste of these yellow grapes is intensely sour, while that of the green-coloured ripe grapes is extremely sweet. The author regrets that the foolish practice alluded to is not authoritatively prohibited, on sanitary grounds, and for the reason that it is very injurious to the fruit-bearing of vineyards.

Levels of Two Seas.—M. Faye.—As a proof of the correctness of the geodesical survey made in 1798, during the celebrated Egyptian campaign, it may be stated that the author, on re-calculating the results then obtained for the difference in level between the Mediterranean and Red Seas, and comparing the results with those obtained when a survey for the construction of the Suez Canal was made in our time, found the results to be—0·85 metre for 1798, and 0·86 metre for 1866.

Influence of the Intensity of Coloured Light on the Quantity of Gas Set Free by Plants.—M. Prilleux.—It is well known that, under the influence of direct sunlight, the green-coloured parts of plants decompose carbonic acid. The author, in order to learn the effect of rays of light of equal intensity, has applied coloured solutions which could be rendered more or less deep-coloured by adding thereto dye-stuffs, while the intensity of the light was photometrically measured. In the midst of these coloured aqueous solutions, branches of aquatic plants were placed in large glasses filled with water saturated with carbonic acid. The undermentioned figures denote the activity of decomposition of carbonic acid for two kinds of aquatic plants thus exposed during one minute of time. No 1. refers to the *Potamogeton perfoliatus*, Nos. 2 and 3 to *Elodea canadensis*.

White light	64·75 ..	74·5 ..	51·36
Blue light	56·00 ..	58·8 ..	52·92
Orange light	55·30 ..	57·0 ..	38·00

There may, therefore, be deduced from these experiments that the differently coloured lights do also act differently upon the green parts of plants, and call forth an equal disengagement of oxygen, when the intensity of the light remains the same, and, consequently, all the rays of the solar spectrum cause the decomposition of carbonic acid by plants.

August 14, 1869.

For those interested in very speculative matters, we mention that this number contains, as did a preceding, and as will, in all probability, one or more of the next numbers, an article on the—

Means of Communication between our Earth and the Planets.—M. C. Cros.—We do not enter into the details, as they do not belong to the domain of chemistry or the sciences more immediately connected therewith.

Les Mondes, August 5, 1869.

We quote from this paper the following:—

Chemical Laboratory at Neufchâtel.—This well-known, beautifully-situated little Swiss town, with a population of about 11,000, has obtained an excellently well-arranged chemical laboratory, placed under the direction of Dr. Sacc. There is ample room provided for forty students to work comfortably, and provided with all useful instruments. The building contains lecture-rooms, and every other requisite. The town possesses excellent educational establishments, and is a very healthy place.

Manufacture of Various Objects from Quills.—M. Clerget.—While the southern parts of France, only a few hundred miles distant by rail from Paris, could throw into the trade large quantities of excellent material (home produced), the cost of transport by rail from Toulouse to Paris, for the same weight and bulk, is only two francs less than the enormously long and circuitous journey from Kasan and Nijni-Novgorod to Paris. The article in question, not being one subject to deterioration, requires, of course, no great speed in conveyance. The quills and feathers are sorted; the smallest are used for ornamenting toys, while the better quills are turned into tooth-picks, and nibs for writing purposes, and almost all the rest, except the pith, is used in ornamental-flower making, brush-making, and imitation of horse-hair work. The feathers have recently been woven into a tissue fit for use as carpets, by means of machinery invented by M. Bardin, the owner of the works inspected by the above-named gentleman officially, to see that all hygienic measures are duly carried out.

Researches on the Illumination of Liquids by means of a Beam of Neutral or Polarised Light.—M. Lallemand.—The author describes minutely in this paper a series of minute optical experiments with liquids suitably held in tubes. When a beam of sunlight is made to illuminate different liquids, there are observed various phenomena dependent upon the substance employed, or under observation. In this aspect, liquids are divided into three categories—(1) some do not possess any perceptible fluorescence, and are devoid of rotatory power; (2) they possess more or less fluorescence, and, akin to the first, are devoid of all rotatory power; (3) these fluids have rotatory power, and exhibit, in addition thereto, often a very strong fluorescence. To the first class belong, among other liquids, water, nitric and hydrochloric acids, and liquid ammonia. Samples of second class—Solutions in pure water of salts of quinine, also esculine, and, among pure liquids, perfectly chemically-pure sulphide of carbon. Third class—A concentrated solution of pure cane-sugar may serve as examples.

NOTES AND QUERIES.

Wood Lice.—Oil of turpentine, or, better yet, carbolic acid, especially if care be taken that the latter be pure and colourless, will destroy these insects, without injury to wood-work or furniture, which should be painted over, as it were, with these fluids. If, however, the smell of these substances be objected to, a solution of corrosive sublimate in water, with the addition of some common salt to increase its solubilty, may be applied; but this solution is highly poisonous to men and animals.

Estimation of Phosphates in Manures.—A very valuable communication appeared in the CHEMICAL NEWS (vol. xx., p. 77) on the "Estimation of Phosphates in Manures." Will Mr. Sutton, or any of your other correspondents, inform me if it is possible for a superphosphate to go back or lose any portion of its soluble phosphate and at the same time contain an excess of sulphuric acid? which I believe all commercial superphosphates do in a certain degree.—FARMER.

THE CHEMICAL NEWS.

Vol. XX. No. 510.

THE BRITISH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

Professor Stokes has spoken wisely in defining the object and aim of the British Association as the "giving a more systematic direction to scientific inquiry." Without doubt, this is the paramount design. It is true that the Association serves as a vehicle for the bringing together of scientific men from various parts of England and the Continent, and thereby promotes a fellowship and a good feeling which workers in the same field should ever possess, and which no paper-war should ever disturb; it is true that it often imports pure science into most unscientific regions, and makes, for the time being, the city honoured by its presence, the focus *par excellence* of scientific thought and activity; and in its train there follows a host of fervid devotees who cry aloud to the inhabitants of the honoured city, "What time ye hear the sound of the cornet, sackbut, psaltery, and all kind of music, ye are to fall down and worship the golden image which we have set up," and the people *do* fall down and worship; and papers are read, and lectures delivered, and *soirées* given, and excursions made, and Mayors exercise the most unbounded hospitality, and the people shout "Hail" till they are hoarse, and the Local Committee works like a galley slave, and all for the glory, and honour, and welfare of science. These things help to make up a great whole, but the real and principal *work* of the Association is the "giving a more systematic direction to scientific inquiry," and the granting of sums of money for well indicated and defined purposes of research. It is by this means that the Association really influences the scientific world; it is by this means that it is leaving its impress upon the scientific progress of the age—an impress which will remain clear and distinct when all lesser matters shall have faded away, the men, the times, the very cities which received them, the very countries which gave them birth, each and all more evanescent than "*scientia immutabilis*;" each and all more destructible than facts "*travaillés jusqu'ii indestructibilité*." Francis Bacon has well compared the modes of research to the three ways of walking in the dark, for a man may either grope about as best he can, or he may be led by the hand of another, or he may direct his steps by a lantern, the last applying to the trying of experiments in definite order, with a determinate design, and in accordance with recognised laws of thoughts, and surely the Association both holds a lantern and leads by the hand when it gives "a more systematic direction to scientific inquiry."

There is no denying the fact that the year which has passed has not been brilliant in scientific results; yet it has been a year for much steady work. It is notable rather as a time for collecting particulars than as a time for the formation of generalisations. It is not that Nature has piped unto us and we have not danced,—it is not that we have ceased to torment phenomena by every known process which can lead to the revealing of secrets, but rather because there can never be a succession of great and notable discoveries or developments either in philosophy, or art, or science; an uniform progression either for good or for evil is an impossibility, and we must neither desire nor expect it. We may well rest content with our extended knowledge of the constitution of the sun as the dominant scientific result of the year which has intervened since the meeting of the British Association was held in Norwich.

ON THE MANUFACTURE OF CHLORINE BY MEANS OF PERPETUALLY-REGENERATED MANGANITE OF CALCIUM.*

By WALTER WELDON, F.C.S.

Since the last meeting of the British Association, chlorine has begun to be manufactured extensively by a process which depends on the production and perpetual regeneration of a compound no mention of which, so far as I can find, as yet exists in chemical literature. As this process, besides thus producing and continually re-producing what I believe to be a new compound, reduces, by fully 80 per cent, the principal item in the cost of the manufacture of chlorine, greatly increases the quantity of chlorine which can be practically obtained from a given quantity of hydrochloric acid, and, moreover, enables the manufacture of chlorine to be carried on without the production of any offensive residue, I have ventured to think that a very brief account of it might not be without interest to this Section.

What has hitherto been the ordinary process of manufacturing chlorine consists simply in digesting with hydrochloric acid ores containing peroxide of manganese. The reaction which takes place, besides liberating chlorine, produces chloride of manganese, which remains behind in solution after the chlorine has gone off, and has hitherto been usually thrown away. There have been proposed and tried a great number of processes for transforming this chloride into peroxide for use over again; but the only one of them which has met with the slightest measure of practical success, prior to that which is the subject of this paper, is the one which is known, from the name of its inventor, as Dunlop's process. Dunlop's process decomposes the chloride of manganese by heating its solution, under a pressure of from two to four atmospheres, with milk of carbonate of lime, and then, in the dry way, transforms the resulting carbonate of manganese into a mixture or compound of two equivalents of peroxide with one equivalent of protoxide, by subjecting it for forty-eight hours to the action of air at a temperature of about 600° Fahr. The product of Dunlop's process is a sufficiently satisfactory one, containing about 72 per cent of MnO_2; but the process requires a very formidable amount of apparatus, and, in this and other ways, is so costly that its use has never been extended beyond a single firm of manufacturers.

Three years ago, I began to endeavour to work out the idea of decomposing, by either lime or magnesia, the chloride of manganese in the residual liquors of the chlorine manufacture, and then blowing air through the resulting mixture of hydrated protoxide of manganese with solution of chloride of calcium, or of chloride of magnesium, as the case might be. I took for granted that one-half of the protoxide of manganese so treated was the largest proportion of it that could thereby be converted into MnO_2—in other words, that one could obtain only sesquioxide by this method; but it was soon found that,

* Read before the British Association, Exeter meeting, Section B.

when using lime to decompose the chloride of manganese, considerably more than half the protoxide operated upon was frequently converted into MnO_2. It was found, eventually, that more than half the protoxide was thus peroxidised only when more lime was used than simply the quantity necessary to decompose the chloride of manganese, and when what was treated with air was thus a mixture of protoxide of manganese and lime; and it was also found that in all such cases there was a definite relation between the quantity of lime associated with the protoxide of manganese and the quantity of the protoxide, in excess of half, which became peroxidised. This led to the discovery that, whereas when protoxide of manganese by itself is treated with air in the wet way, one-half is the maximum proportion of it which can thereby be converted into MnO_2, the association of a certain proportion of lime with the protoxide so treated will enable the whole of it to become converted into MnO_2. It is to this fact, together with that of the much greater rapidity with which protoxide of manganese can be peroxidised by treatment with air in the wet way when lime is present than when lime is not present, that the practical success of the new method of manufacturing chlorine is mainly due.

The action of lime in increasing the proportion of protoxide of manganese which can be peroxidised by treatment with air in the wet way evidently consists in the lime substituting itself for that part of the protoxide which, when protoxide of manganese not having any other basic substance associated with it is treated with air in the wet way, does not undergo peroxidation. It would seem that the production of MnO_2 in the wet way by direct combination between hydrated MnO and atmospheric oxygen absolutely requires the presence of a base with which the MnO_2 can combine as it forms. When protoxide of manganese not having any other basic substance associated with it is treated with air in the wet way, a part of the protoxide itself has to act as the required base; and this is the reason why, in that case, not more than half of the protoxide can become peroxidised, the other half being required to combine as MnO with the half which becomes converted into MnO_2. When, however, the protoxide of manganese which is treated with air in the wet way has lime associated with it, the MnO_2 which forms (or part of it, according to the proportion of lime present) combines with CaO instead of with MnO, thus leaving free to undergo peroxidation that part of the MnO which, but for the presence of the CaO, this MnO_2 must have combined with, and which would thus have got locked up in a state in which it would have been incapable of being peroxidised, at least in the wet way and by air alone. Hence, the presence of enough lime to take the place of that half of the protoxide which, if no lime were present, would have to go into combination as base, and also to supply enough base for that half itself to combine with after undergoing peroxidation, will enable the whole of the MnO operated upon to be raised to the state of MnO_2. The minimum quantity of lime which is enough for this purpose is an equivalent for each equivalent of MnO operated upon, or the quantity necessary to supply an equivalent of lime to all the MnO_2 which can be produced by the peroxidation of all the MnO.

By treating with air, then, a mixture of protoxide of manganese and lime suspended either in water or in solution of chloride of calcium, there is formed a compound containing MnO_2 and CaO, in the proportion of an equivalent of one to an equivalent of the other. This compound may be regarded as sesquioxide of manganese, or Mn_2O_3, the MnO in which is replaced by CaO. I call it manganite of calcium, and I believe it to be a new compound. Gorgrew, in 1862, described a compound which he called manganite of calcium; but his compound contained five equivalents of MnO_2 per equivalent of CaO, and the CaO in it was so feebly combined that it readily decomposed chloride of manganese. My compound contains only one equivalent of MnO_2 per equivalent of CaO, and has no action upon salts of manganese.

This compound has now been produced and re-produced to the extent of some hundreds of tons. The process of producing it and applying it to the manufacture of chlorine is conducted as follows:—The residual liquor which remains after a charge of manganite has reacted upon hydrochloric acid in any suitable still is run from the still into a well or other receptacle, in which it is treated with carbonate of lime, to neutralise any free acid, and to decompose any sesquichloride of iron or sesquichloride of aluminium which may be contained in it. The neutralised liquor is then pumped up into an elevated cistern, in which it is left at rest for a few hours, in order that it may deposit certain solid matters which it now holds in suspension. The most abundant of these is usually sulphate of calcium, due to the somewhat considerable quantity of sulphuric acid which is nearly always coutained in the hydrochloric acid produced in alkali works; but there are also small quantities of sesquioxide of iron, derived from the sesquichloride of iron in the hydrochloric acid, and sometimes partly from the lime used in the process, and larger or smaller quantities of alumina and silica, due to the lime. These impurities having deposited, the supernatant liquor, which is a mixed solution of chloride of manganese and chloride of calcium, and is now quite clear, and of a beautiful rose-colour, is run off into another vessel, where there is added to it the quantity of lime necessary to decompose the chloride of manganese in it, and nearly an equivalent more. A blast of air is then injected into the resulting mixture, and what was at first a perfectly white mud (all the manganese in which was in the state of MnO) soon becomes a very black mud, nearly all the manganese in which is in the state of MnO_2. This is then allowed to settle for about twelve hours, at the end of which time it has separated into a denser black mud and a supernatant, clear solution of chloride of calcium. This solution of chloride of calcium having been drawn off, what remains is ready for use in the still. It is used as mud, without drying, being conveyed to the still by pipes, and entering by a hydraulic lute. In the still it meets with hydrochloric acid, from which it liberates chlorine, at the same time re-producing exactly such a residual solution as was commenced with. With this solution, the round of operations is re-commenced, and so on, over and over again, continually. The samples I exhibit are portions of a charge of manganese which, at the works of Messrs. J. C. Gamble and Sons, of St. Helen's,—where this process has been worked out, by the liberal co-operation of Lieut. Colonel Gamble, the proprietor of those works, and the invaluable assistance of Mr. Bramwell, the very able manager of them,—has actually generated chlorine from which bleaching-powder has been made, something like fifty successive times.

Hitherto, the principal item in the cost of chlorine has been that for native peroxide of manganese. Last year, in Great Britain, France, Belgium, and Germany together, there were produced about 120,000 tons of bleaching-powder, which cost, on an average, for native oxide of manganese, not much, if any, less than £5 per ton. My process substitutes for this cost for native oxide of manganese a cost for the regeneration of manganite of calcium not exceeding fifteen shillings per ton of bleaching-powder, being about ten shillings for lime, one shilling for steam, one shilling for wages, and two shillings for interest and wear and tear. Moreover, whereas hitherto, at least in this country, and in all but an extremely few exceptional cases, the production of a ton of bleaching-powder has required the acid from about 75 cwts. of salt: my compound yields chlorine enough for a ton of bleaching-powder from the acid from less than 45 cwts. of salt. This larger yield of chlorine is mainly due to the artificial manganite being so easily soluble that it can very readily be caused to neutralise from 95 to 99 per cent of the acid employed, which is a very much larger proportion than can be neutralised when working with manganese ores. A third very important advantage of the new process over the old one consists in this—that, whereas the immense quantities

of acid which escape neutralisation in the old process are usually—and have almost necessarily to be—sent into the rivers as free acid, the only product of the new process which has to be thrown away is a perfectly neutral solution of chloride of calcium.

Seeing that manganite of calcium, or $CaMnO_3$, is only of the very same value precisely in respect of the quantity of chlorine which it can liberate from a given quantity of acid as sesquioxide (otherwise manganite of manganese, or $MnMnO_3$), it may be well to explain why it is preferable to produce and re-produce the former rather than the latter. The reasons for this are two. There is, firstly, the obvious reason that, when all the manganese is converted into MnO_2, twice as much work is done per given bulk of material operated upon as when only half the manganese is converted into MnO_2; and this, of course, would be a very important consideration, even if the transformation of chloride of manganese into manganite of calcium occupied the same time as its transformation into manganite of manganese. Really, however (and this is the second reason), the former operation, in which all the manganese is converted into MnO_2, does not occupy more than one-fifth of the time required for the latter operation, in which only half the manganese is converted into MnO_2; and hence, while the manufacture of chlorine by means of perpetually-regenerated manganite of calcium effects the very considerable economy above stated, it is questionable whether chlorine could be manufactured by means of manganite of manganese regenerated by the same method so cheaply as by means of manganese ores.

The length of time which, when protoxide of manganese by itself is treated with air in the wet way, is required for its complete conversion into sesquioxide is very remarkable, and the fact that hydrated protoxide of manganese is somewhat freely soluble, alike in water and in neutral solution of chloride of calcium, would seem to have something to do with it. It is a curious fact that the peroxidation of protoxide of manganese by treatment with air in the wet way is greatly retarded by the presence in the medium in which the protoxide is suspended of any proto-compound of manganese in the state of solution. Thus, in a solution of either chloride or any other proto-salt of manganese, peroxidation will go on only extremely slowly; and solution of the protoxide itself, which will be present until the very end of the operation when protoxide alone is treated with air in the wet way, has the same retarding influence. On the other hand, when treating with air a mixture of protoxide of manganese and lime suspended in solution of chloride of calcium, there are formed solutions containing peroxide of manganese, in the presence of which peroxidation goes on with extreme rapidity. All these solutions are more or less deeply coloured, solution of the protoxide being without colour. I exhibit a sample of one of the coloured solutions, called by the workmen "the port-wine solution." The nature of these coloured solutions has not yet been fully investigated, but I believe them to consist of manganite of calcium dissolved in solution of oxychloride of calcium.

I may be permitted to mention, in conclusion, that, while there is every prospect, from the rapidity with which the new process of manufacturing chlorine has been and is being adopted both in this country and on the Continent, that, within a period to be measured only by months, nearly all the chlorine made in the world will be made by it, there is every likelihood that, in nearly all cases, a portion of the hydrochloric acid saved by it will be applied to the recovery of sulphur from alkali-waste. The chief reason why the recovery of sulphur from alkali-waste has been so little practised hitherto is that the manufacturers have considered it more profitable to use all their acid for the manufacture of bleaching-powder than to use any part of it for the recovery of sulphur; but the process which I have had the honour to describe will enable them to make even more bleaching-powder than they have made hitherto, and yet have enough acid left to permit of their applying to all their alkali-waste the only process for the recovery of sulphur therefrom which as yet has been found practically successful; and I am able to state that this application of a portion of the acid saved by my process will be extensively adopted.

ON ELECTRIFICATION.*

By THOMAS T. P. BRUCE WARREN.

ELECTRICIANS must have noticed this singular phenomena at the very earliest date of testing; but it is very certain that it has been until now regarded as an unintelligible and uncertain property of an insulator.

The paper read by Mr. Warren has contributed greatly to our knowledge of its effects, so that it no longer remains the inconvenience that it had been to electricians; for he has shown that the laws which it follows admit of being formularised.

We notice that these researches have been carried out on cores of Mr. Hopkin's manufacture, several miles of which were tested under the varied conditions stated by the author. He believes that the very excellence of Mr. Hopkin's insulated wires has enabled him to examine so completely the whole of the subject.

ON THE NEW METHODS OF ESTIMATING THE AMOUNT OF REDUCED PHOSPHATES.

By JOHN HENRY CHESSHIRE.

IN a case recently tried at the Gloucester assizes, a dispute arose whether reduced phosphates could be estimated correctly. Notwithstanding the weighty evidence of Dr. Voelcker and others to the contrary, it was decided in the affirmative, and it was proved by the results of a series of experiments, conducted by men of equal scientific attainments, who pronounced my method (the bicarbonate of soda process) to be the one upon which the greatest reliance could be placed.

The plan I propose is as follows:—Take 1 grm. superphosphate, extract the soluble part. To the residue add 5 grms. bicarbonate of soda, ½ of a litre of cold water, and boil from two to three hours; filter, wash, &c. To the filtrate add hydrochloric acid in excess, then tartaric acid and the magnesia mixture in the usual way.

I now propose to tabulate a series of experiments, showing, side by side, the results of the oxalate of ammonia, and the bicarbonate of soda processes.

No. 1. Action of 10 grms. bicarbonate of soda on 1 grm. Bedford and Cambridge coprolite, with a ½ of a litre of water, and boiling for two hours—soluble phosphate = 0·97 per cent.

No. 2. Action of 5 grms. bicarbonate of soda on 1 grm. Bedford and Cambridge coprolite, with a ½ of a litre of water, and boiling for two hours—soluble phosphates = 0·69 per cent.

No. 3. Action of 5 grms. bicarbonate of soda on 1 grm. (so-called) gypsum, with a ½ of a litre of water, and boiling for two hours—soluble phosphate = 0·83 per cent.

No. 4. Action of oxalate of ammonia on 1 grm. gypsum, with a ½ of a litre of water, and boiling for half an hour—soluble phosphate = 0·97 per cent.

No. 5. Action of 5 grms. bicarbonate of soda on 1 grm. gypsum, with a ½ of a litre of water, and boiling for two hours—soluble phosphate = 8·98 per cent.

No. 6. Action of oxalate of ammonia on 1 grm. gypsum, with a ½ of a litre of water, and boiling for half an hour—soluble phosphate = 8·45 per cent.

* Abstract of a paper read before the British Association, Exeter meeting, Section A.

No. 7. Action of 5 grms. bicarbonate of soda on 1 grm. steamed bone, with a ½ of a litre of water, and boiling for two hours—soluble phosphate = 0·69 per cent.

No. 8. Action of oxalate of ammonia on 1 grm. steamed bone, with a ½ of a litre of water, and boiling for half an hour—soluble phosphate = 2·18 per cent.

No. 9. Action of 5 grms. bicarbonate of soda on 1 grm. guano, with a ½ of a litre of water, and boiling for two hours—soluble phosphate = 1·25 per cent.

No. 10. Action of oxalate of ammonia on 1 grm. guano, with a ½ of a litre of water, and boiling for half an hour—soluble phosphate = 2·11 per cent.

I obtained these results, 4, 6, 8, 10, by taking care to have only a slight excess of oxalate of ammonia at the end of the half hour's boiling.

Nos. 1 and 2.—My usual results with bicarbonate of soda have been only ½ per cent, but, as ½ a milligramme makes a difference of about 1-14th per cent, the results are practically the same.

Nos. 3 and 4.—The so-called gypsum is the waste after the soluble phosphate has been extracted from a superphosphate made from a mineral phosphate. It contained 12·57 per cent unacted-upon phosphate.

Nos. 5 and 6.—A superphosphate made from Bedford coprolite. I extracted the soluble portion, and worked on the remainder for the reduced. It contained 2·01 per cent unacted-upon coprolite.

Nos. 9 and 10.—A sample of good guano, which I boiled for half an hour, filtered wash, &c., and worked on the remainder for the reduced.

You will see by these experiments that you can distinguish between reduced phosphates and unacted-upon coprolite; and, if Mr. Hughes will take care to have only a slight excess of free oxalate of ammonia at the end of half an hour's boiling, his results will not be so high.

83, Newhall Street, Birmingham,

ON THE

EXAMINATION OF WATER FOR ORGANIC MATTER.*

By R. ANGUS SMITH, Ph.D., F.R.S., &c.

(Continued from p. 30.)

There are two columns giving the amount of oxygen required by the Clyde water. One giving the grains is correct, but, in altering the mode of expression, an error occurred not in the original. The amount in the 2nd is in 100 millions.

Having had occasion to examine another stream, very slow, rather a canal, receiving sewage, and flowing about twenty miles, the following results were obtained with the chameleon:—

Oxygen Required by the Decomposed and Decomposing Matters.

Grains per gallon.	
2·835	1·205
1·249	1·630
1·949	1·205
1·170	1·453
0·425	0·425
0·815	0·177

The gradual diminution of the decomposed organic matter is here seen very plainly. As new sewage comes forward in certain places, the amount rises.

These numbers correspond entirely with the apparent condition of the stream; they do not, however, correspond with the total volatile matter, which was as follows:—

Volatile matter.	Fixed matter.
9·33	44·27
6·23	28·91
3·99	24·08
3·08	36·75
3·43	31·85
4·16	30·31
5·22	29·92
5·04	69·30

I believe the results obtained by the chameleon are more useful in a sanitary point of view than the other results.

Let us take another case.

When heavy rains drove the impure water forward, the chameleon gave the following:—

Oxygen in Grains per Gallon Required for the Decomposed and Decomposing Matter.

0·992	1·106
0·284	1·134
0·638	1·276
0·709	1·347
0·992	

In such a case, the ordinary analysis gave—

Volatile matter.	Fixed matter.
4·20	20·72
4·48	21·21
7·14	26·39
6·02	34·02
4·27	28·28
4·69	32·27

These latter do not at all show the fine distinctions made by the permanganate, which agrees entirely with our senses, and may be used instead of them for putrid substances.

The permanganate must be used with consideration, like all other chemical tests. We must be careful that there are no lower metallic oxides in the water, which will remove the colour as suddenly as the sulphuretted hydrogen from putrid matter. Much has been said against the permanganate; but nothing even pretends to do what it does. Those who neglect it leave out the putrid matter, or drive it off in boiling. If it is used as the only reagent the results are certainly without value.

Nitrites decompose chameleon instantly. They are the result of the oxidation of azotised matter, and must be estimated.

The decomposition of the chameleon may be caused by the organic matter present, or by nitrites, &c. The presence of nitrites or nitrous acid will show if the organic matter is only recently oxidised.

Generally, there may be found organic matter and nitrites together, showing that some is oxidised and some ready to become so.

Schönbein has found traces of nitrous acid in the efflorescence of walls. In judging of the time, we must make allowance for this, and not judge from small traces such as he alludes to.

When nitrites and organic matter are found together, they may be estimated separately: the chameleon will be decomposed by both. 158 of chameleon solid is equivalent to 95 of nitrous acid, or 1000=606. It will be necessary to find one of the substances separately, and to subtract it from the whole, in order to find the amount of the second.

The amount of nitrous salts may be found by using ozone-paper, that is, paper with iodide of potassium and starch. The water to be tried is made acid with a little dilute sulphuric acid—not more than three drops to 1000, and a drop put upon the paper. If nitrous acid is present, it becomes blue. This blue is obtained immediately by putting a drop of the solution on ozone-paper when there is 1 of NO_3 in 30,000 of water; and, by waiting patiently, and giving time, it may be seen with much less.

* From vol. iv., 3rd series, of the *Memoirs of the Literary and Philosophical Society of Manchester*. (Communicated, with emendations and alterations, by the author).

In order to find how much nitrite is in water, the solution may be diluted until the reaction ceases to be distinct, even after waiting. The amount in the water will then be 1 in 100,000. If, in another case, when we find the reaction distinct in water, we take 100 grains and add 900 to it and find it beginning to be indistinct, the undiluted quantity must have been ten times as strong as the diluted. The amount in the 1000 grains is 1 in 100,000; the amount in the 100 grains is ten times as great, or 1 in 10,000; and thus we may arrive sufficiently near to the total amount. The amount of water added in order to bring the reaction to the adopted minimum is the measure of the strength of the solution.

A test like this depends partly on the eye and partly on the delicacy of the test-paper. The same result will be attained if the same eye and tests are regularly used.

The method of testing with paper is not so refined as the use of a larger amount of water—say 1000 to 10,000 grains. With this amount, the presence of 1 of NO_3 in 3¼ millions of water may be detected on adding starch and iodide of potassium. Three drops of sulphuric acid are also added to the 1000 grains, *i.e.*, 3 grains by measure. If no nitrous acid is present, no blue colour will be seen with this amount. If nitrous acid is present, the colour will begin in a few seconds. Some may prefer one way, and some the other. I do not look on this as quantitatively very exact; I simply thought it a useful method. Some more work is required.

The methods given of estimating the amount of nitrous acid are minimetric, proceeding by dilution instead of concentration. The value with gases is better known than in liquids; but it is believed that it will be sufficiently exact with the latter in cases where pure scientific accuracy is not attainable and not necessary, and where it is important to save time, labour, expense, and patience.

Now suppose 1000 of the water decolourise 5 of chameleon, we must subtract from 5 the amount which would be due to the NO_3, which then would give the amount of chameleon solution decomposed by the organic matter.

The estimation of both is interesting; but it is much more important to obtain the total chameleon used, as the presence of NO_3 must be considered a great objection to water, partly on its own account, and chiefly because of its origin.

It is to be observed that water containing much animal matter becomes extremely acid. It is a common thing to find water extremely clear, with no apparent organic matter; even on standing, also, extremely acid, and retaining nitrates. I have found it so filled that it appeared to flow less readily than pure water, and had a most nauseous taste. It was close to a churchyard, and was considered excellent water. This perversion of taste is difficult to understand, but it must be combated; it is not natural, and causes illness and death. This acid water is an excellent solvent of metals; and, if lead is present, the solution becomes rapidly so strong as to taste of the metal. This acidity, in conjunction with nitrates, does not, so far as I know, exist when the organic matter is very old—probably because the organic acid is oxidised. Some of it—probably all—is caused by the formation of organic acids. Similar organic and entirely colourless solutions, acid, but free from nitric acid, may be found by allowing peaty water to stand, without evaporation, but in contact with the air, for some years.

In the nitrous waters, no organic matter will be apparent on burning, unless there is more than the acid can oxidise. A very white ash is, therefore, a suspicious circumstance; and, unless the matter is extremely free of organic matter, this white ash is a certain indication of nitric acid. If there is a great deal, the ash melts readily. By white is meant white as soon as it is incinerated.

These acid nitrous waters contain phosphates generally. Phosphate of lime, or even alumina and iron, may be precipitated from them by ammonia, if they are direct from animal matter, and have not passed through porous matter sufficient to deprive them of some of the less soluble substances.

There are many interesting questions to be asked regarding nitrates. I am inclined to think that their presence shows that the most dangerous state of the organic matter is past. When they appear in any solution, the chief escape of putrid gas seems to have ceased; the water may, however, be still dangerous to use, and, of course, is revolting to the imagination. It will be well to examine how far these suspicions are correct. When complete nitrification has occurred, all that class of evils arising from organic matter direct are prevented.

This paper was written for a special purpose, and does not pretend to say all that may be said regarding organic matter in water. As to the purification, there are many points to be observed. It has been generally held that nitric acid is the ultimate form which nitrogenous substances of organic origin assumes; but we must remember that plants have the power of decomposing nitrates, and of using the nitrogen for their own purposes. There are conditions, therefore, in which the organic matter may be entirely removed from water; and, when we remember how readily soils absorb phosphates and potash, we easily see why common salt should chiefly be left. The oxygen of the nitrates may even be used for the purification of water, whilst the earthy salts and phosphoric acid are precipitated. This operation of decomposing the nitrates seems to be the final one which is at hand for purifying water, and probably explains the marvellous results we frequently see. This decomposition is performed by living plants apparently; but some observations seem to indicate that the effect may be produced by the organic dead matter in water. The nitrites found in plants by Schönbein may possibly have been formed from the nitrates by deoxidation.

Animal and Vegetable Matter—The Common Salt of Sewage.

This subject deserves a further separate treatment.

As animals are formed out of vegetables, the elements which compose each are of course the same; and even the proximate organic principles are difficult to distinguish, especially in a state of decomposition. Still, it is remarkable what a clear insight is given into the quality of water by simply boiling down a few thousand grains and burning the residue. We can, by the eye and the smell, detect humous or peaty acids, nitrogenous organic substances and nitrates, and estimate their amount to a very useful point of accuracy. There may be times when this is the only experiment that can be made. After doing this, and trying other methods many hundred times, I still return to it as delicate, and little liable to fail. The want of numerical results is a serious objection, rendering the plan unfit for use when public reports are to be made of the analyses; but it is an excellent guide for the chemist in his laboratory: we may even decide by it the animal or vegetable origin of the matter.

This, however, is not enough; we require to obtain some knowledge of the quantity as well as of the quality, and we even require to know something of the previous history of the water, supposing decomposition to have gone so far that nothing definite can be affirmed as to the organic substances. It has already been shown that the carbon and the nitrogen may entirely disappear, the phosphorus may be precipitated, and the sulphur be, to a large extent, removed, nothing whatever remaining of the original substances, except alkalies, some of the alkaline earths, and chloride of sodium, or common salt. The latter, in reality, is the only substance which, so far as I know, is neither dissipated nor precipitated in whole or in part, potash excepted. The common salt, therefore, may be taken as an indication of the amount of original or organic matter, if we subtract from it any portion which we know to have appeared originally connected only with inorganic substances.

Perhaps all natural waters contain common salt;

although rain, in a quiet day, and in a clear district, is nearly free from it, possibly, in some places, entirely so. In passing through the soil, it always collects some chlorides; some of these are the measure of the amount of vegetable matter decomposing in the soil. If we were to estimate the amount of chlorides dissolved by the water alone out of the inorganic soil, and subtract that from the total, we should obtain the amount dissolved by the action of vegetation breaking down the rocks or soil allowing for rain also. If the organic matter were decomposed, the common salt would still flow down the streams, and tell its tale. These quantities, however, vary excessively on every soil, and in every climate, and with every wind, and degree of wind.

The common salt which comes down our streams comes from the wear and tear both of animals and vegetables in the process of living. We cannot tell which comes from the animals and which from the vegetables.

From pasture-land, and land generally, the greatest amount is from vegetation; and, if we collected the organic matter, we should find also there that vegetation gave the greatest amount of matter, except from recently-manured fields, or when the water comes from shallow or surface drains, where the land had upon it a good deal of animal matter.

When, however, we come to towns, or great collections of animals, the chlorides, as well as the organic substances with which they are allied are the products mainly of changes taking place in animal life. Let us compare the amount of chlorides to be found in plants and in animals.

Chlorides in the Blood of Animals (Nasse and Poggiale in Gmelin) *as Chloride of Sodium in* 1000 *parts.*

Dog	4·490
Cat	5·274
Horse	4·659
Calf	4·804
Goat	5·175
Sheep	4·895
Rabbit	4·092
Swine	4·281
Goose	4·246
Hen	5·396

If we take the ashes, the amount is, according to Stölzel,

For ox blood	51·190
For ox flesh	4·860
Ashes of the serum in man*—	
Chloride of sodium	61·087
Chloride of potassium	4·085
The ashes of the blood in man	57·641
The ashes of the blood of the horse, according to Lehmann	67·105
Urine	22·972

But, as the latter is produced so rapidly and frequently, it is the greatest and most constant source of common salt. No plant can be compared with animals in this respect.

When animals decay, they must, according to the above analyses, give out much more common salt than the same amount of vegetable matter; and this we find to be the case in the drainage of grave-yards. But it is from living animals we find the greater amount of common salt: that which goes into the blood is rapidly thrown out; and, as we take with our food amounts varying from 100 to 250 grains of common salt per day—let us say 150, an equal amount must be abstracted from us. It is for this reason sewage water constantly is found to contain common salt, increasing according to the amount of sewage. For this reason, common salt is found in the saltpetre of all countries. It is a part taken from the blood of the dead or the living animal, remaining with the nitrogen unchanged, even when the organic matter has been so

* Robin and Verdeil's "Traité de Chimie Anatomique."

highly oxidised that nitric acid takes the place of albumen.

Pure spring, or very fine stream water, gives only a slight precipitate with nitrate of silver. This has a bluish tinge, not being dense enough to become white. When there is more than this slight precipitate, nitric acid is generally found, especially if the water has passed through porous materials.

These tests must be used and the inferences drawn with great discretion. We know that near the sea there may be found a certain amount of chlorides in the springs, rising, according to circumstances, until the water becomes brine. The same thing occurs near great deposits of salt, such as in Cheshire and elsewhere. There are, also, saline wells scattered over most countries, the origin of whose chlorides is quite unknown to us. There is in the rain driven violently from the sea an amount of common salt sufficient, on crystallising, to dim the windows of houses many miles inland. In manufacturing towns where coal is burnt, the rain contains more chlorides than rain in the country. Many large districts of tropical countries contain nitrates and common salt in the soil, but these salts in all probability result from oxidised animal matter. Chlorides are found in some districts in this country rather in excess of the average from superficial causes. But notwithstanding all these exceptions, which appear for the moment numerous, I must still consider that the test is one which may be generally used.

In England it is almost universally the case that the presence of much chloride in drainage water indicates drainage from animal matter, and no water containing chlorides to a great extent ought to be used without careful examination as to the source. One grain per gallon is too much, and is, in many places, to be suspected of being caused by impure drainage. Of course we must in this case, as in all inquiries, be careful that no disturbing causes intervene. In this country chlorides may be given out from manufactories, in which are constantly made chemical experiments sufficiently large to interfere with our accuracy, if we are not very careful.

It may be supposed here that I am adding many qualifications, but the same may be done in the case of nearly all experiments. No experiment is of value, unless it is viewed on all sides to prevent the admission of errors, and I do not know that more care is required in this case than in many others. In the case of chlorides we learn readily the average amount in a district, either in the rain or the drainage, and we detect the smallest increase. Any amount of common salt above the average of the district obtained in a well in a city or camp, or near habitations of men or animals, is an almost certain proof of impure drainage; when the clue has been followed up, I have found the origin in a sewer or some such spot, times without number and for many years. The presence of the sea or manufactories, or of disturbed strata with mineral waters, will seldom, after all, cause any error with a careful person.

Nitrates are very common in small quantities. They are found in water from manured land, in gardens, wells near houses, and, as a consequence, in nearly all town wells; in great abundance near churchyards, if the drainage is direct. They are not necessarily found in sewage which has not flowed through strata. The amount from the atmospheric sources is so minute that it will not interfere with any inquiry regarding the wholesomeness of water at present.

Although caution must be exercised in drawing conclusions from the presence of the chlorides, their absence may be held as conclusive against the presence of decomposed animal matter, and excretions of animals in large quantities.

If chlorides and nitrates are found together in water, we may take it for granted that animal matter has existed there, or does exist in the water. Of course a very rigid scientific inquiry shows at once that vegetable matter may be present, especially from grain or seeds; but, practically, this need not affect the question, especially in a sanitary point of view, because, if this accumulation of vegetable matter occurred capable of giving as much nitrogen as animal matter, it would be sufficiently, and perhaps equally, hurtful when putrid.

If chlorides and nitrates are found in water still capable of decomposing chameleon, the presence of animal matter, or injurious gases or nitrites, may be assumed, a part only being oxidised.

If the chlorides and nitrates are present, but the power of decomposing chameleon absent, then animal matter in a putrefying state is absent, but whether it disappeared minutes or ages before is not shown by chemistry.

The chloride of sodium in a sewage stream of a very sluggish nature was estimated. The following numbers were obtained in a course of 14 miles:—

8·97	7·93
7·53	7·78
6·25	6·62
7·78	40·89

The numbers are pretty uniform, although they rise and fall with evaporation and the additions made to the stream; but whenever certain manufactures come in a sudden rise is observed. Before this occurs, I believe the chloride of sodium is a perfectly exact comparative measure of the amount of sewage. It may, in many cases, also be made into a positive measure. This will, however, depend on the mode of managing the sewers.

The conclusion simply is, that chloride of sodium is the most abiding constituent of sewer water, and, with due precaution, the best index of comparative amounts in the original sewage. When decomposition has not taken place, it may also be used for indicating the comparative strength or value of sewage water.

Perhaps it will be thought that in here speaking of the impurities of water, when the River Commissioners are making their inquiry in Lancashire, it would be better if I spoke less of the laboratory side of the question, and more of the great evils which have destroyed the beauty and use of our rivers. On one important point I am of the same opinion which, years ago, I expressed in this Society—that we waste an enormous amount of water. We throw into a stream, without compunction, impurities which will destroy the value of many hundred times, or, perhaps, thousand times, their bulk; and this evil may, to a certain extent, be cured with our present knowledge. We try in vain to take out that which we have thrown in. A large part of the evil can be cured by little trouble, although I confess that there is much remaining which demands more time and space than is everywhere conveniently found. Time and space, although by many treated as mere forms of thought, are expensive in Lancashire.

The following may be regarded as a summary of the results required for sanitary purposes:—

1. Quality of the organic matter.
2. Condition of the gases of decomposition.
3. Organic matter: easily-decomposed organic matter, and slow to decompose.
4. Nitrates as remnants of organic matter.
5. Nitrites.
6. Chlorides, with precautions, as indicating animal sources when greater accuracy is wanted.
7. Oxygen of the dissolved air as indicating the activity of the decomposition.
8. Total organic matter.

(This the author found by weighing).

9. The usual inorganic analysis, to be spoken of in a second paper.

The author considered that, for purely sanitary purposes, the Nos. 1, 2, 3, and 6 were the most important.

The organic matter may be divided into many parts; nitrogenous into several parts; and carbonaceous into several. The total nitrogen has been taken by Dr. Frankland very carefully, and the mode of taking oxides of nitrogen improved. The division of the nitrogenous into separate parts has been begun by Wanklyn. The carbonaceous has not been much studied of late years.

ON SOME NEW SUBSTANCES EXTRACTED FROM THE WALNUT.*

By Dr. T. L. PHIPSON, F.C.S.

BETWEEN the shell and the kernel of the walnut there exists a thin membrane, called the episperm, which closely envelopes the cotyledons, and is composed here, as in most other fruits, of a double membrane, the inner one being very thin, quite white, translucid, and perfectly devoid of taste, whilst the external one is much coarser in structure, more or less coloured, has a very bitter, disagreeable taste, and contains the substances mentioned in this paper.

When the episperm of the walnut is digested for several hours in alcohol, it yields a yellowish liquid, from which a notable amount of gallic acid, ellagic acid, and a new species of tannin, which I will call *nucitannic acid*, or *nucitannin*, can be obtained. The latter is the principle to which the thin walnut skin chiefly owes its disagreeable bitter taste; and this nucitannic acid possesses the property, when boiled for several hours with dilute hydrochloric acid, of splitting up into *glucose* and a red substance, which I will call *rothic acid*, the composition and properties of which I have fortunately been able to determine, although I started on this research last season with a very small supply of walnut skin.

Nucitannin is soluble in water and in alcohol, very slightly soluble in ether; it precipitates solution of gelatine, but not exactly like ordinary tannin does. The mixture solidifies only after a little time. It forms insoluble salts with lime and oxide of lead, and is left as a kind of yellow varnish, devoid of crystallisation, when its alcoholic solution is evaporated at a moderate temperature. Its composition has not yet been ascertained.

When an aqueous solution of nucitannin is boiled for eight or nine hours with dilute hydrochloric acid, the pale yellow liquid becomes more and more red, until it finally assumes a tint similar to that of a dilute solution of permanganate of potash. It is then allowed to cool, when the red substance, rothic acid, separates, along with some gallic acid and ellagic acid; these are collected on a filter, and the clear liquid which passes is found to contain glucose and gallic acid.

Rothic acid is separated from the other substances by a dilute solution of ammonia, and re-precipitated by hydrochloric acid; a second treatment gives it quite pure. It is a brownish red amorphous substance, combining readily with ammonia, potash, lime, &c.; its lead-salt is remarkable by being insoluble in cold acetic acid. Rothic acid is very soluble in alcohol; its solution exercises no particular action on the spectrum; it yields no absorption bands; it is, also, very soluble in ammonia. Dried at 100° C., it was found to lose water for a long time; it was, therefore, heated in an oil-bath to 118° C., and then burnt with chromate of lead. The analysis gave:—

		Calculated for $C_{28}H_{12}O_{14}$.
Carbon	57·81	.. 57·52
Hydrogen..	4·16	.. 4·11
Oxygen	—	.. 38·37

The lead-salt was formed by precipitating acetate of lead with an alcoholic solution of rothic acid; it forms an olive-coloured amorphous precipitate, which becomes brown when dried in the air, and appears quite black when dried at 100° C. It leaves metallic lead when calcined carefully in a porcelain crucible. 370 milligrms. of rothate of lead yielded, to analysis, 150 milligrms. of lead, or 40·5 per cent.

Calculated for $C_{28}H_{12}O_{14},2PbO$.	Found.
Lead, per cent .. 40·2	40·5

The lime-salt of rothic acid forms a brownish precipitate, obtained by adding an ammoniacal solution of chloride of calcium to a solution of rothic acid. It is like the lead-salt in appearance, but contains only one equivalent of base:—

$$C_{28}H_{12}O_{14},CaO.$$

The rothates of potash, soda, and ammonia are soluble; the rothate of silver forms a fawn-coloured precipitate, which becomes darker on drying, but does not appear to be very sensitive to the action of light.

Rothic acid is a member of a rather numerous class of bodies, some of which are mentioned below:—

$C_{28}H_{12}O_{14}$ = 1 eq. rothic acid.
$C_{28}H_{12}O_{20}$ = 2 ,, gallic acid.
$C_{28}H_6O_{16}$ = 1 ,, ellagic acid.
$C_{28}H_8O_{16}$ = 2 ,, rufigallic acid.

Somewhat similar substances extracted from oak-bark, quinine bark, root of *Tormentilla erecta*, &c., appear, on analysis, to contain C_{26} instead of C_{28}.

I will reserve for a future occasion, an account of the preparation, properties, and composition of pure nucitannin; I may briefly state, however, that the alcoholic decoction of the walnut skin contains a substance described here as nucitannin, yielding, by the action of mineral acids, rothic acid, gallic acid, ellagic acid, and glucose; and, since ordinary gallotannic acid may be represented as a glucoside, yielding 3 eq. of gallic acid—

$$S\left\{\begin{matrix}G\\G\\G\end{matrix}\right\}-8HO,$$

it is possible that nucitannin may be—

$$S\left\{\begin{matrix}R\\G\end{matrix}\right\}-xHO,$$

in which R represents rothic acid, and takes the place of 2 eq. of gallic acid. If so, there is another tannin present in the walnut skin, an *ellagic tannin*—

$$S\left\{\begin{matrix}E\\G\end{matrix}\right\}-xHO,$$

which explains the fact that alcohol takes up, from the walnut skin, a substance yielding a notable amount of ellagic acid, these glucosides being all very soluble in alcohol, though the acid derived from them may be very much less soluble.

* Read before the British Association, Exeter meeting, Section B. Abstract by the author.

NOTICES OF BOOKS.

Abridgments of Specifications Relating to Acids, Alkalies, Oxides, and Salts. A.D. 1622—1866. Printed by order of the Commisioners of Patents. London, 1869.

WE have here before us, condensed into a neat volume containing about 1100 small octavo pages, a most useful as well as a most valuable record of the history and course of inventions on the domain of practical and technical chemistry for a period of nearly two and a half centuries. The number of specifications, from the earliest period to the end of the year 1866, amounts to no less than 59,222.

This work, besides embracing all inventions relating to the making or obtaining by any direct or indirect methods of acids, alkalies, oxides, or salts, includes inventions relating to the making or obtaining of several elementary bodies; among which are bromine, iodine, chlorine, fluorine, carbon, hydrogen, nitrogen, oxygen, and sulphur, and some compounds—as, for instance, cyanogen.

There is in this excellent work such an *embarras de richesse* as regards the subjects for quotation that it is very difficult to make a choice out of such an abundance of matter. For curiosity's sake, we quote, from the first page, the following:—

A.D. 1623, February 23, No. 23.—Jones, Roger, and Palmer, Andrewe, "Makeing of hard soape with a material called berilia, and without the vse of any fire is the boyling and makeing thereof; and also of makeing of

soft soape without the use of fire in the boyling thereof." The "berilia" consists of ashes of "beanestrawe," "peasestrawe," and of English kelpe. *Qucritur*—What is, in this phrase, the meaning of the words "without fire?" does it refer to saponification in the cold? or was steam already used by some for boiling other liquids? Since no specification is enrolled, this question remains unanswered.

This work, to which are added copious indices of subject matter, and of names, will be highly welcomed, both by manufacturers and parties directly interested in patents, and specifications thereof; the work is a valuable addition, also, to the scientific bookshelves and libraries of the day; and the whole manner of execution and abridging of abtruse matters, too often very imperfectly worded, reflects great credit upon the gentlemen to whom the excellent head of the Patent Office has entrusted a task which deserves the praise of all who can understand the difficulty of the proper execution of that task.

Notwithstanding that the book contains nearly 1100 closely-printed pages, it is sold at a very reasonable price, while the paper and typographical execution are also commendable.

MISCELLANEOUS.

Vorläufiges Programm der 43. Versammlung Deutscher Naturforscher und Aerzte, Innsbruck, 1869.—From the printed programme above named, we abstract the following:—The meeting begins on the 18th, and ends on the 24th of September, and will be held at the town of Innsprück, Tyrol. Although this meeting is chiefly an association of German natural philosophers and medical men, foreigners are very welcome, and are admitted as members the same as Germans, on payment of three thalers (nine shillings). Tickets for membership are obtainable by application to Prof. Dr. O. Rembold, Innsprück, on payment of the sum just mentioned; and on the 17th and 18th of September next tickets are to be had at the Hotel de l'Europe, opposite the railway-station of the town of meeting. The following sections are arranged:—Mathematics and Astronomy; Natural Philosophy (Physics) and Mechanics; Chemistry and Pharmacy; Mineralogy, Geology, and Palæontology; Botany and Phytophysiology; Zoology; Anatomy and Physiology; Medicine; Medical Reform; Surgery and Ophthalmology; Gynæcology and Midwifery; Psychiatry; Naturwissenschaftliche Pædagogik (the manner of teaching natural sciences in lower schools); Public Hygiène and Forensic Medicine; Medical Practice of Infants and Young Children; Anthropology and Ethnology; Military Medical Practice. The first general meeting is appointed to take place on Saturday, the 18th of September. Several excursions of interest in the beautiful neighbourhood of Innsprück have been arranged to take place; and most of the German and other Continental railway companies intend granting facilities for the conveyance of visitors to this meeting at greatly reduced tariff.

Explosion caused by Ammonia Gas.—M. Werner.—On the 18th of February last, an explosion took place at the chemical works of Messrs. Kunheim and Co., Berlin. It appears that a large iron vessel of cylindrical shape, 6 feet in diameter, and 4½ feet high, and 13-16ths of an inch in thickness, was used for the evolution of ammonia gas from a somewhat thickish magma; but this operation had been carried on in the same manner for twenty years, and with iron vessels of similar description, which were properly renewed when required. It was this apparatus which exploded; and the author states that the vessel was strong enough to withstand a pressure of 20,000 pounds to the square inch. The apparatus have since been provided with safety-valves; for it appears that the explosion took place immediately after the apparatus had been filled with about 4000 lbs. of ammoniacal liquor, and that the explosion was the joint effect of steam and ammonia gas. The iron apparatus was found to be throughout well made, of good quality and strength, and only a suddenly-applied force would break it.—*Zeitschrift des Vereines Deutscher Ingenieur.*

Testing Acetic Acid.—The value of commercial acetic acid can be estimated by ascertaining how much soda, or carbonate of soda, a given weight can neutralise. Inorganic acids, if present, would also neutralise the alkali; they must be tested for separately, or the determination corroborated, by evaporating the neutralised liquor to dryness, and calcining it at a red heat. All the acetate of soda is then converted into carbonate, the quantity of which may be dosed by the test acid; if it corresponds in quantity with the alkali first required to neutralise the acid, there is no mineral acid present; if it falls short the difference may be ascribed to some mineral acid, the soda-salt of which is not decomposed by red heat. Good commercial acetic acid contains from 18 to 22 per cent of anhydrous acetic acid, and traces only of sulphates and chlorides. When 100 grains of acetic acid neutralise 62 grains of crystallised soda, the acid contains 23 per cent of anhydrous acetic acid. Acetic acid should be tested for lead and copper, for sulphuric, hydrochloric, and nitric acids, should be entirely volatile on being boiled, and, when concentrated, its vapour should readily ignite on being approached by any flame. The strength of vinegar can also only be determined by the same means as indicated for acetic acid. When acetic acid or vinegar are evaporated to dryness on a water-bath, after addition thereto of a few drops of a strong clear solution of loaf-sugar, there should not ensue a deep brownish or black colouration on the residue becoming dry, which would indicate the presence of sulphuric or hydrochloric acids. Vinegar always contains sulphates and chlorides, and, if deeply coloured, also organic matter; the presence of the salts just named is due to the water applied in making the vinegar. Acetic acid should be free from tarry matters and aceton; they will be discovered on gently evaporating, and also on saturation, best with pure carbonate of lime.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

In accordance with the generally expressed wishes of our friends and readers, we have effected arrangements to enable us to give, under the above heading, notices of EVERY CHEMICAL PAPER IN THE WORLD, *as soon as possible after publication. Whenever possible, these notices will appear in the form of carefully prepared, although necessarily brief, abstracts; as respects papers either too long or too abstruse to render condensation possible, their titles will be chronicled; and in all cases accurate reference will be made to the original publication. The two half-yearly volumes of the* CHEMICAL NEWS, *with their copious indices, will therefore be equivalent to an English edition of the "Jahresberichte," with the additional advantage of keeping the readers week by week on a level with the latest advances of science.*

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus des Séances de l'Académie des Sciences, August 23, 1869.

This number contain the following memoirs and communications bearing more especially upon chemistry:—

Researches on the Ethereal Derivatives from Propylic Alcohol.—MM. Pierre and Puchot.—Iodide of propyl, prepared by the reaction of phosphorus upon a mixture of pure propylic alcohol and iodine, exhibits, after repeated purification, a colourless liquid, having a sweetish, somewhat alliaceous odour, boiling at 104·5°; sp. gr., 1·784 at 0°. When this fluid is exposed to air, it is slowly decomposed, and iodine is set free.—Valerianate of propyl, prepared by distilling a mixture of pure propylic alcohol, pure valerianate of potassa, previously dried, and sulphuric acid, very cautiously and gradually added to the mixture, is, after having been purified, a colourless liquid boiling at 157°; sp. gr. at 0°, 0·887.—Butyrate of propyl, $C_8H_7O_3,C_6H_7O$, is obtained by the very cautious distillation of a mixture of previously-dried butyrate of potassa, propylic alcohol, and sulphuric acid. After repeated rectification, a fluid is obtained which boils at 137·25°, is colourless, and exhales the odour of fruit and herb of mint, mixed; sp. gr. at 0°, 0·888.—Acetate of propyl, $C_4H_3O_3,C_6H_7O$, is prepared by distilling a mixture of propylic alcohol, dried acetate of soda, and sulphuric acid. After repeated rectifications, a very limpid, colourless, agreeably-smelling liquid is obtained, boiling at 103°. Sp. gr. at 0°, 0·910.—Formiate of propyl, C_2HO_3,C_6H_7O. After rectification, a liquid is obtained boiling at about 83°. Sp. gr. at 0°, 0·9197.—Propionate of butyl, $C_6H_5O_3,C_8H_9O$, is obtained by distilling a mixture of previously-dried propionate of potassa, butylic alcohol, and sulphuric acid, after repeated distillation and rectification of the raw liquid first obtained. The pure ether is a very fluid, colourless, agreeably-smelling liquid, boiling at 135·7°. Sp. gr. at 0°, 0·8934.—Propionate of ethyl, $C_6H_5O_3,C_4H_5O$, obtained by distilling a mixture of previously-dried propionate of potassa, pure strong alcohol (95 per cent), and sulphuric acid. The purified liquid boils at 100°; its odour is somewhat akin to that of acetic ether. Sp. gr. at 0°, 0·9137.

The Metrical System.—M. J. Dumas.—The report of the committee on this subject, of which this eminent *savant* is the spokesman, reviews the labours of a very select committee of eminent men, representing not only France, but also Switzerland and Holland, who commenced their work in the year 1790, and finished it on the 4th of Messidor, of the year VII. (23rd of June, A.D. 1800). The present committee recommends that the standards of weights and measures in the custody of the Academy shall on no account whatever be altered or tampered with in any way. Since these standards have been made and verified by an international committee of *savants*, and every care was taken to ensure the perfection of these standards, the committee also recommend that the French Government shall give permission to delegates of foreign nations to get copies made of the standards alluded to under proper supervision, and that these delegates do take what care they deem proper to ensure correctness of these copies.

Manufacture of Special Kinds of Pig-Iron.—M. Jordan.—This is a metallurgical memoir, wherein the author discusses the calorific phenomena produced by the injection of jets of air, steam, or oxygen into molten cast-iron. The tendency of this paper, is entirely practical, and it is, moreover, too lengthy for useful abstraction.

Chloride of Acetylen and the Synthesis of Julin's Chloride.—MM. Berthelot and Jungfleisch.—Instead of making chlorine in free state act upon acetylen, the authors have applied chloride of

his researches, consisted, in 100 parts, of:—Lime, 18·89; boracic acid, 46·11; water, 35·00. Since the time this analysis was made, the mineral locally known as teza has become an article of commerce, and is brought over to Europe with the view of being applied to the manufacture of boracic acid and borax. According to the author, this mineral, which is chiefly found in nodules among the nitrate of soda beds of Peru, when dried at 100°, has, in 100 parts, the following composition:—Borate of lime, 52·39; borate of soda, 10·23; sulphate of soda, 1·06; chloride of sodium, 3·76; residue insoluble in acid, 4·23; water, 28·33.

The Manufacture of Borax from the Native Borate of Lime.—Dr. Graeger.—The author states that, since he found that what is stated in treatises and handbooks on chemistry concerning pure borate of lime is generally quite erroneous, he commenced by studying the properties of that substance more minutely. Pure borate of lime is only slightly soluble in pure water, 100 parts of which, at about 18°, only dissolve from 0·304 to 0·333 parts of that salt; boiling water does not dissolve, perceptibly, more of this salt. A solution of pure borate of lime in water behaves, with the following reagents, in the following manner:—Ammonia, no precipitate; caustic potassa solution, very slight precipitate, due to a trace of carbonate present along with the caustic alkali; carbonate of ammonia, copious precipitate, soluble in excess of precipitant; carbonates of potassa and soda, permanent precipitates; neither the nitrate of protoxide, nor of peroxide of mercury, nor, also, neutral chloride of iron, exhibit any reaction with the solution in question; solution of sulphate of copper gives a greenish blue precipitate. Since borate of lime is less soluble, even in alcohol, than sulphate of lime, a solution of the former salt in water containing only 1000th part of the salt is readily precipitated by alcohol containing 60 per cent of absolute alcohol. The presence in solution in water of some salts, especially chloride of sodium and ammonium, largely increase the solubility of borate of lime in water. Such acids as form with lime readily soluble salts, do readily dissolve borate of lime, both pure and native; and from such solutions, if concentrated, boracic acid is precipitated. The portion of this paper relating to the manufacture of borax and boracic acid from the native borate of lime alluded to, is rather a practical receipt for the proper performance of this branch of industry, and, therefore, not well suited for abstraction, the less so as the price of fuel, soda, and other things necessarily influence the applicability of the borate of lime for that purpose.

Glycerine as a Substitute for Spirits of Wine for the Preservation of Zoological and Anatomical Preparations.—Dr. Koller.—The author recommends concentrated glycerine as being cheaper, not liable to evaporation, not combustible, and, moreover, as better preserving the natural colour of various preparations usually kept and preserved in spirits of wine. According to the author, glycerine answers this purpose eminently.

New Method of Fusing Difficultly Decomposable Minerals.—Dr. Vorwerk recommends that 1 part of the previously very finely-powdered mineral should be mixed with 3 parts of fluoride of sodium, and that this mixture, after having been placed in a platinum crucible, should be covered with 12 parts of powdered bisulphate of potassa. Minerals such as chrome iron ore, hard hæmatite, tin ores, and rutile, corundum, and the like, are very readily brought to fusion and disintegrated by this flux, even with no more heat than that obtained from a good Bunsen gas-burner.

Sindor Oil and Sindor Balsam.—M. Maier.—These substances are used externally, in some diseases of the skin, by the Javanese. The real sindor tree belongs to Borneo, and is called there pohon-sinampar. The balsam investigated by the author has the consistency of balsam copaivæ, and exhibits a smell not unlike the latter substance; sp. gr. at 27·5°, 0·9221. The sindor balsam boils at 255°; burns, when heated to a higher temperature, with a flame emitting much soot and smoke; on being distilled along with water, the balsam left a reddish brown-coloured transparent resin. The balsam is difficultly soluble in alcohol, and on being brought into contact with strong sulphuric acid, became blood-red coloured. The essential oil, obtained by distilling the balsam with water, was of a light yellow colour, very fluid, boils at between 245° and 250°; sp. gr. at 27°, 0·914; soluble in from 4 to 5 parts of cold, and from 1 to 1½ parts of hot alcohol. The author extended his researches to other balsams, which, though bearing the same name, are evidently either obtained from different trees, or have undergone peculiar preparations whereby their physical and chemical properties are very much altered. As to the trees yielding these balsams, the eminent botanist, M. Teysmann, who has resided for upwards of forty years in Java, states that they are not precisely known.

Distinction between Gum Arabic and Gum Senaar.—M. Schlosser.—According to the author, these two kinds of gum are not, as generally supposed, different only in quality from each other, but the senaar gum is undoubtedly derived from another tree. The behaviour of these two kinds of gum with acetate of lead is, according to the author, a ready means of distinguishing between the two with certainty; take 3 grms. of pure gum arabic, dissolve in 15 grms. of water, add gradually, and whilst stirring the mixture, 30 grms. of acetate of lead (from the wording in the original, it is impossible to infer whether an aqueous solution is meant or the dry salt in powder) there thus ensues a whitish precipitate, forming a rather thickish magma, which is transferred to a filter, the filtrate, about 18 to 20 grms., running off, exhibiting a hardly even opalescent fluid; the filtration is finished in an hour's time, and the residue left on the filter is no more fluid; take about 6 grms. of the filtrate, add 5 grms. of pure water and 1½ grms. of liquid ammonia, specific gravity 0·960, the fluid will remain quite clear, and even if, after twelve hours' time, a sediment were deposited, this does not amount to more than ¼ c.c. When gum senaar is treated in the same way it yields a milky filtrate; the filtration is extremely slow, and even after twenty-four hours the substance on the filter appears fluid. When 6 grms. of this filtrate are treated precisely as just described, the contents of the test tube, on being shaken about, become solidified, exhibiting a gelatinous mass.

A New Preservative Against Fire.—M. Reinsch.—The author states that, having been requested to report to a fire insurance company about the best means of preventing timber bursting into flame, he experimented with various salts, and at last came to the conclusion, as the result of his experiments, that impregnating timber with a concentrated solution of rock salt is as good, if not better, a preservative against its bursting into flame as water glass (silicate of soda), while the price of the former salt is, of course, only a mere trifle; moreover, rock salt thus applied to timber is a preservative against dry rot and noxious insects. The author recommends the use of salt water, that is to say, a solution of rock salt of moderate strength for the use of fire engines during a fire as by far more effective than water; but in order that the salt should not injure the working parts of the engines, they will immediately afterwards have to be played with fresh water again.

Cosmos, August 28, 1869.

This number contains, amongst its very varied information, the following:—

What becomes of Old Shoes.—They are cut up in small pieces, and these are put for a couple of days in chloride of sulphur, the effect of which is to make the leather very hard and brittle. When this is found to have been effected, the material is withdrawn from the action of the chloride of sulphur, washed with water, dried, ground to powder, and mixed with some substance which causes it to adhere together, for instance, shellac or any other resinous material, or also good glue or thick solution of gum; it is then pressed into moulds and shaped into combs, buttons, knifehafts, &c.

The Poisoned Fountain.—In La Limagne, Département Puy de Dôme, France, carbonic acid is nearly everywhere given off in smaller or larger quantity from the limestone formation which occurs there. Near Aigueperse, a town in the Département just named, a locality exists which is popularly named the "poisoned fountain;" it consists of a round hole placed in a depression of the soil, and this hole contains somewhat turbid water, from which carbonic acid constantly escapes, accompanied by a noise as if steam were blowing off from the safety valve of a steam boiler. It often happens that birds and other animals which come near this hole to drink from the water it contains, are asphyxiated at once by the carbonic acid. Such sources are often found in volcanic districts; near Naples the well-known "Grotto del cane" occurs, and the "Death valley" in the island of Java is the most extensive instance of this kind known.

NOTES AND QUERIES.

Aniline Colours.—Can any of your correspondents kindly favour me with the best and cheapest method of dissolving aniline colours suitable for calico-printers?—Alexis.

Tungstate of Soda.—Can you tell me if tungstate of soda is a conductor or non-conductor of heat, and where I can get it, and price? I want it to make paper fireproof, or can you tell me of anything else that will make paper fireproof, and at the same time a non-conductor of heat, and cheap?—Alfred Burn.

Printing Scarlet.—Can any of your courteous readers inform me of a substance that will prevent a solution of bichloride of mercury from being decomposed when boiled in a copper kettle, but afterwards permit it to be precipitated as a scarlet biniodide by a solution of iodide of potassium? I wish to print it upon cotton-cloth, using the same *modus operandi* as calico printing. I find that the copper colour-kettles and printing-rollers decompose it, in consequence of the mercury uniting with the copper. The effect is not satisfactory if I use the solution of iodide of potassium as a mordant. How can I prevent the chloride solution from being decomposed?—William.

TO CORRESPONDENTS.

*** The Students' Number of the Chemical News will be published on Friday, September 17th. Gentlemen holding official positions in the Universities, Medical Schools, &c., of the United Kingdom, where Chemistry and Physical Science form a part of the Education, who have not yet forwarded the necessary information to our office for publication in that number, will confer a favour by sending it with the least possible delay.

ON THE

DETECTION OF FIXED OILS IN PLANTS.*

By T. T. P. BRUCE WARREN.

THE object of this communication was to point out a simple method applicable, on a small scale, to the determination of oils in vegetable juices, &c.

To juice containing caoutchouc, hydrochloric acid is first added, to coagulate it. The residue is treated with bisulphide of carbon, which dissolves out the oily and fatty matter. The addition of dichloride of sulphur causes a granular precipitation in the clear decanted solution.

Fibrous substances are preferably treated with rectified ether, and the caoutchouc, if present, removed by the addition of alcohol, before digesting in bisulphide of carbon.

ON THE

PRESENCE OF SOLUBLE PHOSPHATES IN SEEDS.†

By F. CRACE CALVERT, Ph.D., F.R.S.

SOLUBLE PHOSPHATES IN COTTON PODS.

SOME results which I had obtained on the presence of the acid phosphate of magnesia in cotton-fibre, and which I had the honour to lay before the Chemical Society some time since, induced me to continue these researches with a view of ascertaining if the same phosphate existed in the other portions of the cotton pod, viz., the husk and the seed, and, if not, whether the phosphoric acid existing in the same was combined with other bases. It will be, no doubt, also remembered that I found that the mean quantity of acid phosphate of magnesia, $2MgO,HO,PO_5$, in ten samples of cotton fibre which had been imported from various parts of the globe, was equal to 0·05 per cent PO_5, or 0·084 $2MgO,HO,PO_5$.

But, before examining the nature and amount of phosphates present in the husk and seeds constituting the cotton pod, I deemed it advisable to repeat my former experiments, and to confirm them by separating the cotton fibre from the same pods from which I intended to submit the husks and seeds to analysis, and I am glad to say that I obtained results confirming entirely the previous ones, viz., that 100 parts of cotton fibre yielded, when repeatedly washed with water, a quantity of acid phosphate of magnesia = 0·084 of acid phosphate of magnesia, or 0·050 of phosphoric acid, and, further, as in my previous results, only a trace of potash and lime were found in solution, and that no other salts of magnesia existed in solution.

HUSKS.

To ascertain if the amount and nature of the phosphates in the husks of the cotton pods were the same as in the fibre, 14·45 grms. of husks were reduced to fine powder, and steeped for twelve hours with 250 grms. of distilled water. This operation was repeated four times each, and the whole of the washings were filtered off, evaporated to dryness, and the residue calcined, and the following results were obtained on the analysis of the ash:—Only a small quantity of magnesia and lime was detected, nearly the whole of the phosphoric acid being combined with potash and with oxide of iron. The following results being obtained—

One hundred parts of husk gave—

Phosphate of potash, 0·531 = 0·178 PO_5, combined with potash.
Phosphate of iron, 0·227 = 0·106 PO_5, combined with sesquioxide of iron.
Phosphate of lime, 0·030 = 0·016 only PO_5, combined with lime.
And a trace of magnesia.

Therefore the phosphoric acid in the husk is not combined with magnesia, as in the fibre, but with potash and oxide of iron, and the total amount of phosphoric acid, instead of being 0·050, as in the cotton fibre, is 0·300, or six times as large.

SEED.

I now proceeded to determine the composition and amount of phosphates in this portion of the cotton pod, and obtained the following results:—

0·650 of phosphate of potash = PO_5, 0·217
0·117 of phosphate of magnesia = PO_5, 0·069
0·025 of phosphate of iron .. = PO_5, 0·011

These results, which are the mean of two analyses, as in the previous cases, show that the phosphates exist in much larger quantity in the seed than in the other parts of the pod—being, in fact, about sixteen times as large as in the fibre, and between three and four times that found in the husk.

Thus the quantity of phosphoric acid and phosphate existing in the various parts of the cotton pod are—

	PO_5.
Husk	0·300
Fibre	0·050
Seeds	1·092

The above results reveal two important facts—viz., that phosphates of potash, magnesia, and iron predominate in seeds, and not the phosphate of lime, as it was generally admitted; also that the nature and amount of the phosphates vary with each part of the said pod.

Further, it will be observed, that, in the husk, the phosphates of iron and potash predominate; in the fibre, phosphate of magnesia; and in the seed, phosphates of potash and magnesia. And what increases the interest is that nearly the whole of the bases existing in the cotton pod are combined with phosphoric acid.

THE AMOUNT OF SOLUBLE AND INSOLUBLE PHOSPHATES IN WHEAT SEED.

English White Soft Wheat.—220·8 grms. of very carefully picked and cleaned white wheat, dried at 230° F., were repeatedly washed with distilled water, and the washings evaporated, and the residue calcined, when only—

0·010 of residue was left, thus showing that water had little or no action upon the grain when acted upon in such a condition.

I therefore decided to act on the same grain when crushed, so that water could penetrate into the mass, and dissolve all soluble salts; but, before doing so, I deemed it advisable to determine the total amount of phosphoric acid existing in the wheat operated upon, and obtained, in one analysis, 0·633 per cent of phosphoric acid, and, in a second analysis, 0·677 per cent, or 55·5 on 100 parts of ash.

These results clearly show, as Fresenius has done before me, that nearly the total of the ashes left by wheat is represented by phosphates.

With a view of ascertaining what amount of these phosphates would be dissolved by water in crushed wheat, 50 grms. of white, crushed soft wheat, dried at 230° F., were placed in a bottle with 150 grms. of distilled water, mixed with a little carbolic acid, so as to prevent any fermentation, or the production of any acid. After twenty-four hours, the aqueous solution was removed, and a fresh quantity of distilled water added; and these washings were repeated until all mineral matter was dissolved, the whole of the washings were evaporated, and the residue calcined. The amount of phosphoric acid determined

* Abstract of a paper read before the British Association, Exeter meeting, Section A.

† Read before the British Association, Exeter meeting, Section B.

was equal to 0·394; therefore nearly two-thirds of the phosphoric acid or phosphates existing in wheat are soluble in water.

English Red or Hard Wheat.—I deemed it advisable to determine the total amount of phosphates and of soluble phosphates in red or hard wheat, as I had done in soft or white wheat, and thus found that 100 parts of red hard wheat, dried at 230° F., yielded 0·749 phosphoric acid; and that 100 parts of the same, when dried at 230° F., and crushed, yielded 0·376 of soluble phosphates.

I regret that I had not the opportunity of repeating these results on white and hard wheats obtained from various countries, or cultivated on different classes of soils, viz., clay, lime, or sand formations, as the phosphates are in larger proportion in red wheat than in soft, and that half the phosphates are soluble in the red wheat and two-thirds in the white soft wheat, and therefore I cannot, under these circumstances, assume that the difference in amount of the phosphates is due to the nature of the wheat, and not to the soil.

These results led me to enquire if the various parts which constitute the grain of wheat contain the same amount and nature of phosphates when separated by the successive and different operations carried out by a miller.

The results of my experiments, as it will be seen, have fully answered my expectations—viz., the phosphates in each section of the cortical parts of the grain do not so much vary in their nature as they do in quantity: their amount decreases gradually from the outer sections towards the central ones; thus, whilst the flour contains only a trace of phosphates, especially soluble ones, the bran contains a large quantity.

The total amount of phosphoric acid in—

Bran	1·682
Flour	0·971

Soluble phosphates—

Bran	1·264
Flour	0·080

A large miller in the neighbourhood of this city having kindly consented to grind and bolt a few sacks of wheat, to enable me to obtain in a separated state the various parts constituting the grain, and placed in my hands the five distinct specimens, as representing in a rough way those various layers presented by a grain of wheat.

No. 1. Coarse bran.
No. 2. Coarse bran.
No. 3. Coarse sharps.
No. 4. Fine sharps.
No. 5. Flour.

AMOUNT OF PHOSPHORIC ACID AND PHOSPHATES IN THE VARIOUS PARTS OF WHEAT.

	Corn and bran.	II.	III.	IV.	Flour.
Phosphoric acid combined with sesquioxide of iron	0·042	0·047	0·037	0·015	0·022
Phosphoric acid combined with magnesia and a small quantity of CaO	1·485	1·259	0·657	0·329	0·047 0·144
Phosphoric acid combined with potash	1·071	1·046	0·459	0·280	0·758
Total—	2·598	2·352	1·153	0·624	0·971
Phosphate soluble in water	1·942	1·666	0·918	0·529	0·080

These facts also tend to show that most of the phosphates contained in wheat are not combined with the organic matter, but are in a free condition.

Further, that the greatest part of the phosphates are soluble, and combined with potash and magnesia, whilst the insoluble phosphates are represented by lime, iron, with a small proportion of MgO, the latter salt being probably neutral phosphate of magnesia, $3MgO,PO_5$, whilst the salt of MgO in solution is $2MgO,HO,PO_5$; and what tends to support this view is that, although the same weights of bran were washed with the same quantities of water, and for the same space of time, the quantities of phosphates of magnesia decrease rapidly in each successive layer of the seed as we proceed from its external part towards its interior.

Also that, whilst in No. 1 bran only one-fifth of the phosphates are retained as insoluble, in No. 4 one-sixth remains in an insoluble condition.

These analyses clearly illustrate that, although habit and pride have gradually led us to prefer white bread to brown, or more so bread made with nearly the whole of the constituents of wheat grain, still this practice is an error when we consider the nutritious properties of wheat, especially as a food for children, when phosphates are so essential to the formation of bone and blood; and medical men would confer a great boon on society if they were to impress the importance of feeding children with a wheaten preparation in which all the constituents of the grain were preserved.

These views are further supported by some very interesting researches published in the *Comptes Rendus* by M. Mège Morries, in which he proved that there was, in the inner cortical parts of the wheat, a special ferment, which converted most rapidly starch into sugar, and thereby facilitated the conversion of wheaten flour into bread.

These observations of M. Morries led him to devise a peculiar mode of grinding wheat, and making bread from the flour thus obtained, and the results were such that, from every hundredweight of wheat, he was enabled to obtain of bread—

Wheat, 100.

Ordinary process ..	70 flour ..	92 bread
M. Morries	82 „ ..	110 „

This method was so satisfactorily carried out that the Emperor of the French adopted it at the military bakery of Paris, in which bread is baked every day for 100,000 men.

In conclusion, I may be permitted to state that I am aware of the analyses of wheat which have been made by Professor Way and Dr. Voelcker, and especially of those remarkable and extensive researches published by G. B. Lawes, F.R.S., and G. H. Gilbert, F.R.S., "On the Composition of the Ash of Wheat Grain," and, by the last-named gentleman, "On Wheat Grain and its Product in the Mill." But the researches of these gentlemen only give the total amount of phosphoric acid in these products, but do not give, as I have attempted to do, the respective various proportions of phosphates of potash, magnesia, lime, and iron which exist in the various parts of wheat grain.

ON THE PHOSPHORESCENCE OF THE SEA, AND ON OZONE IN CONNECTION WITH ATMOSPHERIC CONDITIONS.*

By J. MOFFAT, M.D., F.R.A.S., F.G.S., &c.

As it appears from results deduced from observations taken at sea, that ozone periods (as on land) commence, and that ozone is in maximum quantity with decreasing readings of the barometer and the conditions of the south or equatorial current of the atmosphere, and that ozone periods terminate with increasing readings of the barometer and the setting in of the polar current, and that phosphorus is luminous and non-luminous under similar conditions, I supposed that there might be some con-

* Read before the British Association, Exeter Meeting, Section B.

nection between ozone and the phosphorescence of the sea.

Observations are still taken, and I hope to be able to give results from a larger area. The following are deduced from observations taken between latitudes 58° and 79° N., and longitudes 6° E. and 67° W. :—

TABLE I.

Shewing the Amount of Ozone with (at Sea)—

BAROMETER.		DIRECTIONS OF THE WIND.				PHOSPHORESCENCE.	
Increasing.	Decreasing.	N. to E.	S.E.	S. to W.	N.W.	None.	Brilliant.
2·9	4·7	1·6	2·7	3·7	3·2	2·4	3·0

TABLE II.

Shewing the Mean Reading of the Barometer, Mean Temperature, and Daily Mean of Ozone at the Commencement and Termination of Phosphorescence of the Sea, between latitudes 58° and 79° N., and longitudes 6° E. and 67° W.

Phosphorescence.	Barometer.	Thermometer.	Ozone.
Commencement of	29·46	34·8	2·9
Termination of	29·65	30·0	1·5

TABLE III.

Shewing Mean of the Barometer and Thermomcter, and the Daily Mean of Ozone, with Commencement and Termination of Periods of Luminosity of Phosphorus, deduced from the Observations of Six Years (on Land).

Periods of Luminosity of Phosphorus.	Mean of Barometer.	Mean of Thermometer.	Mean of Ozone.
Commencement	29·640	47·3	5·0
Termination	29·734	43·4	3·0

By these results, it appears that the phosphorescence of the sea and luminosity of phosphorus occur under similar atmospheric conditions.

The amount of ozone the day before phosphorescence			0·8
,,	,,	day of	,, 2·5
,,	,,	day after	,, 1·9

Of auroral displays, one was without ozone, and 50 per cent were accompanied by phosphorescence.

A FEW REMARKS ON THE

REDUCED OR PRECIPITATED PHOSPHATE OCCURRING IN SUPERPHOSPHATES.

By ALFRED SIBSON, F.C.S.

THE fact of superphosphate "going back," or losing in soluble phosphate, on keeping, will hardly at present be disputed, the question at issue being whether the phosphate so reduced can be estimated or not.

It often happens that a quantity of superphosphate, which, when freshly made, contains, say, 25 per cent of soluble phosphate, is found, after keeping (in some cases only a short time), to have lost 2, 3, 5, or even more, per cent of its soluble phosphate; in fact, the paper of Mr. Sutton, which appeared two or three week's since, and which, although averse to the above question, the superphosphate operated on is stated to have contained, originally, 23 per cent, while it then had only 17 to 18 per cent, or a loss of 5½ per cent. Instances of this kind are, however, familiar to all who have had much to do with this class of manures.

As it is, also, found impossible by the manufacturer to calculate upon the extent of this retrogression, it is a constant source of dispute between buyer and seller, and also tends to bring discredit on analysis, as there is no apparent reason why a superphosphate should contain less soluble phosphate at one time than it did at an earlier period; in fact, the contrary would naturally be expected from the concentration of the bulk through the loss of moisture.

There thus appears an urgent necessity for some means of determining the phosphate so reduced; and if a scientifically-accurate method be not forthcoming, it appears to me only reasonable to be satisfied, under the circumstances, with some method which, for all practical purposes, gives comparative and reliable results; such a method I have found to be the following:—

The point is to find some reagent which does not affect the undecomposed coprolite (that being the mineral now more especially considered). I soon found that dilute acids, including acetic, citric, and oxalic (this least so), were objectionable on this account, and was led to try oxalate of ammonia, which, as a perfectly neutral salt, would be altogether unlikely to decompose a perfectly mineralised substance like coprolite. As well known, the decomposition of gelatinous phosphate of lime by oxalate of ammonia is a quantitative reaction, which takes place at once, the only necessity for boiling being to assist the subsequent filtration. Boiling for ten minutes at the most is sufficient to effect this object, while the oxalate does not, under these circumstances, attack the coprolite to any material extent. I am aware this statement is somewhat at variance with the results of other contributors which have lately appeared, but, as the process they state differs from that I have adopted, the different results may, perhaps, be accounted for. I have no intention, however, of entering into a controversy on this subject, but give the full particulars of the process, so that any one interested in the matter can try it for himself. I have since found that oxalate of ammonia had been suggested by others for this purpose, but was unaware of the fact when I selected it.

25 grains of Cambridge coprolite are boiled, with an equal weight of oxalate of ammonia, in 2 ounces of water, for ten minutes, and filtered; the filtrate acidified with hydrochloric acid, and made alkaline with ammonia (merely to ensure the presence of chloride of ammonium); and ammoniacal sulphate of magnesia added. No precipitate will probably be obtained; but, *if it be obtained*, it is not conclusive of the presence of phosphoric acid; and great errors may be made if a precipitate in this place be accepted as phosphate of magnesia and ammonia. After standing for two hours, the small precipitate is collected (which often resembles the phosphate closely, but consists of oxalate of magnesia, which sometimes separates from a concentrated solution, and a little oxide of iron) and re-dissolved in hydrochloric acid, citric acid added, and re-precipitated with ammonia. A precipitate, if now obtained, consists of phosphate of magnesia and ammonia only, and if burned and weighed as phosphate of magnesia in the usual way, will be found to amount to less than 0·50 per cent, calculated as bone-earth. This was found to be the case with coprolite ground as fine as it is possible to get it for analysis; but I have just been through the process again with coprolite in the state usually employed by manufacturers, and find no weighable quantity of phosphate of magnesia after standing three hours. I thus consider that 0·50 per cent of phosphate of lime is the utmost error that can be made by this process under proper management.

In the case of a superphosphate containing reduced phosphate, and treated as above, after having first extracted the soluble phosphate, by cold water, the phosphate of magnesia calculated as bone-earth will represent the phosphate so reduced.

I am aware of the new process, suggested by Mr. Chesshire, and adopted by the chemists for the plaintiff (with the exception of myself) in the late trial at Gloucester, referred to by that gentleman, and have, therefore, every confidence in its value, but have not yet satisfied myself whether it is superior to the plan I have hitherto adopted as above described.

I need scarcely add that it is not my intention to introduce the determination of precipitated phosphate into my ordinary analysis of superphosphate, nor include it in the

usual determination of soluble phosphates, but only give it when especially requested, and state it separately; since, whatever its agricultural value may be (space forbids my entering upon this part of the question), it is no longer soluble phosphate, and will not obviously pass as such when a definite percentage of soluble is bargained for; its value is, however, at the same time very superior, I consider, to undecomposed, or ordinary insoluble phosphates.

There is one objection to the introduction of this constituent into the ordinary analysis of manures—viz., that it would be likely to lead to greater discrepancies than occur at present, and which, I believe, are caused far more by a want of sufficient attention and method in the details of the analysis on the part of the operator than by any defects in the method of analysis.

Finally, as regards the ordinary determination of soluble phosphates in superphosphates, I find the method of precipitation perfectly satisfactory and consistent when carefully performed, and believe it to be by far the best method; while, in point of time, it leaves nothing to be desired under proper management. I gave much attention to the uranium process some time since, but did not find it satisfactory in the case of superphosphates made from a mixture of phosphates.

ON

SOME DERIVATIVES OF TRICHLORMETHYL-SULPHON-CHLORIDE.

By O. LOEW,

Assistant in the Chemical Department of the College of the City of New York.

This chloride, discovered by Berzelius and Marcet in 1812, was the subject of extended investigations by Kolbe. Since that time, no investigations on this compound have been made, although it possesses many interesting properties. I find that the simplest way to prepare it is the following:—300 grms. of bichromate of potassium, in pieces the size of a pea, 500 grms. of common hydrochloric acid, 200 grms. of nitric acid of the common strength, and 30 grms. of bisulphide of carbon, are mixed in a flask, filling it to one-fourth of its capacity, and loosely stoppered. It is kept cool in the beginning, and shaken from time to time. In about eight days the process is finished; in direct sunlight, only four days are required. By addition of water, the chloride and nitrate of potassium are dissolved, and there remains the insoluble trichlormethyl-sulphon-chloride. It is filtered off, washed, and pressed between sheets of filter-paper.

When this chloride is dissolved in absolute alcohol, and treated with sulphuretted hydrogen, sulphur is deposited, and hydrochloric acid and another compound of an acid character remain in solution. By neutralisation with dry carbonate of sodium, the sodium-salt of this new acid remains dissolved in the alcohol, and crystallises by evaporation in shining scales.

0·469 grm. yielded 0·146 grm. of sulphate of sodium = 11·33 per cent Na.

0·236 grm. yielded 0·490 grm. AgCl = 51·37 per cent Cl.

0·511 grm. yielded 0·605 grm. of sulphate of barium = 16·24 per cent S.

The sodium-salt of the trichlormethyl-sulphurous acid requires—11·14 per cent Na; 51·95 per cent Cl; 15·56 per cent S; 15·56 per cent O; 5·81 per cent C.

To obtain the free trichlormethyl-sulphurous acid, the sodium-salt is decomposed by dilute hydrochloric acid and agitated with ether. The ether yields, by evaporation, this new acid in radiating needles. Both the acid and its salts are not of great stability; at a moderate temperature, especially when water is present, decomposition takes place, and a very offensive odour is evolved.

The formation of this acid takes place according to the following equation:—

$$\underbrace{(CCl_3)SO_2Cl}^{\text{Trichlormethyl-sulphon-chloride.}}{}^{*} + H_2S = \underbrace{(CCl_3)SOOH}_{\text{Trichlormethyl-sulphurous acid.}} + HCl + S.$$

The decomposition of this acid and its salts, by bromine and nitric acid, is very striking; the acid disappears, and new insoluble compounds are formed.

The action of bromine is expressed by the following equation:—

$$\underbrace{(CCl_3)SOOH}_{\text{Trichlormethyl-sulphurous acid.}} + Br_2 = \underbrace{(CCl_3)SO_2Br}_{\text{Trichlormethyl-sulphon-bromide.}} + HBr.$$

And the action of nitric acid—

$$\underbrace{(CCl_3)SOOH}_{\text{Trichlormethyl-sulphurous acid.}} + \underbrace{NO_3H}_{\text{Nitric acid.}} = \underbrace{(CCl_3)SO_2(NO_2)}_{\text{Trichlormethyl-sulphon-nitride.}} + H_2O.$$

The trichlormethyl-sulphon-bromide is a white crystalline body of a faint acrid smell, insoluble in water but soluble in alcohol and ether. On the application of heat a part is sublimed without change, while another part is decomposed. Ammonia dissolves it with evolution of nitrogen.

0·358 grm. yielded 0·313 sulphate of barium, corresponding to 12·01 per cent S.

0·492 grm. yielded 1·158 grms. AgCl + AgBr, and this mixture yielded, by reduction, 0·808 Ag, which proportions correspond to 30·77 per cent Br, and 40·22 per cent Cl.

The theory demands 12·19 per cent S, 40·57 per cent Cl, 30·48 per cent Br.

When trichlormethyl-sulphurous acid is brought into contact with concentrated nitric acid, a violent reaction takes place, and a blue oil is deposited which loses nitrous acid by contact with the air, and is converted into a white crystalline body, the odour of which inflames the eyes and is very suffocating when inhaled. This is the trichlormethyl-sulphon-nitride, especially interesting in this, that a nitride of an organic sulph-acid has been hitherto unknown. It is insoluble in water, soluble in ether and alcohol. Water added to the alcoholic solution precipitates it unchanged. It does not melt in boiling water, but is volatilised with the steam. Ammonia dissolves it slowly, with decomposition: alcoholic solution of caustic potassa decomposes it quickly. When it is treated with zinc and hydrochloric acid, it disappears, and is converted into sulphydrate of methyl and ammonia—

$$\underbrace{(CCl_3)SO_2(NO_2)}_{\text{Trichlormethyl-sulphon-nitride.}} + 18H = \underbrace{CH_3SH}_{\text{Sulphydrate of methyl.}} + H_4NCl + 2HCl + 4H_2O$$

0·5285 grm. yielded 0·532 sulphate of barium and 0·973 AgCl, corresponding to 13·83 per cent S and 46·12 per cent Cl.

Theory demands 14·00 per cent S and 46·61 per cent Cl.

On treating trichlormethyl-sulphon-chloride with ammonia, trichlormethyl-sulphurous acid is formed in an unexpected manner, nitrogen is evolved, and the chloride is slowly dissolved. On evaporation, broad tabular crystals are obtained. In the mother liquor, there remains chloride of ammonium, some sulphate of ammonium, and a certain quantity of this new compound. The crystals must be re-crystallised with great care, because, at a moderate temperature, an acid reaction sets in and a partial decomposition begins. These crystals show, with bromine, as well as with nitric acid, the formation of the above-mentioned bromide and nitride. The action of the nitric acid is extremely violent.

By mixing with diluted hydrochloric acid, and agitating with ether, the above-mentioned trichlormethyl-sulphurous acid is obtained.

* C=12 S=32 O=16.

0·431 grm. yielded 0·911 grm. AgCl = 52·24 per cent Cl.
0·668 grm. yielded 0·725 ammonio-chloride of platinum = 6·80 per cent N.
0·753 grm. yielded 0·894 grm. sulphate of barium = 16·23 per cent S.
Theory demands 53·11 per cent Cl, 6·98 per cent N, 15·96 per cent S.

The crystals are, therefore, the ammonium salt of the trichlormethyl-sulphurous acid, and their formation can be expressed by the following equation :—

$$\underbrace{3[(CCl_3)SO_2Cl]}_{\text{Trichlormethyl-sulphon-chloride.}} + 8H_3N = \underbrace{3[(CCl_3)SO_2H_4N]}_{\text{Trichlormethyl-sulphite of ammonium.}} + 2N + 3H_4NCl$$

On treating trichlormethyl-sulphon-chloride with cyanide of potassium, evolution of cyanogen and hydrocyanic acid takes place, and the potassium salt of trichlormethyl-sulphurous acid is formed—

$$(CCl_3)SO_2Cl + 2KCy = (CCl_3)SOOK + KCl + 2Cy.$$

But, when the solution is hot and very concentrated, there is, also, another derivative of this acid formed, one atom of Cl being replaced by one atom of OH—

$$(CCl_3)SOOK + H_2O = (CCl_2OH)SOOK + HCl,$$

which latter decomposes another part of the cyanide of potassium.

A glance at the following formulæ will show the relation between these new bodies and several others already known :—

Trichlormethyl-sulphon-chloride $(CCl_3)SO_2Cl$ (Kolbe).
Trichlormethyl-sulphon-bromide $(CCl_3)SO_2Br$.
Trichlormethyl-sulphon-nitride $(CCl_3)SO_2(NO_2)$.

Trichlormethyl-sulphur*ic* acid $(CCl_3)SO_2OH$ (Kolbe).
Trichlormethyl-sulphur*ous* acid $(CCl_3)SOOH$.
Methylsulphur*ic* acid $(CH_3)SO_2OH$ (Kolbe).
Methyl-sulphur*ous* acid $(CH_3)SOOH$ (Hobson).

ARTIFICIAL PRODUCTION OF ICE.

By P. H. VANDER WEYDE, M.D.

CALCULATION OF THE AMOUNT WHICH CAN BE PRODUCED FROM A GIVEN AMOUNT OF COAL IN THE MODERN ICE MACHINE.

THE amount of ice produced by an ice machine, worked by means of an exhaust or condensing air-pump, driven by steam power, is easily determined, theoretically, from the amount of coal burned in the furnace of the steam boiler. It has been proved that the combustion of one pound of anthracite coal produces, in round numbers, 14,000 units of heat, and that in order to freeze water of 72° Fahr., it is necessary to abstract, besides 40° of sensible heat, 140° of latent heat—together 180°—which, for one pound of water is, of course, equivalent to 180 units of heat. As this number of the units is the eightieth part of the 14,000 units produced by the combustion of one pound of coal, it is clear that the heat produced by the combustion of one ton of coal is equivalent to the heat to be abstracted from 80 tons of water of 72°, in order to change it into ice.

But in practice we find here exactly the same state of affairs as is the case with the steam engine. Theoretically, a steam engine ought to produce at least 700 units of force (foot-pounds) for every unit of heat consumed; in practice, good machinery only produces from about 70 to 100 foot-pounds, from about one-tenth to one-seventh part of the theoretical amount. In the best ice machines thus far constructed, instead of freezing 80 tons of water, for every ton of coal consumed, only from about 8 to 11 tons of ice are produced, also, from one-tenth to one-seventh part of the theoretical amount, proving, thus, the remarkable fact, that in both the steam engine and the ice machine, exactly the same relation exists between the theoretically calculated effects and the practical results.

As, however, all the best ice machines accomplish the conversion of the heat of the fuel into the freezing operation by the intervention of a steam engine, the fact that they practically produce only from one-tenth to one-seventh of the amount of the cold they theoretically should produce, is solely due to the other fact, that the steam engine itself practically produces only from one-tenth to one-seventh of the amount of power which would be strictly equivalent to the number of heat units consumed. It must not be lost sight of that it is only the power of the steam engine which generates the cold in the freezing machines, and that, therefore, improvements in the steam engine, which bring its practical results nearer to the theoretical standard, will at once exert their influence on the amount of ice the ice machines can produce, and, consequently, also on the cost of the ice manufactured in these machines.

Moreover, it appears that the kind of freezing machines in question, which convert power into cold, notwithstanding they are yet in their infancy, have already attained such a degree of excellence, that they are ahead of that class of machines which convert heat into power, either by steam, hot air, or any other possible means, as it is proved that they produce the full theoretical equivalent of cold (negative heat) for the number of foot-pounds employed; namely, cooling one pound of water one degree for a power equivalent to 700 pounds, descending one foot, which, expressed in the adopted scientific manner, is one unit of negative heat for every 700 foot-pounds consumed.—*Scientific American.*

ON A

NEW SOURCE OF THE FIRST TERMS OF THE FATTY ACIDS,

AMONGST OTHERS OF PROPIONIC ACID.

By M. BARRB.

THE dry distillation of wood produces a very acid liquid, from which acetic acid is extracted in large quantities. The general mode of purifying the latter is to saturate the liquid with carbonate of soda, when concentration produces crystallised acetate of soda and mother liquors. These latter diffuse a strong smell of molasses. When a certain degree of concentration has been reached, the crystals cease to form, and, if evaporation be continued, they assume a confused and hygrometric mass. This latter has been the subject of my experiments. On treatment with sulphuric acid, it decomposed, forming two liquid films, which were mingled into one by the addition of water. Instead of separating these acids by fractional distillation, I operated upon their ethers, first separating them into volatile portions—

I.	Between	55°	and	58°.
II.	,,	74°	,,	77°.
III.	,,	95°	,,	98°.
IV.	,,	114°	,,	119°.
V.	,,	133°	,,	136°.
VI.	,,	162°	,,	165°.

and then saponifying with baryta.

I. The baryta salt produced by the ether boiling at 55° or 58°, being heated with monohydrated sulphuric acid, disengaged pure oxide of carbon. This salt reduced nitrate of silver at the boiling point; formed with perchloride of mercury a white precipitate of protochloride, &c.; and it presented the crystallographic characteristics of formiate of baryta. The ether produced was therefore nearly pure ethylformic ether.

II. The baryta salt No. 2 was acetate, as might be foreseen.

III. Baryta salt No. 3, after purification by successive crystallisations, assumed the form of perfectly defined oblique prisms. The dry salt remained unaltered in the air. Its solution, left in contact with the atmosphere, evolved a slight odour, which proved the commencement of decomposition. When dried at 100°, it decomposed slowly, losing its water of crystallisation, and changed into a salt insoluble in water. It was impossible to obtain a sensibly-pure salt, except by evaporation at a very low temperature in a receiver whose atmosphere had been dried by sulphuric acid. Analysis gave 50·7 of baryta per cent of the salt. The propionate of baryta, according to the known formula, $C_6H_5BaO_4.HO$, contains 50·7 per cent of baryta.

The lead-salt, dried at 110°, yielded a syrupy, transparent, non-crystallisable mass.

IV. Baryta salt, No. 4, took the form of flattened prisms, melting below 100°. On analysis, it yielded 44·0 per cent of baryta; the butyrate of baryta, $C_8H_7BaO_4.2HO$, contains 44·6. This salt, when treated by chlorhydric acid and chloride of calcium, decomposes, and leaves a film of butyric acid floating on the surface of the liquid. Treated with a mixture of alcohol and sulphuric acid, it forms ethyl-butyric ether, having the characteristic smell of pine-apple.

V. Ether, No. 5, treated like the preceding, gives a salt which crystallises in thin flakes which effloresce quickly on contact with the air. The dry crystals, finely powdered and thrown into water, perform rapid gyrations.

When again dissolved in water and treated with sulphuric acid, an acid is formed, insoluble in water, distilling between 172° and 178°; this is valerianic acid.

VI. Baryta salt, No. 6, was crystallisable, but with difficulty. Its solution, treated with sulphuric acid, sets free a liquid acid lighter than water, but slightly soluble in the cold, soluble when warmed, soluble in every proportion in alcohol, distilling at from 198° to 205°. When saturated by a standard solution of caustic baryta, its equivalent was found to be 118·1, whilst that of caproic acid is 116. The difference of the equivalent is owing to the presence of a small quantity of acid boiling at a higher temperature, which hinders the crystallisation of the caproate.

On examining the relative proportions of these acids, formic acid is found to occur in small quantities only. Acetic acid is most abundant, the relative proportion of each diminishing as it rises in the series.

Propionic acid, whose soda-salt is very soluble in water, is found thus concentrated in the preparation of acetate of soda. The mother liquors, which contain a large quantity, might become an abundant source of its production, which has hitherto been attended with difficulty. The transformation of soda-salt into ethylic ether allows of complete purification.

This series of homologous bodies produced by a single reaction is dependent upon a general law in organic chemistry, that of simultaneous production; either in the order of analysis, the homologous bodies being produced by successive divisions, or in the order of synthesis, being formed inversely by successive additions.—*Comptes Rendus*, vol. lxviii., p. 1222.

Non-Poisonous Colours.—We have received two samples from Mr. F. Pettit, viz., yellow zinc and green zinc; and, after having tested them we are satisfied that the statements made by the makers of these colours are correct. Of the beautiful yellow and green pigments we have had the opportunity of testing, we affirm with pleasure that (1) they are not poisonous; (2) they do not become discoloured by the effects of burning gas; (3) they are not affected by sulphuretted hydrogen gas, and are not altered in shade—as far especially as the green is concerned—by artificial light. For paper-stainers, the manufacture of surface-coloured paper, for mixing with plaster-of-Paris for ornamental stucco work on walls, these colours will answer well, as they also will for mixing oil pigments, while, for pigment cotton printing, chromo-typography, and lithography, they will supply colours of great brilliancy, durability, and quite sufficient body.

ON A NEW REACTION OF PHENOL.

By C. CRUMP.

If fragments of caustic potash be added to a solution of phenol in chloroform, the potash becomes covered with a rose-coloured coat, which gradually dissolves in the liquid. Considerable heat is produced, and the action goes on rapidly until the mixture which at first was red has become brown and thick. It then slackens, but may be renewed by a gentle heat, until potash has been added equal in quantity to about three times the weight of the phenol.

The final product of the reaction is a brown amorphous mass, soluble in alkaline liquids, and precipitated therefrom by acids. It seems to be a mixture of two substances, differing in solubility in alkalies and in their behaviour with strong sulphuric acid.

The first substance dissolves very easily in carbonate of potash or soda, less readily in strong sulphuric acid. From the latter solution a precipitate is thrown down by water, which behaves with alkalies like rosolic acid.

The second substance dissolves less freely in alkalies, very easily in strong sulphuric acid, forming a brown liquid from which nothing is precipitated on dilution. With tetrachloride of carbon instead of chloroform no action takes place in the cold; at 100° C. the liquid assumes the colour of rosolic acid.

When creosote from wood-tar is treated with chloroform and caustic potash, a reaction takes place very similar to that with phenol, but the product of the reaction is quite different, forming with sulphuric acid a deep crimson solution, from which a dingy green precipitate is thrown down by dilution. Moreover, the substances produced from phenol in alkaline solution colour silk or wool brown, while those from creosote have no colouring power.

NOTICES OF BOOKS.

Alkali Act, 1863; *Fifth Annual Report by the Inspector of His Proceedings during the year* 1868. Presented to both Houses of Parliament. 1869. Eyre and Spottiswoode.

It will be in the memory of all of us that, in 1863, Lord Derby brought in a bill for the removal of the nuisance caused by alkali works. It had long been noticed that, in the neighbourhood of such works, no kind of vegetation could flourish; and other evils were found to result. It was hence proposed that means should be adopted for preventing the escape of hydrochloric acid into the air, and that an Inspector should be appointed to see that the enactments of the bill were properly carried out. Inasmuch as the bill was entirely free from any party influence, it rapidly received the assent of both sides of both Houses, and became law somewhat more than five years ago. Dr. Angus Smith was appointed Inspector, and he has annually issued a report, that which we are about to notice being the fifth.

In the report for 1867, the escape from the hydrochloric acid condensers was stated to be under 1 per cent, while 2 per cent was allowed for leakages through the brickwork. No diminution of this amount can be shown for the succeeding year, although, in the case of "open-furnace works," the escape is much smaller, and is considered to be not more than 0·5 per cent, leakage included. Various new furnaces have, however, been constructed, and it is confidently expected that the escape may ultimately be reduced to almost a vanishing quantity.

From page 6 to page 22, the space is occupied by accounts of various alkali works, and the improvements effected during the year; and first in the case of works with open roasters:—

No. 53. To each condenser is connected a wash-tower

containing 400 cubic feet of condensing space. The escaping gases were found to be reduced in temperature 400° F. between the roaster and condensers; the acid obtained was of 19° Twaddle, and the escape was 0·9 per cent.

No. 115. These are new works, and consist of one decomposing pan, a pan condenser 60 feet high, containing 2,400 cubic feet of condensing space, and one roaster condenser with two shafts, each containing 1400 cubic feet. Charge, 6 cwts. per hour; escape, 1·9 per cent.

No. 68. The escape varied from 1 to 5 per cent.

Secondly, in the case of works with close roasters:—

No. 45. March 3.—Two pots with flanges and rims, and close furnaces are used. A large quantity of acid found in the flue. April 7.—A large quantity of acid found in flue. July 16.—A new furnace, constructed with great care, was set to work; but the results were unsatisfactory, and the escape large. Ultimately, after many trials, another new furnace was set to work, on November 12th, and the result was found to be satisfactory, and the escape of acid small. However this may be, the above results sufficiently indicate the advantage of the "open-furnace" system, unless there are certain drawbacks connected with it in reference to other matters than the provisions of the Alkali Act. The testing-glasses of Mr. Kane continue to work well, and to indicate with precision an undue escape of acid into the flues. The main difficulty appears to be to prevent leakage through the hot brickwork of the furnaces, since the amount of acid escaping with the smoke can be reduced by condensation to certainly 0·5 per cent, and, by lessening the velocity of the escaping current, to even less than this.

In regard to the matter of cooling flues, experiments have been made as to the relative cooling powers of brick and iron flues, with the following results:—

An underground brick flue cooled 7° F. per 10 feet.
An overhead brick flue cooled 18° per 10 feet.
An overhead cast-iron flue cooled 30° per 10 feet.

Thus the iron flues are most advantageous as regards cooling effect, but they are somewhat rapidly acted upon by the evolved gases, and do not last so long as brick flues. The following analyses show the composition of the deposit from cast flues in Mr. Mease's works. The "up pipe" was 65 feet from the furnace, and the temperature 468° F. The "down pipe" was 130 feet from the furnace, and the temperature 289° F.

Analysis of the Deposit in Cast-Iron Flues.

	Up pipe.	Down pipe.
Peroxide of iron	19·866	26·946
Alumina	3·171	4·614
Lime	0·371	0·486
Magnesia	0·414	0·298
Soda	11·311	2·808
Sulphuric acid	53·212	48·077
Chlorine	2·141	2·034

Water, loss, &c., in addition.

A number of estimations of the sulphur in coal have been made by Dr. Angus Smith and Mr. Fletcher. An examination of 70 specimens of South Lancashire coal by the former showed an average percentage of 1·1 of sulphur; while the examination of some specimens of St. Helen's coal by Mr. Fletcher showed a minimum of 0·6, and a maximum of 2·22, per cent of sulphur. If 300 cubic feet of air are used to burn 1 lb. of coal containing 2 per cent of sulphur, the amount of sulphurous acid in the smoke will be a little more than 1 grm. in a cubic metre, since that is equal to 35·318 cubic feet.

A number of very interesting analyses are given of the composition of coal-smoke (pp. 26 to 34), from which we extract the following:—

Chimney of a sugar refinery, 200 feet high. Smoke taken from a height of 30 feet from the ground. Speed of smoke, 12 feet per second. Internal diameter of the chimney at 30 feet from the ground, 10 feet. Amount of coal burnt per day, 35 tons.

	Black smoke.	Common brown smoke.
CO_2	6·64	4·26
CO	0·40	—
O	11·17	16·63
H	—	—
CH_4	0·02	—
C_nH_{2n}	—	—
N	81·77	79·11
	100·00	100·00

One hundred cubic feet of black smoke were found to contain, in addition to the above gases, 1047·44 grains of water, and 18·52 grains of soot.

It was considered very advisable that the condition of the air at some distance from alkali works should be known; and this, as regards its acidity, would be obviously best determined by examining the rain-water collected direct in porcelain vessels.

The maximum acidity (*calculated as sulphuric acid*) of rain which fell in Manchester in 1857 was 7·3960 grains per gallon, and the minimum 0·3169 grains per gallon.

Pendleton, Manchester. 1857.

Maximum acidity, 3·3810 grains per gallon.
Minimum „ 0·2641 „ „

Hulme, Manchester. 1857.

Maximum acidity, 2·5886 grains per gallon.
Minimum „ 1·3734 „ „

Rain; Manchester. 1868.

Maximum HCl, 1·2775 grains per gallon.
Minimum „ 0·0278 „ „
Maximum $HOSO_3$, 5·6000 „ „
Minimum „ 1·4000 „ „

The total acid in rain collected from various sources bears the following relationship:—

Row, Dumbartonshire	100·00	= 1
Whiston, ten miles from Liverpool	470·67	= 4⅔
Birkenhead	528·29	= 5¼
Liverpool	938·21	= 9⅓
Waterloo, on the shore	961·98	= 9½
Newcastle-on-Tyne	1054·73	= 10½
Manchester	1175·54	= 11⅔
Near an alkali work	1539·27	= 15⅓

We can scarcely be surprised, after glancing at this table, at the rapid decay of stone in certain localities, compared with others, and the long endurance of buildings of antiquity which are far from large towns, and in a pure and open air—such as the Parthenon, and the Pyramids of Egypt.

Some very interesting drawings are given by Dr. Angus Smith, on page 46, of the microscopic appearance of rain-water residues; and we are told that oxide of iron, sulphate of soda, phosphates, chloride of ammonium, and other substances may be readily detected in the rain of some localities. We are surprised to find that Dr. Smith has not examined any of the residues spectroscopically, as this would appear to offer the best means of detecting the minute traces of substances which are present; or is it that, in point of fact, almost every element would be detected by such an infinitely delicate test? Certainly, Bunsen has found that lithia is generally present in the air near the sea shore. According to M. Robinet (*Comptes Rendus*, 1863, p. 493), the Paris rain-water contains a substance which gives a garnet-red precipitate with nitrate of silver. In a summary of results obtained, Dr. Smith gives, among others, the following conclusions:—

"The rain from the sea (Western Islands) contains chiefly common salt, which crystallises clearly.

"The sulphates increase inland before large towns are reached.

"The sulphates rise very high in large towns, because of the amount of sulphur in the coal used, as well as decomposition.

"When the air has so much acid that two or three grains are found in a gallon of the rain-water, or forty parts in a million, there is no hope for vegetation in a climate such as we have in the northern parts of the country.

"Free acids are not found with certainty where combustion or manufactures are not the cause.

"Experiments in the direction indicated above may enable us to study and express in distinct language the character of a climate, and certainly of the influences of cities on the atmosphere."

In the Appendix to the Report will be found an interesting letter by Mr. A. E. Fletcher, "On the Speed of Air in Flues," as determined by the ether anemometer invented by himself, and described some time ago in this journal (vol. xvi., p. 141). The tables will be found of especial value: the one giving the corrections for temperature in a range of from 0° to 1000° F.; the other to show the conversion of the anemometer indications into the speed of the air current, with a range from 0·903 to 40·37 feet per second.

The report, as a whole, contains much valuable information, and is an important contribution to our knowledge of technology. Its range extends far beyond the more immediate subject of inquiry. The composition of the air of towns, as indicated by the solid residue of the rain, affects all of us, not alone as regards our health, but further, in relation to the preservation of our national monuments and public buildings. The comparison of the death-rate of various towns indicates the influence of impure airs upon the duration of our lives. Dr. Angus Smith has done much towards the examination of the influences of impure air and water upon mankind, and we hope he will continue his labours in the same fertile field.

CORRESPONDENCE.

IMPURITY OF INDIGO.

To the Editor of the Chemical News.

SIR,—Having been in the habit of experimenting on indigo, in order to arrive at a relative value of different samples, in order to rate the proper quantities for dyeing stated quantities of fabric, I was not under the necessity of examining the article for anything but its active colouring principles. But, a short time since, in making sulphate of indigo, I poured the solution from the dregs, and, throwing the sediment away, I kept the solution in a glass-stoppered bottle, exposed to strong light, and, at the end of a couple of months (not being at leisure to attend to this lot sooner), I found, on examination, that the contents of the bottle were almost solid, only about one-fifth of the whole being liquid.

I filtered the fluid portion from the solid, and obtained only a very small quantity of indigo carmine as result of examination, the solid mass being composed of a dirty-blue powder, which I washed away, being anxious to get at the principal matter in the mixture. After washing thoroughly, I obtained a heavy lot of fine, white needles, which had formed during the time that the solution was standing. Some blue spots adhering, I washed with dilute nitric acid, and then with water, obtaining the crystals tolerably clean.

I have consulted Watts's "Dictionary," and other works at my command, and, of all the reactions mentioned in connection with any of the salts of indigo, not one of them makes an impression on the mass.

Tested with SO_3, NO_5, HCl, and with aqua ammonia, sulphuric ether, alcohol, hot and cold water, also a solution of caustic potassa, none of which have any effect, as a drop on glass dries off without leaving a crystalline residue to show solution having taken place.

Heated to a cherry-red heat, the silky needles lose their pearly brilliancy, but still obstinately refuse to answer any of the reagents applied to them.

I have not applied hydrofluoric acid for fear of using all my stock of crystals up without arriving at a satisfactory solution, and have none left to send you.

I transmit herewith the balance of the crystals left in good order for your inspection, hoping you can throw some light on the compound.

The indigo from which these were obtained is an article known in the American market as "Madras" indigo, and, as this must indicate very extensive adulteration, I have ventured to trouble your patience with a history of it, in the hope that it may be of interest. If the subject is worth further efforts, I am ready to follow any suggestions as to the mode of procedure you may see fit to offer.

In conclusion, I will state that the SO_3 used to form the sulphate was bought as being chemically pure, but I did not test it; although, if it had been sophisticated with sulphate of soda, the result would not have been an insoluble compound, and, as the indigo was pounded fine in a mortar, and passed through a very fine sieve, the crystals could not have been in their present shape previous to the examination of the specimen.—I am, &c.,

NEW BERNE.

New Berne, N.C., U.S.A., July 27th, 1869.

[The substance of which our correspondent sent a sample proves to be soluble in boiling dilute hydrochloric acid. This solution yields a dense precipitate with chloride of barium, a flocculent precipitate with ammonia (alumina), and a strong precipitate with oxalate of ammonia. It is evidently a mixture of sulphate of alumina and sulphate of lime: other tests which have been applied confirm this statement. If the indigo had been ignited, our correspondent would have been able to judge of its quality from the quantity of ash. Good indigo leaves from 4·5 to 5·0 per cent of ash; but the less the better, of course. A mixture of pipe-clay and milk of lime is frequently used in the preparation of indigo; hence the phenomenon which puzzled "New Berne."—*Ed.* C. N.]

IMPROVED BUNSEN'S FILTER.

To the Editor of the Chemical News.

SIR,—Bunsen's filter being now in such general use, and such a necessary adjunct to a good laboratory, it seemed to me that any small improvements in connection with it could not fail to interest your readers.

In the place of the cone of platinum foil recommended by Bunsen, I now use a cone made either of platinum or copper gauze. When the fluid which passes through the filter does not act on copper, I prefer the latter. The cones are cut just as Bunsen describes, but can be fitted to the funnel direct, that is without the use of a matrix of plaster-of-Paris. This is accomplished by pressing the cone into the funnel to be used, with a piece of wood turned as nearly as possible to the proper angle. I may add that during the last three months, in which these cones have been in almost daily use, I find them to filter much quicker than the foil cones, and with quite as little risk of breaking the paper.—I am, &c.

R. S. DALE, B.A.

Cornbrook Chemical Works, Hulme, Manchester, September 8th, 1869.

London Gas.—It is stated that one hour after the gas of London is lighted the air is deoxidised as much as if 500,000 people had been added to its population. It is also stated that, by the burning of gas twenty-four hours in London, more water is produced than would supply a ship laden with emigrants on a voyage from England to Australia.

MISCELLANEOUS.

Professor Church, M.A.—The *Lancet* of August 28th, in noticing a report read at the Exeter meeting of the British Association, "On the Spectroscopic Examination of Animal Substances," refers to Professor Church's investigation of the red colouring matter of the wings of the turaco, and believes that Professor Church is the Assistant Physician to St. Bartholomew's Hospital. We have been requested to state that the investigator is not Dr. W. Church of St. Bartholomew's Hospital, but A. H. Church, M.A., Professor of Chemistry at the Royal Agricultural College, Cirencester.

New Chemistry Chair at Anderson's University.—A special meeting of the trustees of Anderson's University was held on Wednesday last for the purpose of considering the proposal of Mr. James Young, of Kelly, to found a chair of technical chemistry in connection with the University. Mr. Harvie was called to the chair. A letter was read from Mr. Young, intimating his intention to invest £10,500, in six trustees and himself, for the purpose of establishing a chair of technical chemistry, and requesting the managers and trustees to lease to him the building adjoining the University recently presented by Mr. William Euing, to be altered and fitted up by the trustees. The managers had given their assent, and they now asked the concurrence of the trustees. The Secretary read the deed of trust by Mr. Young in favour of his trustees, directing how the 10,000 guineas were to be appropriated in providing for the lecturer, providing apparatus, altering the building, &c. The trustees were empowered to establish bursaries, scholarships, &c. His six trustees must be trustees of Anderson's University. It was intimated that Mr. Young, with the consent of his fellow trustees, appointed Mr. W. H. Perkin, F.R.S., to the lectureship. This gentleman, like Mr. Young himself, is the founder of an important chemical industry, he being the first discoverer in the department of the aniline or coal-tar dyes. The offer was accepted, with one dissentient.—*Scientific Opinion.*

Spiders' Silk.—A bar of iron 1 inch in diameter will sustain a weight of 28 tons; a bar of steel 50 tons; and, according to computation, based upon the fact that a fibre only 1-4000th of an inch in diameter will sustain 54 grains, a bar of spiders' silk 1 inch in diameter would support a weight of 74 tons.

Contribution to the History of Pyrrol.—N. Lubavin.—It is pretty well known that this substance is the product of the destructive distillation of bones, pit-coal, and other nitrogenous substances. Pyrrol has been only slightly submitted to research. It is known to have the formula C_4H_5N. It does not form salts; is not decomposed by fusing with caustic potassa. Treated with acids, it yields pyrrol-red; while it has the property of colouring a piece of fir-wood, previously moistened with hydrochloric acid, red. About two years ago, M. Goldschmidt discovered that, when pyrrol is oxidised with moist oxide of silver, it is converted into a crystalline substance endowed with the properties of an acid. However, only a very small quantity of this substance was obtained by him. M. Lubavin, although operating upon large quantities of pyrrol, succeeded no better than M. Goldschmidt, when repeating his researches on pyrrol and its oxidation by means of oxide of silver; while the very small quantity of the crystalline substance obtained by him by this reaction proved to be as ready a reducing-agent for the said oxide as the pyrrol itself. Pyrrol appears to be extremely indifferent to any reagents at all, or, if acted upon, is readily converted into pyrrol-red. Sodium does not affect pyrrol at the ordinary temperature of the air: when heat is applied, some gas is disengaged. Potassium, however, acts strongly upon pyrrol; a large quantity of gas is disengaged; heat is developed; and, on cooling, the entire mass solidifies, forming a crystalline compound; this appears to be pyrrol-potassium, since, on treating it with water, pyrrol is obtained unchanged, while, on treating it with iodide of ethyl, ethyl-pyrrol is produced. The potassium combination has the formula C_4H_4KN. When large quantities of pyrrol are operated upon, some resinous substance is also produced. Ethyl-pyrrol is a colourless liquid, which, however, soon becomes first yellow, next red. Its smell is akin to that of oil of turpentine. It is hardly at all soluble in water, and specifically lighter than that fluid. Ethyl-pyrrol becomes resinous when exposed to air; is soluble in hydrochloric acid, thereby becoming deep-red coloured, and emitting dense white fumes. On boiling this solution, no solid substance is deposited, but, on addition of an aqueous solution of caustic potassa, an amorphous, solid substance is precipitated. The vapours of ethyl-pyrrol have the same characteristic property as pyrrol, viz., to render red-coloured a piece of fir-wood previously moistened with hydrochloric acid. The percentical composition of ethyl-pyrrol for the formula $C_4H_4(C_2H_5)N$= Carbon, 75·8; hydrogen, 9·5; nitrogen, 14·7. The boiling point is between 160° and 175° C.—*Berichte d. Chem. Gesel. z. Berlin.*

CHEMICAL NOTICES FROM FOREIGN SOURCES.

In accordance with the generally expressed wishes of our friends and readers, we have effected arrangements to enable us to give, under the above heading, notices of EVERY CHEMICAL PAPER IN THE WORLD, *as soon as possible after publication. Whenever possible, these notices will appear in the form of carefully prepared, although necessarily brief, abstracts; as respects papers either too long or too abstruse to render condensation possible, their titles will be chronicled; and in all cases accurate reference will be made to the original publication. The two half-yearly volumes of the* CHEMICAL NEWS, *with their copious indices, will therefore be equivalent to an English edition of the "Jahresberichte," with the additional advantage of keeping the readers week by week on a level with the latest advances of science.*

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus des Séances de l'Académie des Sciences, August 16, 1869.

This number contains, among a large number of purely mathematical, mathematico-physical, and papers on other subjects not at all allied to chemistry, the following memoirs:—

Constitution of Luminous Spectra.—M. Lecoq de Boisbaudran.—The author says, in the year 1865, I stated "that, when the spectral rays of the metals of the alkalies and alkaline earths are classified according to their refrangibility, they are placed according to the chemical properties and the atomic weights of these bodies." The author now says—"I can explain the formation of the spectra by the four following points:—1st, the molecules should present certain inequalities, and should not be solids rotating round a circular axis; and, they must be in rapid motion; 3rd, that motion ought to be an eccentric elliptic; 4th, the ellipse itself should move in a perihelical manner. From the combination of the spherical and elliptical movements, I can explain the formation and the entire mode of existence of a spectrum; that is to say, groups which are repeated in several points of the luminous part, shadowed rays or stripes decreasing either towards the right or left hand, and repetition of these stripes in the spectrum."

Researches on the State Salts are in when Dissolved in any Menstruum.—MM. Berthelot and St. Martin.—The authors find—1st, that there do not exist in solution acid salts formed by a monobasic acid; 2nd, the acid salts formed by a bibasic acid are, when in solution, partly decomposed; 3rd, the quantity of salt thus decomposed increases steadily and continuously when dilution takes place; 4th, the quantity which is decomposed varies according to the relation existing between the neutral salt and the excess of acid; the stability of the acid-salt is increased by the presence of a neutral salt, or by the presence of excess of acid. The authors have, moreover, found that—1st, the acetates of the alkalies are entirely decomposed, when in aqueous solution, by sulphuric, hydrochloric, oxalic, and even tartaric acids; 2nd, ammonia, when added to solutions of acetate or oxalate of potassa, or soda, in solution, does not seize upon any of these acids; 3rd, oxalic acid partly decomposes a solution of chloride of sodium, when, in a litre of water, 14 grms. of oxalic acid and 20 grms. of chloride of sodium are dissolved (larger quantities of these substances cannot be taken, on account of the difficult solubility of binoxalate of soda). The authors found that about 1-10th of the oxalic acid was converted into binoxalate of soda.

Fermentation of Fruit.—MM. Lechartier and Bellamy.—In this paper the authors relate their experiments whereby they discovered that fruit—apples and pears, more especially—when kept, gives off carbonic acid; but, at the same time, in the interior of the fruit, alcohol and acetic acid are formed. We quote the following figures:—Duration of experiment, 184 days; weight of apples, 348·8 grms.; loss of weight, 14·3 grms.; loss of sugar, 26·0 grms.; gas given off, 13·10 grms.; alcohol formed, 10·01 grms.; acetic acid formed, 0·11 grm. From these and some other experiments made by the authors, it appears that fruit of the kind alluded to is best and most advantageously kept so as to admit of free circulation of air round every individual fruit as much as possible. To keep fruit in closed vessels causes rapid destruction.

On Bromotoluen and the Toluidines derived therefrom.—MM. Rosenstiehl and Nikiforoff.—This paper is a critical review of the labours of MM. Koerner, Huebner, and Wallach, and not suited for abstraction.

On Propylamine.—M. Silva.—The substance obtained by this author, by means of a complicated process, is a liquid exhibiting a strongly ammoniacal smell; very alkaline, inflammable, precipitating solutions of alumina, and re-dissolving the precipitate thus formed; also precipitating solutions of salts of magnesia, nickel, cobalt, and iron; boiling point about 50°; vapour density referred to air, 2·01; specific gravity at 0°, 0·7283; formula—

$$(CH_3—CH_2—CH_2)\left.\begin{matrix}\\ H\\ H\end{matrix}\right\}N.$$

In 100 parts:—C, 61·01; H, 15·26; N, 23·73. The author has studied some of the salts this basis forms.

Constitution of Pseudotoluidine.—M. Koerner.—The author discusses in this paper the correctness or incorrectness of certain results published on this subject by M. Rosenstiehl. The paper is full of formulæ and not well suited for abstraction.

Testing the Antiquity of Manuscripts by means of Studying the Age of the Ink Employed in Writing it.—M. Gaultier de Claubry.—The chief result the author points to is that M. Carré's method alluded to by us in a former number of an abstract of this periodical, is entirely unfit to be used as a test for indicating the age of any writing.

Synthesis of Crotonic Aldehyde.—MM. Paterno and Amato.—The authors have tried, but in vain, to prepare this aldehyde by heating, in sealed tubes, aldehyde and chloride of ethyliden. The reason that they publish this, as they themselves confess, very imperfect work, is due to the publishing of the results of experiments on this subject by M. Kekulé.

Preservation of Stone from the Ravages of Cryptogamic Plants by means of the Oxide or Salts of Copper.—M. Robert.—The gist of this paper is, that the pedestals upon which are placed statues made of bronze, or to which copper ornaments are added, are protected by the salts of copper which are gradually formed under the influence of wind and weather; and these salts, being washed down by rain, prevent, by their poisonous action, the formation of small cryptogamic plants, and hence, also, prevent the decay and deterioration of the stone. The author thinks that salts of copper, or copper or bronze ornaments, might be applied successfully to pedestals, as well as buildings, in order to preserve the stone they are made of from decay, the chief cause of which is, according to the author, the growth of minute cryptogamic plants.

We learn from this number that, on the 8th of April last, the Imperial Academy of Sciences of St. Petersburg appointed a committee with a view of propounding measures to be taken in order to submit to an international committee several questions relating to the making of standard weights and measures according to the decimal system. The report of that Russian committee was read at this meeting of the French Academy, and gave rise to a lengthy discussion. The chief points of the Russian report may be briefly stated as follows:—That steps be taken by the Academy of St. Petersburg to induce the Russian Government to use its influence to invite a meeting of delegates of all foreign states, in order to discuss and regulate everything requisite to the proper manufacture of standard weights and measures according to the decimal system; the place of meeting to be afterwards designated; and that M. Jacobi be requested to bring this matter before the meeting of the British Association for the Advancement of Science, at Exeter, and be also requested to urge the necessity of the general adoption of the metrical system by all men of science in all countries.

Bulletin de la Société Chimique de Paris, August, 1869.

From the abstracts of the *procès verbaux* of the meetings of this Society, held on the 4th and 18th of June last, and published with this number, we learn that M. Longuinine spoke about his—

Researches on Birch-Wood Tar.—When this tar is distilled along with water, there is obtained a light, yellowish-coloured oil, which, on being treated with caustic potassa, yields a crystalline compound, due to a peculiar phenol, which constitutes about 1-15th of the entire quantity of oil obtained. The remainder of this oil yields chiefly tereben, boiling and distilling over between 160° and 180°. The phenol obtained exhales the peculiar and well-known smell of Russian leather, chiefly employed for bookbinding purposes.

M. Friedel spoke on the—

Formation of the Chlorides of Acids.—Anhydrous phosphoric acid does not, at 0°, act upon crystallised acetic acid; when this mixture is treated with dry hydrochloric acid gas, chloride of acetyl is formed.

M. Joffre communicated the composition of a native crystalline carbonate of soda found in Fezzan (a great oasis in Tripoli, Africa); this salt is a sesquicarbonate, $2NaO,3CO_2+4HO$.

M. Thiercelin called attention to the formation of the saltpetre beds on the coast of Peru, and states that the beds situated close to sources of water impregnated with common salt are yet quite free from iodine.

M. Bouchardat said that, according to his experiments, cinchonine fuses at from 256° to 262°. Kept at an elevated temperature in a current of carbonic acid, this base begins to volatilise, without decomposition, at 275°; when, however, cinchonine is kept for a length of time at 150°, it is converted into liquid volatile bases.

This number contains the following original papers:—

Synthesis of a New Butylen, Ethyl-Vinyl.—M. Wurtz.—The author mixes zinc-ethyl and bromide of ethylen, heats in a sealed tube up to 140° for some hours, and next leaves the tubes quietly standing for several weeks. Previous to opening the tubes, they are placed in a strongly-cooling mixture, and arrangements made to collect the gas which may escape on opening the tubes into bromine. After proper purification, the bromide obtained constitutes a perfectly colourless liquid boiling at about 166°; sp. gr. at 0°, 1·876. The ethyl-vinyl obtained from this bromide boils at 5°; and, on being re-converted again into a bromide, that latter compound boils again at 166°.

Synthesis of Aromatic Acids.—M. Wurtz.—The method described by the author consists in treating an organic chloride or bromide with chloroxycarbonic ether and sodium-amalgam. In this way, the chlorine or bromine seized upon by the sodium-amalgam is replaced by $CO_2(C_2H_5)$. The author has applied this method in some instances, and thus prepared benzoic ether according to the following formulæ:—

$$\underbrace{C_6H_5Br}_{\text{Bromide of ethyl.}} + CO\left\{\begin{matrix}O\\Cl\end{matrix}\right.\underbrace{C_2H_5}_{\text{Chloroxycarbonic ether.}} + Na_2 = NaCl + NaBr + \underbrace{C_6H_5,CO_2(C_2H_5)}_{\text{Benzoic ether.}}$$

Researches on the Propylic Alcohol of Fermentation.—Dr. G. Chaucel.—This lengthy and very concisely written paper, full of formulæ, does not admit of suitable abstraction.

Ethylic Series of Silicium.—MM. Friedel and Ladenburg.—The authors describe in this paper, at great length, their experiments to obtain compounds wherein silicium replaces one or more atoms of carbon. Silicium-ethyl, $Si(C_2H_5)_4$, is a liquid boiling at from 150° to 154°. Silicium-hexethyl, $Si_2(C_2H_5)_6$, is also a liquid, readily inflammable, and giving off, while burning, fumes of silica; vapour density, 7·96.

On Acetochlorhydrine and Octylglycol.—M. de Clermont.—Acetochlorhydrine of octylen is a liquid, insoluble in water, soluble in alcohol, ether, and acetic acid; rather readily inflammable, and burning with green-bordered flame; boiling point, 225°; sp. gr. at 0°, 1·026. Composition, in 100 parts:—C, 58·11; H, 9·20; Cl, 17·19.

Some New Ferrocyanides and Ferricyanides.—M. Wyrouboff.—This paper is chiefly a critical review of the labours of M. Riendel, published in a German periodical some years ago. This author's paper is too lengthy, and too much filled with a large number of formulæ, to admit of useful abstraction.

Analysis of a Native Carbonate of Soda.—M. Joffre.—Composition, in 100 parts:—Soda, 39·41; carbonic acid, 39·58; water, 19·52; sand, 0·53; oxide of iron, 0·01; carbonate of lime, 0·05; chloride of sodium, 0·46; sulphate of soda, 0·44. This salt, therefore, belongs to the mineralogical species known as urao.

Action of Hydrogen upon Acetylen when Platinum Black is simultaneously present.—M. de Wilde.—The author finds that, when acetylen and hydrogen, both chemically pure, are brought together, at the ordinary temperature, in a space wherein platinum-black is placed, hydride of ethyl is formed—

$$\underset{\text{2 vols.}}{C_2H_2} + \underset{\text{4 vols.}}{2H_2} = \underset{\text{2 vols.}}{C_2H_6}.$$

When less hydrogen is applied, it appears, says the author, that ethylen is formed.

Acetic Derivatives from Mannite.—M. Grange.—This paper and the following—

Acetic Derivatives obtained from Amylum Gum and the Hydrocarbonates (MM. Schutzenberger and Naudin), have been already briefly abstracted from the *Comptes Rendus*, a remark which equally applies to—

Butyrate and Valerate of Isopropyl (M. Silva) and—

New Sulphur Acid.—M. Schutzenberger.

Researches on the Ethers of Phenol.—M. Lipmann.—Ethylen-diphenol, obtained by the author by a complicated series of operations, is, when pure, a solid substance, fusing at 95°, insoluble in water, readily soluble in chloroform, and also in boiling alcohol; formula—

$$\left.\begin{matrix}(C_6H_5)_2\\C_2H_4\end{matrix}\right\}O_2.$$

Ethylen-diphenol sulphuric acid; the lead- and barium-salt of this acid have been studied, the former has the following formula:—

$$\left.\begin{matrix}(C_6H_4SO_3)2Pb''\\C_2H_4\end{matrix}\right\}O_2.$$

Tetrabromide of ethylen-diphenol is a solid substance, crystallising in small needles, fusible at a little above 100°. The real constitution of ethylen-diphenyl is, according to this author—

$$C_6H_5CH_2,C_6H_5CH_2.$$

Berichte der Deutschen Chemischen Gesellschaft zu Berlin, No. 11. 1869.

This number contains the report of the meeting of this Society, held under the presidency of Dr. A. W. Hofmann, on the 28th of June last. From the *procès verbal*, we learn that a committee has been formed for the purpose of erecting a simple, yet appropriate, memorial tombstone on the grave of the late Dr. F. F. Runge, who died at Oranienburg, near Berlin, on the 25th of March, 1867. The deceased was well and deservedly known, and well deserved from science and industry this posthumous memorial of services rendered.

The following papers were read:—

Chlorides of Carbon.—M. H. Kolbe.—Through the kindness of Dr. Marquart, the celebrated practical and operative chemist, and owner of chemical works at Bonn, the author has obtained a large quantity of the solid sesquichloride of carbon, C_2Cl_6. (To some of our readers the fact may be of interest to learn that this preparation has been used with comparative success in the worst forms of Asiatic cholera.) This substance is readily converted into the fluid chloride of carbon, C_2Cl_4, by means of the action of zinc and sulphuric acid, although there is simultaneously formed a compound, C_2HCl_3. Since the compound C_2Cl_4 enjoys the property of combining directly with chlorine and bromine, the author thought it might be possible to make that compound enter directly into combination with two atoms of hyponitric acid. This nitro compound, $C_2Cl_4(NO_2)_2$, is prepared when the simple chloride of carbon, C_2Cl_4, is mixed with hyponitric acid, kept very cold by means of cooling mixture, and next heated in a sealed tube at from 110° to 120°. The quantity of dinitro-perchloride of ethylen, or

dinitro-chloride of carbon, thus obtained is rather small in quantity, since, during the preparation, a mass of by-products are formed, among which is chlorocarbonic oxide. The substance alluded to is a solid volatile body, soluble in alcohol and ether, insoluble in water, crystallises like the sesquichloride of carbon, and, like that substance, cannot be reduced to powder. This compound cannot be fused without decomposition. The elementary analysis gave results leading to the formula $C_4Cl_4(NO_2)_2$.

Compound of Ethylen and Nitric Acid.—M. Kekulé.—The author has caused pure nitric acid, and, next, a mixture of nitric and sulphuric acids, to act upon ethylen. In the first instance, a large portion of the ethylen is destroyed by oxidation; but, with great care, and the application of strongly-cooling mixtures, an oily fluid was obtained, on addition of water in small quantity. Large quantities of this oil were obtained when ethylen was made to pass through a mixture of nitric and sulphuric acids, kept cold by means of very cold water. The substance obtained is, after purification, a colourless oily liquid of 1·472 sp. gr.; its vapour attacks the eyes, and causes headache; it is not volatile with decomposition. Far below its boiling point this substance is decomposed, giving off red vapours; even when water is present, the distillation is impossible without the simultaneous formation of nitrous acid, deutoxide of nitrogen, oxalic acid, glycolic acid, and some glyoxylic acid. The same decomposition takes place when this compound is boiled with solutions of alkalies. The author assigns to this body the empirical formula, $C_2H_4N_2O_5$, but he considers it to be an ether of glycol—

$$\left.\begin{matrix} NO \\ \| \\ C_2H_4 \\ NO_2 \end{matrix}\right\} O \quad \left.\begin{matrix} \\ \\ \\ \end{matrix}\right\} O$$

Phenol-Sulphuric Acid and Nitro-Phenol-Sulphuric Acid.—M. Kekulé.—The author observes that he was the first who pointed out the fact that, when phenol and sulphuric acid act upon each other, there are formed two isomeric sulpho acids, para-phenol-sulphuric acid and meta-phenol-sulphuric acid. Since there have been different experimenters on this subject, some of whom have altogether overlooked this meta acid, and since the author has found that, with different modes of preparation the quantity obtained of this acid varies greatly, he instituted some experiments to ascertain under what conditions either of the two isomeric modifications are chiefly formed. The result obtained is that, when a mixture of phenol and sulphuric acid is left quietly standing at the ordinary temperature, it contains, not only at first, but for weeks after, chiefly the meta acid. When the mixture is heated, the quantity of the para acid increases, and continues to do so until, when the temperature is for some time kept at from 100° to 110°, the para acid only is present in the mixture. When the meta acid, obtained in pure state from its salts, is heated for some time on a water-bath, it is thereby entirely converted into the para acid. As regards the nitro-phenol-sulpho acid, the author found that there does not exist any doubt that, by whatever method this acid is prepared, the product obtained is always identically the same.

Artificial Alizarine.—MM. Graebe and Liebermann.—The authors say the publishing of their French patent on this subject makes it necessary not to delay any further the completion of their brief paper read before this Society, on the 11th of January, on the preparation of alizarine from anthracen. The authors, at the same time, state that, since they reserve their right of publishing full details of experiments and analysis on this topic, they only read a brief, rough, outline sketch. They succeeded in reducing alizarine obtained from madder to anthracen; and, suspecting that alizarine is a chinon acid, the idea of obtaining alizarine artificially became a feasible matter, as may be learned from the following formulæ:—

$C_{14}H_{10}$. Anthracen. $\qquad$ $C_{14}H_6\{(O_2)'' \atop (OH)_2$. Alizarine.

The affair rested upon the possibility of substituting in anthracen, for two atoms of hydrogen, the group $(O_2)''$, characterising the chinons; and, for two other atoms of hydrogen, two atoms of hydroxyl. Prof. Anderson, of Glasgow University, discovered that, when anthracen is treated with nitric acid, oxanthracen is formed; this is, according to the authors, the chinon of anthracen (anthrachinon, $C_{14}H_8(O_2)''$). This substance is also obtained from anthracen, by means of other oxidising agents, as, for instance, bichromate of potassa, and sulphuric or acetic acids. The authors tried to introduce into this anthrachinon two atoms of bromine or chlorine, in order to be able, by this means, to obtain the two atoms of the hydroxyl group, which are wanted. Chlorine does not act readily upon anthrachinon; with bromine, the substitution ensues at 100°. When, therefore, anthrachinon is heated for several hours in sealed tubes placed in a water-bath, after addition of four atoms of bromine, it is converted into bibrom-anthrachinon, while hydrobromic acid is simultaneously formed—

$$C_{14}H_8(O_2)''+4Br=C_{14}H_6Br_2(O_2)''+2BrH.$$

This body is a solid substance, soluble in benzol, crystallising from that solution, or by sublimation, and exhibiting bright yellow-coloured needle-shaped crystals. On being heated with a thoroughly concentrated solution of caustic potassa to about 170° (at which temperature the reaction sets in), the mixture assumes a deep blue colour, and the mass becomes soluble in water, exhibiting thereby the well-known and beautifully violet colour of alizarinate of potassa; when an acid is added to this solution, alizarine is precipitated from it, in the shape of a reddish brown flocculent matter. The following formula exhibits the formation of alizarinate of potassa from bibromide of anthrachinon:—

$$C_{14}H_6Br(O_2)''+4KHO=C_{14}H_6(OK)_2(O_2)''+2KBr+2H_2O.$$

The authors next state that they discovered another method for the preparation of bibromide of anthrachinon, and its conversion into alizarine. Since the bibromide of anthracen is converted, by means of being heated along with nitric acid, into anthrachinon, according to this formula:—

$$C_{14}H_8Br_2+2NHO_3=C_{14}H_6(O_2)''+2Br+2NHO_2,$$

the authors suspected that tetrabromanthracen, $C_{14}H_6Br_4$, would be readily converted into bibromide of anthrachinon by the same means. On trying this experimentally, they found that their opinion proved correct. By treating the bibromide of anthrachinon thus obtained with a strong solution of caustic potassa, alizarine was again obtained. The authors positively state that the artificial alizarine thus obtained is in every respect identical with that obtained from madder; this is, be it observed, the first instance of the preparation of a naturally-occuring vegetable colouring matter by artificial means.

Behaviour of the Salts of Silver towards Iodine.—M. Weltzein.—After referring to experiments made by himself in 1854 and 1860, on this subject, the author states:—(1) When iodine acts upon the nitrate of silver, no free oxygen is given off; (2) that, not the anhydride of nitric acid, but hyponitric acid, is obtained, the reaction being represented by—

$$3AgNO_3+3I=3NO_2+AgIO_3+2AgI.$$

The author further says that he hoped to obtain, by the action of iodine upon the acetate and benzoate of silver, the respective anhydrous acids, but failed, and next winds up his paper with a long series of formulæ, not deduced from his own experiments, but made up from theoretical reasoning. The formulæ are too complicated and lengthy to be quoted.

There follows in this number, under the title of Correspondence, letters written from London, from Zürich (Switzerland), and from Cambridge, U.S. M. Meister, secretary of the Chemische Harmonika, a chemical society established at Zürich, writes—"At our meeting, on the 22nd of June last, MM. Merz and Weith communicated that, when powdered sulphur is strewed on the surface of boiling aniline, a strong evolution of sulphuretted hydrogen gas is observed, while a base containing sulphur is thereby formed. Other organic substances, as, for instance, acetanilide, glycerine, and naphthaline, are acted upon by sulphur in the same way at a higher temperature. When pure and dry hydrogen gas is made to pass through boiling sulphur, sulphuretted hydrogen gas is developed in large quantities."—Mr. W. Gibbs writes from Cambridge, U.S., communicating the results of some experiments made by him on the—

Action of Nitrites of Alkalies upon Uric Acid and Derivatives therefrom.—When uric acid is heated along with a solution of nitrite of potassa or soda, and sulphuric acid, a strong effervescence takes place, the uric acid is completely dissolved, and the fluid contains alloxan and alloxantin. On evaporation to dryness on a water-bath, parabanic acid is obtained, and very small quantities of two peculiar substances—one a red-coloured, the other a bright bluish fluorescent—both flocculent substances. When acetic acid is applied, instead of a mineral acid, the same phenomena are observed to take place; but the filtered solution deposits a very voluminous salt, which, if nitrite of potassa were applied to the experiment, is composed according to the formula $C_4H_2KN_3O_3$. The peculiar acid contained in this salt has been named stryphnic acid, from στρυφνος, bitter astringent, since the acid and its salts exhibit this taste. The formula of the free acid is $C_4H_3N_3O_3$; it appears to be monobasic, and all its salts, except the lead-salt, are soluble in water. The author read this paper, of which only a brief account is here given, before the National Academy of Sciences, the transactions of which are, we believe, regularly published.

Existence of Molecular Compounds in Gaseous State.—M. A. Naumann.—This paper, which is placed under the section of *Mittheilungen*, and is dated from Giessen, the 1st of July last, is a philosophical essay, and not well suited for abstraction.

We beg to remind our readers that during the months of August and September this periodical is not published.

Bulletin de la Societe d'Encouragement pour l'Industrie Nationale, No. 199, July, 1869.

The only paper relating to chemistry in this number is on the—

Use of Extracts of Madder in Calico Printing, and the Part each of the Different Pigments contained in Madder Plays in this Operation.—M. Schutzenberger.—The author begins by stating that, notwithstanding the discovery of aniline and other artificially-made colours (dyes), madder and its preparation yet occupy a first rank among dyes, and not only will continue to do so, but its use will become more extended. The author next reviews, at some length, the history of madder, and preparations obtained from it, during the last forty years, alluding to garancine, flowers, or bloom of madder, and commercial alizarine—that is to say, madder submitted to high pressure steam. To M. Kopp is due the discovery of preparing, on the large scale, the pure colouring matter from madder, and, also, of getting purpurine separately therefrom; this substance is very little used, but the alizarine (the chief tinctorial matter contained in madder) is largely used. At Cosmarros, a town in Bohemia, and at Thann, France, the direct application of alizarine, without the use of mordants, has been most successfully applied, especially in the last-named town, by M. Scheurer. The author enters into some purely technical details on this subject, which, however interesting, we leave out, following him rather to the more purely chemical part of his paper. Madder contains:—(1). Alizarine, $C_{20}H_{10}O_6$, a solid substance, readily crystallising, forming orange-coloured needle-shaped crystals by sublimation by heat, soluble in benzol, also in warm alcohol, yielding, with alkalies, a bluish purple-coloured solution. (2). Purpurine, $C_{20}H_{12}O_7$, a solid substance exhibiting red-coloured, needle-

shaped crystals, when crystallised from alcohol, or, also, by sublimation by heat; but by this latter process, a large portion of the substance is decomposed; soluble in benzol, also in warm alcohol, and yields, with alkalies, red-coloured solutions. (3). Pseudo-purpurine, $C_{30}H_{12}O_{11}$, a solid substance, exhibiting, when crystallised from its solution in benzol, small brick red-coloured needle-shaped crystals; is decomposed by heat, yielding purpurine; soluble in benzol, very slightly soluble in alcohol, even at boiling point, and yields, with alkalies, a red-coloured solution. (4). An orange-coloured matter, $C_{20}H_{12}O_7+2H_2O$, a solid substance, exhibiting, when obtained by the slow evaporation of its alcoholic solution, a crystalline conglomerated mass; is decomposed by heat, yielding purpurine; insoluble in benzol, very soluble in alcohol, and does not yield a solution with alkalies. (5). Purpuro-xanthine, $C_{20}H_{12}O_8$ (?), a solid substance, yielding, either by sublimation, or by evaporation of its solutions in alcohol or benzol, yellow-coloured needle-shaped crystals; sublimes by heat; readily soluble in benzol, as well as in alcohol; and yields, with alkalies, a yellow-coloured solution. As regards the formulæ here quoted, the author desires it to be understood that they represent exactly the percentical composition, but that, in a scientific point of view, these formulæ do not express the constitution of the substances; moreover, C = 12; H = 1; and O = 16 in this case. Each of these five substances is fit for use as a dyeing material; but alizarine alone is the dye *par excellence*. It appears, says the author, that the solidity (the fastness or goodness) of the different tints of colours produced by these dyes varies in the inverse ratio of the quantity of oxygen contained in the substance in excess of the hydrogen. Where the quantity of oxygen increases, we come from a more violet red to a bright red, and at last to brick red; and from bright violet colour to a more dirty violet, and, next, to greyish violet. Science has to elucidate practice in many points in respect of madder. No doubt a thorough study of this subject will enable us to find the key to the best mode of so mixing the different bodies to be described, as to produce pigments precisely suited to each peculiar shade of colour required.

Quantity of Copper Produced in the Year 1866 over the Whole World.—M. Petitgand.—The quantity of this metal raised on the entire globe, in the year alluded to, the latest period that statistical records of this kind have been reliably brought together, amounts to 93,415 tons, which is nearly double the quantity raised in 1846. From the statements made by this author, there appears to be an increasing tendency to a lower cost price of this metal. Large and valuable deposits of excellent copper ore known to exist, especially in Polynesia, are as yet untouched.

Moniteur Scientifique, No. 304, August 15, 1869.

This number contains the following original papers and communications:—

Limit of Magnetisation of Iron and Steel.—M. Waltenhofen.—The result of the author's researches on this subject are, that the magnetic moment of the unit of weight of iron may attain a certain limit which is constant and independent of the form and dimensions of the electro-magnet. The absolute value is about 2100 absolute units, expressed in milligrammes. The limit of magnetisation which soft iron can temporarily attain is about five times greater than the permanent magnetism obtained with steel bars, which rarely exceeds 400 units to the milligramme.

Mercury Mines of Almaden.—M. Jouglet.—From this lengthy paper, we learn that mercury, as metal, has been known from the most remote antiquity—that there have been mines worked for mercury ore in Asia Minor in the time of Xenophon; the mines of Almaden, Spain, is yet the largest source of mercury for Europe. The cost of 100 kilos. of the ore is, everything included, only 16 francs and 10 centimes; but it yields, as this author says, by unsuitable management, only 6·9 per cent of mercury, 100 kilos. of which cost, on the spot, 141 francs and 30 centimes; but at Sevilla the price is already 177 francs and 80 centimes, in consequence of cost of transport and the iron vessels in which the metal is carried. The average quantity of mercury produced annually amounts to about 15½ tons, by weight.

Poisoning Caused by Green Tarlatan.—M. Bobierre.—The author says that he obtained from Nantes a sample of this kind of tissue, which, on being tested, was found to contain 10·3 grms. of Schweinfurt green (arsenite of copper) to the square metre, equivalent to 6·03 grms. of arsenious acid. The full dress made of this tissue contained, by weight, no less than 391·4 grms. of arsenite of copper, equivalent to 229 grms. of arsenious acid. At even every slight shaking of the tissue, clouds of a greenish dust came off, which readily explain the poisoning of the party who made the dress. The author tested—1st, by treating the tissue with an alkaline lye, passing chlorine through the solution, and converting the arsenic acid into ammonio-arsenite of magnesia: 2nd, by estimating the quantity of black oxide of copper left after burning the tissue in a red-hot muffle.

NOTES AND QUERIES.

Gas-Works' Residuum.—Can any of your readers give me the name of the most practical work on the conversion of gas-works' residuum.—R. W. Johnson.

Utilisation of Waste Vulcanised Rubber.—Would you kindly answer the following question through your Notes and Queries' column?—In large rubber works, how are the waste cuttings, &c., of vulcanised rubber utilised?—D. J. O.

Terra Alba.—"Selenite" desires some information about the artificial sulphate of lime called, in commerce, terra alba. How is it made? by evaporation of sea-water or brine? Where? Why does its quality vary? At what price is it sold? Its uses? To what extent sold? Is it exported largely? To what countries?

Octylic Alcohol.—Can any of your readers kindly inform me as to the best method of preparing octylic alcohol from saponified castor-oil? I cannot find any means of preventing its frothing over on being heated. I have used an apparatus made of tinned iron for distillation, but find, even though the apparatus is 18 inches high, by 3 inches in diameter, and I only put 3 inches of saponified castor-oil and potash into it, that three-fourths of the matter froths over from the lead-off tube. I can nowhere find any instructions for preventing such an occurrence. I have raised the heat gently, but it makes no difference at all.—G. P. Clarke.

Aniline Colours.—If "Alexis" will have the kindness to state what particular colours he refers to, and the strength in ounces per gallon, I shall be able to furnish him with particulars.—J. W. Slater.

Aniline Colours.—"Alexis" is referred to Reimann's work on aniline colours, edited by the Editor of this journal. The work contains everything which can be desired, and far more fully and completely than any reply we could give in limited space. The work may be inspected at the Library of the Commissioners of Patents; but it should be in the possession of any one who puts queries as "Alexis" does.

Tungstate of Soda.—M. A. Burn is informed that most salts are bad conductors of heat. As to the price of the tungstate of soda, we could not well give any information, since it would greatly depend upon the quantity required; but why will not alum or borax do, or even common salt, provided it be free from deliquescent salts? All these salts are cheaper than the tungstate, and would render paper fire-proof, in the sense of preventing it bursting into flame on being ignited.

Printing Scarlet.—No salts of mercury could be boiled with water in copper, or even iron vessels, without decomposition taking place. If you want to apply the brilliant scarlet colour exhibited by biniodide of mercury, you should apply it by fixing it to the cloth by means of albumen. As far back as the year 1827, it was tried to fix this beautiful pigment by means of mordants, but it did not succeed well. M. Bor, of Amiens, published, in 1842, a method of printing upon cotton a colour resulting from a somewhat complicated process, but, really, the mercury compound you allude to; the printing of this scarlet upon wool and silk does not answer at all. There are various methods of preparing the scarlet biniodide, but for these we must refer you to works on chemistry; however, you could only obtain success by avoiding the use of metallic vessels, and operating in vessels of glass or porcelain. The scarlet of the biniodide of mercury is less beautiful than that of pure vermillion (sulphide of mercury).

Estimation of Phosphates in Manures.—A superphosphate, if properly made, cannot become again insoluble, as long as the superphosphate is acid, which can be readily ascertained by the behaviour of the manure with blue litmus paper, which, when brought into contact with the manure, should turn red; when, however, much iron is contained in a superphosphate (the iron being naturally present in the native phosphate employed in manure making), then it may happen that a basic phosphate of iron is formed by the action of the air—and this may constitute the so-called "reduced" phosphate. No makers of superphosphate will use more sulphuric acid than is precisely required: it would be a loss to them. One equivalent of bone-ash requires two equivalents of sulphuric acid; or, in other words, 155 parts of tribasic phosphate of lime require 98 parts of concentrated sulphuric acid, for being converted into superphosphate of lime. Most, if not all, of the manufacturers of superphosphates are men who conduct their business with conscientious care and upon scientific principles, well knowing beforehand the materials they have to deal with, so as to ensure efficiency of the produce without excess of labour or materials.—Chemicus.

TO CORRESPONDENTS.

*** The Students' Number of the Chemical News will be published on Friday, September 17th. Gentlemen holding official positions in the Universities, Medical Schools, &c., of the United Kingdom, where Chemistry and Physical Science form a part of the Education, who have not yet forwarded the necessary information to our office for publication in that number, will confer a favour by sending it with the least possible delay.

Bichrome.—Your letter involves a legal question; we would rather not offer any advice on the subject.

Walter Weldon.—In reporting a paper by this correspondent in our last issue, he was styled "F.C.S." He has written to ask us to correct this error, as he is not yet a Fellow of the Chemical Society.

E. B.—("Explosion Caused by Ammonia Gas.") In the original paper it reads exactly as printed in our issue of the 3rd inst: we believe, however, it is a typographical error in the German paper, and we intended to have made a remark to this effect in our abstract, as we are well aware that no iron vessel of the dimensions specified would stand such an enormous pressure; we venture the explanation that the total force exerted at the time of the explosion was 20,000 pounds, not on the square inch, but over the entire surface of the vessel. On inspection of other German periodicals we find that they also have reproduced this error. The vessel was made of wrought-iron.

THE CHEMICAL NEWS.

Vol. XX. No. 512.

(STUDENTS' NUMBER.)

SCHOOLS OF CHEMISTRY.

EXAMINING BOARDS.

UNIVERSITY OF LONDON.

Candidates for any Degree granted by this University are required to have passed the Matriculation Examination, to which no candidate is admitted unless he has produced a certificate showing that he has completed his sixteenth year.

The Fee for this Examination is £2.

The Examination includes the following subjects:—

Natural Philosophy.*

Mechanics—

Composition and Resolution of Statical Forces.

Simple Machines (*Mechanical Powers*):—Ratio of the Power to the Weight in each.

Centre of Gravity.

General Laws of Motion, with the chief Experiments by which they may be illustrated.

Law of the Motion of Falling Bodies.

Hydrostatics, Hydraulics, and Pneumatics—

Pressure of Liquids and Gases, its equal diffusion, and variation with the depth.

Specific Gravity, and modes of determining it.

The Barometer, the Syphon, the Common Pump and Forcing-Pump, and the Air-Pump.

Acoustics—

Nature of Sound.

Mode and rate of Propagation of Sound.

Musical Tones.

Optics—

Laws of Reflection and Refraction.

Formation of Images by Simple Lenses.

Chemistry.

Heat—its sources. Expansion. Thermometers—relations between different Scales in common use. Difference between Temperature and Quantity of Heat. Specific and Latent Heat. Calorimeters. Liquefaction. Ebullition. Evaporation. Conduction. Convection. Radiation.

Chemistry of the Non-Metallic elements; including their compounds as enumerated below—their chief physical and chemical characters—their preparation—and their characteristic tests.

Oxygen, Hydrogen, Carbon, Nitrogen. Chlorine, Bromine, Iodine, Fluorine. Sulphur, Phosphorus, Silicon.

Combining Proportions by weight and by volume. General nature of Acids, Bases, and Salts. Symbols and Nomenclature.

The Atmosphere—its constitution; effects of Animal and Vegetable Life upon its composition.

Combustion. Structure and Properties of Flame. Nature and composition of ordinary Fuel.

Water. Chemical peculiarities of Natural Waters, such as rain-water, river-water, spring-water, sea-water.

Carbonic Acid. Carbonic Oxide. Oxides and Acids of Nitrogen. Ammonia. Olefiant Gas, Marsh Gas, Sulphurous and Sulphuric Acids, Sulphuretted Hydrogen.

Hydrochloric Acid. Phosphoric Acid and Phosphuretted Hydrogen. Silica.

* The knowledge required of these subjects in Natural Philosophy is such as may be attained by attending a course of experimental lectures.

Bachelor of Science (B.Sc.).

This Degree is conferred on candidates who pass a satisfactory examination in Mathematics, Mechanical and Natural Philosophy, Botany and Vegetable Physiology, Zoology, and Chemistry.

First B.Sc. Examination.

No Candidate (with the exception of such as have obtained Honours at the Matriculation Examination in the preceding January) is admitted to this examination within one academical year of the time of his passing the Matriculation Examination.

The Fee for this Examination is £5.

The examination is conducted by means of printed papers; but the Examiners are not precluded from putting, for the purpose of ascertaining the competence of the Candidates to pass, *viva voce* questions to any Candidate in the subjects in which they are appointed to examine.

The First Examination includes the following subjects:—

Natural Philosophy.

Heat—

Sources of Heat; conduction—convection.

Effects of Heat; expansion generally—of water—of gases and vapours; liquefaction; vaporisation; latent heat; expansive force of steam; dew-point; gases and vapours compared.

Specific Heat.

Thermometers; Pyrometers.

Heat in the Radiant state.

Electricity.

Sources of Electricity.

Static Electricity; dual character—insulation—induction—specific inductive capacity—equivalent antithetic states—disruptive discharge—convection; Electroscopes—Leyden Jar, &c.

Dynamic Electricity; Conduction—the electric current—derived currents—induction of currents; Voltaic Pile and other voltaic arrangements.

Thermo-Electricity; Electro-Thermometer.

Magnetism—

Magnets, the Earth, &c.; Induction—communication—retention—Magnetic relations of iron, steel, &c.

Electro-Magnetism—as in the spark—in conducting media—in soft iron; Magneto-Electricity; principle of Electro-magnetic and Magneto-electric machines.

Terrestrial Magnetism.

Inorganic Chemistry.

Matter; simple and compound.

Elementary bodies classed. Metallic and Non-Metallic bodies.

Chemical Combination and Mechanical Mixture. Solution.

Outlines of Crystallography. Isomorphism. Dimorphism. Allotropic conditions of matter. Chemical Affinity. Laws of Combination by weight and by volume, as deduced from the history of the individual elements. Equivalent Numbers. Equivalent Volumes. Symbolical Notation, including questions on the Unitary System. Formulæ. Nomenclature.

Chemical actions produced under the influence of Heat. Nature of Combustion. Structure and properties of Flame. Principles of Illumination. Chemical action of Light. Photography.

Oxygen. Ozone.

Hydrogen. Water.

Nitrogen. Chemical constitution of the Atmosphere. Diffusion of Gases. The Oxides of Nitrogen; Nitric Acid. Ammonia.

Chlorine, Bromine, and Iodine. Their compounds with Oxygen and Hydrogen. Theory of Bleaching.

Fluorine and Hydrofluoric Acid.

Sulphur. Sulphurous Acid. Manufacture and Chemical applications of Sulphuric Acid. Other Oxygen compounds of Sulphur. Sulphuretted Hydrogen.

Phosphorus. Oxygen and Hydrogen compounds of Phosphorus. Theory of Acids. Monobasic, Dibasic, and Tribasic Acids.

Carbon. Carbonic Oxide and Carbonic Acid. The principal Hydrogen compounds of Carbon. Manufacture of Coal Gas.

Silicon and Boron. Their compounds with the elements previously enumerated.

Metals. Characters of Metals as a class. Metallurgical Processes. Alloys. Classification of the Metals.

Potassium. Nitre. Gunpowder. Theory of the action of Gunpowder.

Sodium. Manufacture of Carbonate of Soda.

Barium. Strontium. Calcium. Mortars. Cements.

Magnesium. Aluminium. Glass. Porcelain.

Manganese. Iron. Composition and properties of Cast-Iron, Wrought-Iron, and Steel. Chromium.

Cobalt. Nickel. Zinc. Cadmium.

Lead. Manufacture of White-Lead.

Copper. Mercury. Bismuth. Tin. Arsenic. Antimony.

Silver. Gold. Platinum.

Principal compounds of the Metals with the Non-Metallic elements. Theory of Salts.

Principles of Mineral Analysis.

Principles of Electro-Chemistry.

For the First Examination, a knowlege of Inorganic Chemistry only is necessary.

EXAMINATION FOR HONOURS.

Candidates for Honours in Chemistry are examined in any of the following subjects, at the option of the Examiners:—

Elementary Substances and their combinations.

Electro-Chemistry.

Radiant Chemical Action.

In the Examination for Honours, the Candidate, being not more than twenty-two years of age, who most distinguishes himself in Chemistry and Natural Philosophy, will receive an Exhibition of Forty pounds per annum for the next two years.

SECOND B.Sc. EXAMINATION.

Candidates for this Examination who have not previously taken the Degree of B.A. shall be required either to have passed the First B.Sc. Examination at least one Academical year previously, or to have passed the First M.B. Examination, in this University.

The Fee for this Examination is £5.

This Examination embraces Organic Chemistry, including the following subjects:—

Ultimate analysis of Organic bodies. Calculation of Empirical Formulæ. Methods of controlling Empirical Formulæ. Determination of the Equivalents of organic acids and bases; examination of products of Decomposition; determination of the Vapour-density of volatile bodies.

Law of Substitution. Compound Radicals. Homologous Series.

The Chemical history of the Cyanogen group. Cyanogen. Hydrocyanic Acid. Cyanic Acid and Urea. Fulminates. Cyanuric Acid. Sulphocyanic Acid. Chlorides of Cyanogen. Uric Acid.

Amylaceous and Saccharine substances. Fermentation. Alcohol, Wine, Beer, Bread, &c.

Homologues of Alcohol. Ethers, simple and mixed. Oxidation of Alcohol. Aldehyd and Acetic Acid, and their homologues. Anhydrides, simple and mixed. Compound Ethers.

Diatomic Alcohols and their Acids, Glycol and Oxalic Acid and their homologues.

Triatomic Alcohols. Glycerine. Fatty and Oily bodies, Saponification.

Vegetable Acids;—the principal.

Ammonia and its derivatives. Ammonium and Ammoniacal Salts. Amides and Amines; their Classification. The chief natural Organic Bases.

Colouring Matters. Indigo and its derivatives. Principles of Dyeing.

The chief constituents of the Vegetable organism. Cellulose. Vegetable Fibrin. Albumin, Casein, Glutin, &c.

The chief constituents of the Animal organism. Animal Fibrin, Albumin, Casein, Gelatin. Blood, Milk, Bile, Urine, &c.

Decay, Putrefaction. Destructive Distillation.

The Chemical principles of the process of Nutrition and of Respiration in Plants and Animals.

EXAMINATION FOR HONOURS.

The Candidate, not more than twenty-three years of age, who, in the Examination for Honours, most distinguishes himself in Chemistry, will receive Fifty pounds per annum for the next two years, with the title of University Scholar.

DOCTOR OF SCIENCE (D.Sc.).

No Candidate is admitted to the Examination for the Degree of D.Sc. until after the expiration of two Academical years from the time of his obtaining the Degree of B.Sc. in this University.

Candidates for the Degree of D.Sc., in any year, must give notice of their intention to the Registrar, and pay to him a Fee of Ten pounds, on or before the 1st of April.

Chemical Candidates can be examined either in Inorganic or Organic Chemistry; but no Candidate will be approved by the Examiners unless he has shown a thorough practical knowledge* of the *Principal Subject*, and a general acquaintance with the *Subsidiary Subject*, or *Subjects*, specified as belonging to the Branch so selected.

Inorganic Chemistry.

Principal Subject—Inorganic Chemistry.

Subsidiary Subjects—Either Organic Chemistry; or, Mineralogy, Crystallography, and Chemical Technology in its relations to Inorganic Chemistry.

Organic Chemistry.

Principal Subject—Organic Chemistry.

Subsidiary Subjects—Either Inorganic Chemistry; or, Chemical Technology, in its relations to Organic Chemistry, and the Chemistry of Animal and Vegetable Life.

EXAMINATIONS IN CONNECTION WITH THE DEPARTMENT OF SCIENCE AND ART, SOUTH KENSINGTON.

A sum of money is voted annually by Parliament for scientific instruction in the United Kingdom.

This sum is administered by the Science and Art Department.

The object of the grant is to promote instruction in Science, especially among the industrial classes, by affording a limited and partial aid or stimulus towards the founding and maintenance of Science schools and classes.

The following are among the Sciences towards instruction in which aid is given:—Acoustics, Light, Heat, Magnetism, and Electricity, Inorganic Chemistry, Organic Chemistry, Geology, Mineralogy, Mining, Metallurgy.

The assistance granted by the Science and Art Department is in the form of—1. Public Examinations, in which Queen's Medals and Queen's Prizes are awarded, held at all places complying with certain conditions. 2. Payments on results to teachers. 3. Scholarships and Exhibitions. 4. Building Grants. 5. Grants towards the purchase of apparatus, &c.

* It must be understood that the Candidate for the Degree of D.Sc. is expected to be so fully conversant with the Principal Subject he may select, as to be able to go through any examinational test (whether theoretical or practical) of his acquirements in it that can be fairly applied.

Examinations in all the before-mentioned Sciences are held annually about May, through the agency of the Local Committee (which must consist of not less than five well-known responsible persons) in any place in the United Kingdom which complies with the requisite conditions. The Examinations are of two kinds, but held on the same evening and conducted by the same committee. *a*. The class examinations for students under instruction in Science Classes, whether taught by teachers qualified to earn payments on results or not. *b*. The honours examinations, of a highly advanced character.

The class examination is of two grades or stages; the first stage or elementary examination, and the second stage or advanced examination.

Application for examination must be made before the end of March, stating the number of persons and the subject or subjects in which they are to be examined.

At the May class examinations the grades of success are:—in the first stage or elementary paper, first, second, and third class; and in the second stage or advanced paper, first and second class. For the third or lowest class the standard of attainment is only such as will justify the Examiner in reporting that the instruction has been sound, and that the students have benefited by it. The standard may be raised from year to year.

To all successful students are given printed lists of results showing their position. To the first class in both stages Queen's Prizes are given, consisting of Books or Instruments' chosen by the Candidates from lists furnished for that purpose.

Four medals, one gold—one silver, and two bronze—are given in each subject for competition among the *bona fide* students of Science Classes who either come within the category of persons on account of whom payments can be earned, or who are under seventeen years of age. The Payments on results are made either directly to teachers or to the committee or managers of the school. Persons are qualified to earn payments who have—(*a*) obtained certificates as teachers in any of the before-mentioned sciences according to the rules in force previous to January, 1867; or (*b*) obtained a First or Second Class at the May examination since that date; or (*c*) who have taken honours at the May examination.

No payments are made to a teacher on account of instruction given in subjects in which he is not so qualified.

The student must have received 25 lessons at least from the teacher or teachers in each subject in which payment is claimed since the last examination, each lesson being an attendance at a meeting of the school of at least three-quarters of an hour's duration on a separate day.

There are two Scholarships provided—the Elementary School and the Science and Art Scholarships. In both cases the scholar must be from 12 to 16 years of age and must have passed in a branch of science at the May examination.

Building Grants for New Schools may be made at a rate not exceeding 2s. 6d. per square foot of internal area, up to a maximum of £500 for any one school, under certain conditions.

A grant towards the purchase of apparatus, diagrams, &c., of 50 per cent on the cost of them, is made to Science Schools and Classes in Mechanics' and similar institutions with a properly constituted committee.

Science teachers who have taught two years consecutively, and passed not less than thirty students each year, are allowed second class railway fare and £3 towards their expenses while living in London for the purpose of visiting the South Kensington Museum and other Metropolitan institutions, in order that they may acquire for the benefit of their students a knowledge of the latest progress in those educational subjects which affect the schools, on condition that they remain there five days at least.

CHEMICAL LECTURES.

UNIVERSITY COLLEGE.

WINTER TERM (Oct. 4 to March 31).

Chemistry.—Professor Williamson, Ph.D., F.R.S.

Lectures daily, except Saturday, from 11 to 12 a.m:

Exercises on Tuesdays, Wednesdays, Thursdays, and Fridays, from 9 to 10 a.m.

Fee for the Whole Course of Lectures, £6 6s.; for a Half Course, £3 3s.; Perpetual, £9 9s.; for the Organic Course alone, £2 2s.

Fee for the Exercise-Class—for the Course, £2 2s.; for the Half Course, £1 1s.

The Instruction in this Class is of two kinds, consisting partly of Experimental Lectures by the Professor, partly of Exercises and personal instruction on the subject of the Lectures by Tutors, under the direction of the Professor.

Students cannot profit duly by attendance on the Lectures unless they work at the subject of each Lecture so as to make it their own.

Attendance on the Tutorial part of the Class enables Students to do their work more effectually and rapidly than they can do it by themselves.

The First Half of the Course to Christmas includes those parts of Chemistry which are required for the Matriculation Examination of the University of London.

The following order of subjects is adopted in it:—

Heat.—Instruments for measuring Temperature. Decompositions produced by Heat. Expansion. Tension of Vapours. Conduction. Convection. Calorimeters. SpecificHeat. Latent Heat. Evolution of Heat by Chemical Action, and by Mechanical Action. Mechanical equivalent of Heat.

Light.—Photometry. Refraction and Dispersion of Light. Study of Spectrum. Heat Rays. Chemical Rays. Construction of common Optical Instruments. Double Refraction. Polarisation. Chemical applications of Phenomena of Polarisation. Combinations and Decompositions produced by Light and Actinic Rays. Photography.

Electricity and Magnetism.—Simple Magnetic Instruments. Magnetic and Diamagnetic Bodies. Electrical Machine, Electrophorous, &c. Positive and Negative Electricity. Electrometers. Conduction. Induction. Leyden-jars, &c. Discovery of Galvanism. Various forms of Battery. Study of the Chemical Action of Galvanic Batteries. Galvanometers. Heating Effects of Battery in relation to Chemical Action. Thermo-Electricity. Rheostat, &c.

Oxygen.—Theory of Combustion. Hydrogen. Nitrogen. Composition and chief changes of the Atmosphere. Carbon, Chlorine, Bromine, Iodine, and Fluorine. Sulphur, &c. Phosphorus. Boron. Silicon.

The chief compounds of these non-metallic elements among themselves are studied in relation to their production, properties, and decompositions. The proportions by weight and by volume in which they combine are explained and illustrated in connection with the atomic theory.

The Second Half of the Course, extending from January to March, includes the following subjects:—

I. Preparation and properties of the chief metals, including their characteristic reactions and most important salts. Detection of Metallic Poisons. Quantitative Estimation of Metals. Principles of Classification. Monatomic, Diatomic Metals, &c.

A weekly *vivâ voce* examination is held during the First Half Course and the commencement of the Second Half Course.

II. *Organic Chemistry*.

This commences in the second week in February, and occupies five Lectures weekly till about the end of March. It includes a study of the characteristics and metamorphoses of the chief organic acids, bases, alcohols, ethers,

colouring-matters, &c. Methods of ultimate and proximate analysis. Determination of molecular weights. Theory of types; of compound radicals. Phenomena of ermentation, &c.

Practical Chemistry.

Mondays, Tuesdays, Thursdays, and Fridays, from 12 to 1.

The Course consists of about Forty Lessons, the first twenty being given in the five weeks preceding the Christmas Vacation, the remainder immediately after it.

The First Half includes the portion of Chemistry required for the Matriculation Examination.

For particulars, see the Prospectus of the Summer Session.

Fee for the Course, £4 4s.; Half Course, £2 12s. 6d.

SUMMER SESSION (May 2 to July 23)

Practical Chemistry.—Professor Williamson, Ph.D., F.R.S.

I. *Elementary Course.*

About Forty Lessons, of one hour each, on Tuesday, Wednesday, Thursday, and Friday, from 11 to 12, commencing in the first week of May. Students are taught the construction and use of apparatus for the preparation of the most important gases, acids, &c. The characteristic tests for the presence of the common acids and bases, including the chief metallic and other poisons. Also the processes for separating these bodies from one another.

Solutions are frequently given in the class for investigation.

The first six weeks of the Course are occupied by the study of the chief non-metallic elements, and their simple compounds. Metallic salts, &c., are subsequently studied.

Fee for the Course, £4 4s., including cost of materials and apparatus.

II. *Senior Course.*

About Ten Lessons, of two hours each, on Mondays, from 10 to 12, commencing in the first week in May. The Course includes tests for fixed and volatile organic acids, nitrogenised acids, sugars, glycerine, &c.; organic bases and alkaloids, constituents of blood, milk, urine, &c.

Volumetric methods of quantitative analysis of acids, alkalies, urea, prussic acid, iron, &c., are practised.

Fee for the Course, £2 2s., including cost of materials and apparatus.

III. *Summer Matriculation Course.*

Professor Williamson, F.R.S., assisted by Mr. F. S. Barff, M.A., F.C.S.

This Course includes those parts of Chemistry which are required for the Matriculation Examination of the University of London.

The Course consists of about Twenty Lessons in Practical Chemistry, and of an equal number of Oral Lessons. The Practical Lessons include the preparation of the common gases and acids, &c., and the study of their characteristic properties in relation to the elementary laws of combination.

The other lessons are chiefly devoted to those parts of the subject which require fuller oral explanation than is given in the practical lessons. They include numerous exercises and questions, to which answers in writing are given by the Students. These Lessons will begin on Wednesday, April 6th, at 11 a.m.

The Class will meet on the first five week days, from 11 to 12; and some other Meetings will be announced when the Class has assembled.

Fee for the Class, £4 4s., including cost of materials and apparatus.

Analytical and Practical Chemistry.

BIRKBECK LABORATORY.

The instruction in the Laboratory is intended for beginners as well as for more advanced students. It includes practice in the construction and use of apparatus for preparing the common gases, acids, bases, salts, &c. study of the qualitative methods of detecting and separating mineral or organic bodies from one another; also quantitative analysis in the wet way, organic analyses, vapour-densities, &c.; instruction in gas analysis.

More advanced students are instructed in the methods of original research, especially in organic chemistry.

When accompanied or preceded by attendance on the Lectures on Chemistry, the Laboratory Course qualifies Students in the application of Chemistry to the Manufacturing Arts, Metallurgy, Medicine, or Agriculture, &c. Instruction is given in the principles and processes of Gas Analysis.

The Laboratory and Offices are fitted up completely with the most improved apparatus and utensils for experimental research, both for beginners and for advanced Students. They are open daily, from 9 a.m. to 4 p.m., from the 4th of October until the end of July, with a short recess at Christmas and at Easter. Saturday, from 9 to 2.

Fees for the Session, 25 guineas; six months, 18 guineas; three months, 10 guineas; one month, 4 guineas; exclusive of the expense of materials. A deduction of about 40 per cent is made for Students who can attend only three fixed days per week.

A Gold Medal and Certificates of Honour are competed for by Students entered for the Session.

EVENING CLASSES.

The Session is divided into three Terms, each of ten complete weeks, exclusive of vacations—

I. The Michaelmas Term, beginning on Monday, the 11th of October, and ending on Thursday, December 16th.

II. The Lent Term, beginning on Monday, the 10th of January, and ending on Thursday, March 17th.

III. The Summer Term, beginning on Monday, the 21st of March, and ending on Thursday, June 9th, the Easter Vacation extending from the 14th to the 25th of April, both days inclusive.

The object of these Classes is to extend the benefits of the College Tuition especially to gentlemen engaged elsewhere during the day, and to provide Instruction in subjects not taught in the ordinary College Classes.

The Beadles have orders to admit gentlemen to any of the Classes, with the permission of the Professor or Teacher, as occasional visitors.

The Library is open for the convenience of the Students between 6.30 and 8.30 on the evenings when the Classes meet, except when it is wanted for other purposes.

Elementary Chemistry—Theoretical and Practical.

Professor Williamson, F.R.S., and Mr. Jones. Monday, from 7.30 to 9.30.

A Course of Twenty Lessons, of two hours each, in the Michaelmas and Lent Terms.

The elements of Chemistry are explained to the Class, and the experiments illustrating the subject are performed by the Students.

The subject will be the common Non-Metallic Elements and the common Metals, their Compounds and chief Properties, and the best methods of distinguishing and separating them.

All the experiments and analyses are repeated by each Student, or by not more than two Students jointly.

Fee, including the cost of materials, &c., £2 2s. per Term.

ROYAL SCHOOL OF MINES AND COLLEGE OF CHEMISTRY.

Professor of Chemistry.—Dr. E. Frankland, F.R.S.

The instruction in Chemical Science embraces:—

1. A Course of Lectures on Experimental Chemistry with special reference to the applications of Chemistry in the Arts and Manufactures.

2 A systematic Laboratory Course for the Practice of Chemical Analysis.

Chemical Lectures.—The Course consists of Forty Lectures on Mineral Chemistry and Thirty Lectures on Organic Chemistry.

The Lectures are delivered at the Royal College of Chemistry, Oxford Street.

Chemical Laboratory.—The general Laboratory for instruction in chemical manipulation, in qualitative and quantitative analysis, and in the method of performing chemical researches, is under the direction of Dr. Frankland. The Royal College of Chemistry having become the property of the Government, its Laboratories are used for the instruction of the pupils of the Royal School of Mines.

There are three terms in the collegiate year, of three months each, commencing in the first week of October, January, and April respectively. The Laboratory hours are from 10 a.m. to 5 p.m., with the exception of Saturdays, when the Laboratory closes at 2 o'clock.

Each Laboratory Student works independently, there being no classes. All operations are superintended by the Professor and his assistants. A table with drawers, cupboards, and shelves, is appropriated to every pupil. The Institution supplies gas, fuel, and reagents. The larger and more expensive instruments of the Laboratory, such as air-pumps, thermometers, barometers, condensers, &c., may be used by the students, who are held responsible for their safety. The students have to provide themselves only with the apparatus specified in the Laboratory regulations. More advanced students engaged in private researches have to supply themselves with such materials as are not included amongst the ordinary reagents of the Laboratory.

Professor of Metallurgy.—Dr. Percy, F.R.S.

The course of instruction in Metallurgy consists of Lectures and Laboratory practice.

The object of the Lectures is the communication of such instruction as the student may be able to apply to the greatest practical advantage, when he may be subsequently engaged in conducting any metallurgical process.

Metallurgical Laboratory.—This Laboratory is conducted by Mr. R. Smith, under the direction of Dr. Percy, and is devoted to practical instruction in Metallurgy. The nature of this instruction will be adapted to the special requirements of the Students. It comprises:—Assaying in all its branches, especially of the more important metals, such as iron, copper, lead, tin, alloys of silver and gold, &c.; and the examination of ores and metallurgical products.

The ability of the student to make trustworthy assays is in every case thoroughly tested; and no certificate of competency is given to a student who has not furnished satisfactory proof that he is able to obtain accurate results.

There are three terms in the collegiate year, of three months each. The Laboratory hours are from 10 to 4 during November, December, January, and February; and from 10 to 5 during the other months, with the exception of Saturdays, when the Laboratory is closed.

The charge for instruction in the Metallurgical Laboratory is £15 for three months; £12 for two months; and £7 for one month.

Lectures to Working Men.—Short courses of lectures at suitable periods of the year are given in the evening to Working Men. These courses are systematic, and arranged so as to illustrate, within the period of two years, the principal subjects taught at the Institution. Those for the ensuing Session include:—Chemistry, Physics, Applied Mechanics, Metallurgy.

KING'S COLLEGE.

Professor of Chemistry—W. A. Miller, M.D. V.P.R.S.

Professor of Practical Chemistry—C. L. Bloxam.

Students of the first and second years are admitted to the Course of Theoretical and Applied Chemistry. The Course commences with a view of the forces which concur to the production of Chemical Phenomena, after which the laws of Chemical Attraction are discussed, and the Non-metallic Elements and their principal Compounds are described,

The metals and their principal compounds are next examined, care being taken to point out the applications of the Science to the Arts, and the processes of the different Manufactures of Metallurgy, and of Domestic Economy, are explained and illustrated.

Examinations of the Class, both *vivâ voce* and by written papers, are held at intervals during the course at the usual Lecture hour. Dr. Miller has published a work on Chemistry, which is used as a text-book by the class.

Third Year.—Students who have completed six Terms in this Department are admitted to a Course of "Practical Chemistry," consisting of Twelve Demonstrations in each term; and they go through a course of Manipulation in the most important operations of Chemistry, including the first steps of Analysis.

Any Student of this department may be admitted to this Class at any period of his study, on payment of an extra fee.

Experimental and Analytical Chemistry in the Laboratory.—The object of this Class is to afford to Students who are desirous of acquiring a knowledge of analysis, or of prosecuting original research, an opportunity of doing so under the superintendence of the Professor and Demonstrator; Students may enter, upon payment of the extra fees, at any time except during the vacation, and for a period of one, three, six or nine months, as may best suit their convenience. The laboratory hours are from ten till four daily, except Saturday, on which day the hours are from ten till one.

In addition to the Laboratory fee, each Student defrays the expenses of his own Experiments. The amount of this expense, which is comparatively trifling, is entirely under his own control.

Analytical and Experimental Chemistry.—Besides the Course of Chemical Lectures and the Summer Class of Practical Chemistry, provision is made for those Students who wish to become more minutely acquainted with the practical details of the science. By means of this Class each Student is enabled to familiarise himself with the methods of analysis and research. After passing through a preliminary course of analytical operations, each Student devotes himself to such portions of the science as are most interesting to himself, or most likely to be practically useful to him. The Daniell Scholarship of £20, tenable for two years, is given every alternate year for original research in the Laboratory.

The Fees for admission to the Laboratory Class, exclusive of materials, are, for one month, £4 4s.; for three months, £10 10s.; for six months, £18 18s., &c.

EVENING CLASSES.

Classes for Evening Instruction are held at King's College from October to March, and during April, May, and June.

The Classes include one for the Elements of Chemistry and one for Practical Chemistry.

The fee for the former is £1 11s. 6d.; for the latter £2 2s. The Classes meet twice a week.

PHARMACEUTICAL SOCIETY OF GREAT BRITAIN.

17, BLOOMSBURY SQUARE, W.C.

School of Pharmacy. The session (1869-70) will commence on Friday, October 1st, and extend to the end of July.

LECTURES ON CHEMISTRY AND PHARMACY, BY DR. REDWOOD.

These Lectures will be delivered on Monday, Tuesday, and Wednesday mornings, at 9 o'clock, commencing on Monday, October 4th.

Part 1.—Physics in relation to Chemistry and Pharmacy.
,, 2.—Chemistry of Inorganic Bodies.
,, 3.—Chemistry of Organic Bodies.

Also Lectures on Botany and Materia Medica, by Professor Bentley. The first and second parts of this course,

extending over the winter months, will be delivered at 17, Bloomsbury Square, on Friday and Saturday mornings, at 9 a.m., commencing on Friday, October 1st. The third part of the course, on Systematic Botany, will be delivered at the Royal Botanic Gardens, Regent's Park, at 8 a.m.

Fees.—For registered apprentices and associates of the Society' for either of the above courses, £1 1s.; for either part separately, 10s. 6d. For those not connected with the Society, £2 2s. for either of the above courses; £1 1s. for either part separately. Students have free admission to the Library and Museum.

Laboratory.—The suite of Laboratories for Practical Instruction in General and Pharmaceutical Chemistry will be opened on Friday, the 1st of October, under the direction of Professor Attfield, Ph.D. Fee for the entire session of ten months, Twenty-five Guineas. The Laboratories are open from 9.30 a.m. till 5 p.m. Students can enter at any period during the session.

Two Scholarships (the Jacob Bell Memorial Scholarship) of Thirty Pounds a year each, are open to competition annually in July.

The Board of Examiners meet monthly, and are required by the Pharmacy Act to examine "all candidates who may present themselves for examination in their knowledge of the Latin Language, in Botany, in Materia Medica, in Pharmaceutical and General Chemistry, and to grant Certificates of Competency.

CITY OF LONDON COLLEGE, LEADENHALL STREET, E.C.

The Annual Courses consist of three terms, each averaging ten experimental lectures; fee, 5s. per term. Subjects:—Junior Class, Chemistry—first year, Non-Metals; second year, Metals and (time permitting) Elements of Organic Chemistry. Senior class, 7 to 8 p.m., Practical Analysis.

LADIES' MEDICAL COLLEGE, FITZROY SQUARE.

The Course of Lectures on Elementary Chemistry, by Mr. John Newlands, F.C.S., will commence on Tuesday, October 5th, at 4 p.m., and be continued on successive Tuesdays at the same hour. Ladies will be admitted to the first lecture on presenting their cards at the College. Further particulars may be obtained on application to the Lady Secretary, at 4, Fitzroy Square.

BIRKBECK LITERARY AND SCIENTIFIC INSTITUTION.

EVENING CLASSES.

Chemistry.—Mr. G. Chaloner. Tuesday, 8 to 9.

NEW KENNINGTON INSTITUTE.

Evening Lectures and Practical Classes in Chemistry, under the direction of Dr. Muter.

POLYTECHNIC INSTITUTION.

Course of Thirty Lessons in Inorganic Chemistry, by Mr. G. F. Downar, under the superintendence of Professor Pepper. Tuesday, 8.30 to 10 p.m.

ROYAL VETERINARY COLLEGE, CAMDEN TOWN.

Chemical Professor.—Mr. R. V. Tuson.

LECTURES AT LONDON MEDICAL SCHOOLS.

ST. BARTHOLOMEW'S HOSPITAL & MEDICAL COLLEGE.

WINTER SESSION.

Lecturers.—William Odling, M.B. Lond., F.R.S., Fellow of the Royal College of Physicians, Fullerian Professor of Chemistry at the Royal Institution, and Dr. Matthiessen, F.R.S. Monday, Wednesday, and Friday, at 10 a.m. One course, £5 5s.

SUMMER SESSION.

Practical Chemistry.—Dr. Matthiessen, F.R.S. One course, £2 2s.

CHARING CROSS HOSPITAL AND COLLEGE.

WINTER SESSION.

Lecturer.—Mr. C. W. Heaton, F.C.S. Monday, Wednesday, and Friday, at 10. One session, £5 5s.

The Laboratory is open daily.

SUMMER SESSION.

Practical Chemistry.—Mr. Heaton, F.C.S. Monday, Wednesday, and Friday. One session, £2 2s.

ST. GEORGE'S HOSPITAL.

WINTER SESSION.

Lecturer.—Dr. H. M. Noad, F.R.S. Tuesday, Thursday, and Saturday, at 11.30. One course, £6 6s.

SUMMER SESSION.

Practical Chemistry.—Dr. Noad, F.R.S. Daily, at 10. One course, including the use of apparatus and materials, £4 4s.

GUY'S HOSPITAL.

WINTER SESSION.

Lecturer.—Dr. Alfred Taylor. Tuesday, Thursday, and Saturday, at 11. One course, £4 4s.

SUMMER SESSION.

Practical Chemistry.—Dr. Stevenson. Monday, Wednesday, and Friday, from 10 to 1. One course, £4 4s.

LONDON HOSPITAL.

Introductory Lecture on October 1st by C. Meymott Tidy, M.B., C.M., F.C.S., Lecturer on Chemistry at the Medical College.

Lecturers on Chemistry.—Henry Letheby, M.B., and C. Meymott Tidy, M.B.

The subjects of this course are Physics in their relation to Chemistry and Chemistry Proper. They are alternately made the chief subjects of the course, so that pupils who are studying for the Universities, may, in the period of two Winter Sessions, obtain a full course of Lectures on each subject.

The Lectures are delivered on Monday, Wednesday, and Friday, at 10·30 a.m.

Dr. Tidy has special classes for those reading for the Universities.

Practical Chemistry.—During the Summer Session, Dr. C. Meymott Tidy will deliver a short course of Lectures on Acoustics, in connection with a course on Diseases of the Ear, by Mr. Walter Rivington, M.S., Senior Assistant Surgeon, Lecturer on Anatomy, and Dean.

ST. MARY'S HOSPITAL.

WINTER SESSION.

Lecturer.—Dr. W. J. Russell, F.C.S. Monday, Tuesday, Thursday, and Friday, at 10.15. £5 5s.

SUMMER SESSION.

Practical Chemistry.—Dr. W. J. Russell, F.C.S. Tuesday and Thursday, at 11.30 a.m.; and Saturday, at 9 a.m. One session, £3 3s.

MIDDLESEX HOSPITAL.

WINTER SESSION.

Lecturers.—Mr. Taylor and Mr. Heisch. Monday, Wednesday, Friday, and Saturday, at 11. One session, £6 6s.

SUMMER SESSION.

Practical Chemistry.—Mr. Taylor and Mr. Heisch. Monday, Wednesday, and Friday, at 11. One session, £3 3s.

ST. THOMAS'S HOSPITAL.

WINTER SESSION.

Lecturer.—Dr. A. J. Bernays. Tuesday, Thursday, and Saturday, at 11. One course, £5 5s.

SUMMER SESSION.

Practical Chemistry.—Dr. A. J. Bernays. Tuesday and Thursday, 10 to 12; Friday, 11; Saturday, 10 to 1. One course, £3 3s.

WESTMINSTER HOSPITAL.

WINTER SESSION.

Lecturer.—Dr. A. Dupré, F.C.S. Tuesday and Thursday, at 3 p.m.; Friday, at 3.30 p.m. One course, £5.

SUMMER SESSION.

Practical Chemistry.—Dr. A. Dupré, F.C.S. Tuesday and Thursday, at 10 a.m. One course, £2.

PRIVATE TEACHERS OF CHEMISTRY IN LONDON.

Mr. J. C. Braithwaite, 54, Kentish Town Road, N.W.—Chemistry and Toxicology, Monday and Thursday; Latin, Tuesday and Friday; Botany and Materia Medica, Wednesday and Saturday. All the classes commence at 8 p.m. Laboratory open daily, except Saturdays.

Mr. Henry Matthews, F.C.S.—Laboratory, 60, Gower Street, Bedford Square. Instruction in all branches of Practical Chemistry, particularly in its application to Medicine, Agriculture, and Commerce. Laboratory open daily, except Saturday, from 10 to 5; on Saturday, from 10 to 1.

Mr. A. Vacher, 20, Great Marlborough Street, Regent Street.

Mr. John Newlands, F.C.S.—Laboratory, 13, Knowle Road, Brixton, S.W. Gives practical instruction in Analysis, and prepares gentlemen for various public examinations.

Dr. John Muter, M.A.—Laboratory, 289, Kennington Road. Instruction in Practical Chemistry and Pharmacy.

UNIVERSITY OF OXFORD.

Professor of Chemistry.—Sir B. C. Brodie, Bart., M.A., F.R.S.

Demonstrator.—E. Madan, M.A.

A commodious Laboratory is attached to the New Museum.

Scholarships of about the value of £75 are obtainable at Christ Church, Magdalen, and other Colleges, by competitive examination in Natural Science.

UNIVERSITY OF CAMBRIDGE.

Professor of Chemistry.—G. D. Liveing, M.A.

MICHAELMAS TERM.

Practical Chemistry, by the Professor, on Mondays, Wednesdays, and Fridays, at 1 p.m.

LENT TERM.

Chemistry, by the Professor, on Mondays, Wednesdays, and Fridays, at 12.

Practical Chemistry, on the same days, at 1 p.m.

EASTER TERM.

Chemistry, by the Professor, on Mondays, Wednesdays, and Fridays, at 12.

Practical Chemistry, on the same days, at 1 p.m.

The Chemical Laboratory of the University is open daily, from 10 a.m. till 6 p.m.; so that Students can work there at such times as may be convenient to them; and the Professor will attend to give instruction at the times above specified.

PROVINCIAL SCHOOLS.

BIRMINGHAM.—MIDLAND INSTITUTE.

Lecturer on Chemistry.—Mr. C. J. Woodward, B.Sc. Tuesday and Thursday, at 8 p.m.

Practical Chemistry.—Mr. C. J. Woodward, B.Sc. Saturday, 3 to 6, and 6.30 to 9.30 p.m.

BIRMINGHAM.—QUEEN'S COLLEGE.

WINTER SESSION.

Professor of Chemistry.—Alfred Hill, M.D., Borough Analyst. Tuesday, Thursday, and Friday, at 12.

SUMMER SESSION.

Practical Chemistry.—Professor A. Anderson. Thursday, at 1 p.m.; Friday, at 2 p.m.

BRISTOL.—BRISTOL MEDICAL SCHOOL.

WINTER SESSION.

Lecturer.—Mr. Thomas Coomber, F.C.S. Monday, Tuesday, Wednesday, and Thursday, at 8.15. One Course, £5 5s.

SUMMER SESSION.

Practical Chemistry.—Mr. T. Coomber, F.C.S. Daily, except Saturday, at 8 a.m. One Course, £3 3s.

ROYAL AGRICULTURAL COLLEGE, CIRENCESTER.

Professor of Chemistry.—A. H. Church, M.A., Oxon.

Assistant to Chemical Professor.—E. Kinch.

The Collegiate year is divided into Two Sessions. The Autumn Session commences August 9th, divides October 6th, and ends about December 16th. During each Session, the Lectures given and Practical Classes held in the Chemical department are as follows:—

1. *Inorganic Chemistry*—Thirty-six Illustrated Lectures; Ten Catechetical Lectures.
2. *Organic Chemistry.*—Thirty-six Lectures.
3. *Agricultural Chemistry.*—Twenty-eight Lectures.

1. *Chemical Manipulation.*—Twenty-eight Lessons.
2. *Qualitative Analysis.*—Thirty-six Lessons.
3. *Quantitative Analysis.*—A certain number of Lessons.

The Laboratory is also open several hours each day for advanced Students, who occupy themselves, under the direction of the Professor and his Assistant, with the Analysis of Soils, Manures, Feeding Stuffs, Waters, &c.

LIVERPOOL ROYAL INFIRMARY SCHOOL OF MEDICINE.

WINTER SESSION.

Chemical Lecturer.—Mr. J. C. Brown, B.Sc., F.C.S. Tuesday, Thursday, and Friday, at 10.15. One course, £5 5s.

SUMMER SESSION.

Practical Chemistry.—Mr. J. C. Brown, B.Sc., F.C.S. Monday, Tuesday, and Friday, at 10.15. One course, £3 3s.

The Laboratory is open daily, from 10 to 4.

SCHOOL OF TECHNICAL CHEMISTRY,

7, IRWELL CHAMBERS, OLD HALL STREET, LIVERPOOL.

Conducted by Mr. A. Norman Tate. Assistants—Mr. Walter Tate and Mr. Arnold Millson.

Pupils may attend at any time between the hours of 9.30 a.m. and 5 p.m. (Saturdays, 9.30 a.m. and 1 p.m.), and may work every day, or any number of days, or portion of a day in the week, and for any period most convenient to themselves.

A separate working bench is provided for each Student; and he will also be supplied with all the ordinary chemicals (with the exception of gold, silver, and platinum solutions, alcohol, ether, and similar costly reagents), books for

reference, gas, and fuel, and will be allowed the use of balances and weights, and the most substantial portions of laboratory apparatus; but he must provide himself with test tubes, beakers, and other glass vessels and apparatus of a fragile nature required in his researches.

The Course of Instruction, in addition to the ordinary chemical studies, comprises such other subjects as may be required in the prosecution of the particular branch or branches of Applied Chemistry in which the pupil is to engage; as, for example, in the case of a pupil intended for manufacturing pursuits, he would study architectural and mechanical drawing, so far as is required for the preparation of plans, &c., of chemical apparatus and manufactories, the nature and use of building materials, and the scientific principles and practical rules involved in building and constructive operations, and other scientific and practical information required in the arrangement, construction, and management of chemical manufactories, and the application of chemistry to industrial pursuits.

COLLEGE OF CHEMISTRY, LIVERPOOL.

Principal.—Dr. Sheridan Muspratt, F.R.S.E., M.R.I.A., F.C.S., &c.

Assistant.—Mr. Martin Murphy, F.C.S.

The Course of Instruction in this College is entirely devoted to Laboratory work. The term is three months, and dates from time of entrance. Fee for working six days per week, £12 12s; five days, £11 11s.; four days, £10 10s.; three days, £9 9s.; two days, £8 8s.; and one day per week, £6 6s. Hours of attendance, from 10 a.m. till 5 p.m. The students' laboratories close at 1 p.m. on Saturdays.

Medical students may enter for one hour per day per session. Fee, £3 3s.

Certificates of attendance recognised by the University and Apothecaries' Hall of London, and Apothecaries' Hall of Ireland.

LEEDS SCHOOL OF MEDICINE.

WINTER SESSION.

Lecturer.—Mr. J. Chapman Wilson, F.C.S.

Daily, except Saturday, at 11 a.m. One course, £4 4s.

SUMMER SESSION.

Practical Chemistry.—Mr. Wilson, F.C.S.

Tuesdays and Thursdays, 11 to 12.30. One course, £2 2s.

LEEDS MECHANICS' INSTITUTION AND LITERARY SOCIETY'S LABORATORY.

SESSION 1869-70.

Chemical Classes for Instruction in Elementary, Practical, and Analytical Chemistry.

Teacher.—Mr. George Ward, F.C.S.

The usual Sessional Course of Instruction in abstract and Applied Chemistry will commence on Thursday, September 23rd, at 8 p.m., on which evening the teacher of the classes will introduce the general subject in a Lecture explanatory of its principles, of the mode in which these should be studied, and also of the plan which he purposes to adopt in conducting the classes during the session.

Fees, payable in advance:—Elementary Chemistry, Thursday, per session, £1 15s.; or 5s. 6d. per month. The subscription includes a selection of apparatus and material specially adapted for the course of instruction. To pupils providing their own materials, £1 1s. per session. Organic Chemistry, Friday, per session, 10s. 6d. Practical Chemistry, Tuesday, per session, £1 1s.; or 3s. 6d. per month. including apparatus and material. The session extends over seven months, from October to April inclusive.

HIGH HARROGATE COLLEGE, YORKSHIRE.

Professor of Chemistry.—W. G. Mason, F.C.S., Certificated Science Teacher.

MANCHESTER GRAMMAR SCHOOL.

DEPARTMENT OF MATHEMATICS AND PHYSICAL SCIENCE.

Masters.—T. S. Aldis, M.A. (Cantab.), W. M. Watts, D.Sc. (Lond.); J. Angell Esq.

There is a large Chemical Laboratory attached to the School, and Chemistry and the various branches of Physics are regularly taught. Arrangements can be made for students to devote their whole time to Physical Science and Mathematics.

MANCHESTER ROYAL SCHOOL OF MEDICINE.

Lecturer on Chemistry.—Mr. Daniel Stone.

The usual course for the Medical Boards.

A Laboratory is connected with the school.

OWEN'S COLLEGE, MANCHESTER.

(IN CONNECTION WITH THE UNIVERSITY OF LONDON.)

Chemistry.—Professor H.E. Roscoe, B.A., Ph.D., F.R.S., F.C.S.,

Junior Class.—Wednesday and Saturday, from 9·15 to 10·15 a.m.

Subject: Inorganic Chemistry, comprising the laws of chemical combination, and a description of the properties and mode of preparation of the non-metallic elementary bodies and their most important compounds.

Senior Class.—Tuesday and Thursday, from 9.15 to 10.15 a.m.

Subjects: Inorganic and Organic Chemistry, including the properties of the metals and their compounds, and the composition and relations of the best defined groups of organic bodies, and the laws regulating their formation.

Students are expected to answer the written exercises and attend the *viva voce* examinations given in these classes.

Fee, for each class, £3 3s. For both classes, £5 5s.

A Recapitulatory Lecture, without additional Fee, will be given on Friday at 9.15 a.m., which members of both classes will be required to attend.

Extra Class.—Wednesday, from four to five p.m.

Subject: Technological Chemistry.

The Chemical Principles involved in the most important Chemical Manufactures will be chiefly considered in this course. The subject will be discussed as follows, and as far as time will permit.

1. Production of Heat—Heat of Combustion—Combustibles—Coal.
2. Production of Light—Coal Gas—Meaurement of Illuminating Power of Coal Gas—Distillation of Coal.
3. Water and Air, as regards their Sanitary and Technological Relations.
4. Processes concerned in the manufacture and application of the Alkalies.
5. Dyeing and Calico Printing.
6. Manufacture of Acids.
7. Manufacture of Glass and Porcelain.

Students attending this class must be acquainted with the principles of Chemical Science. Fee, £2 2s.

Analytical and Practical Chemistry.

LABORATORY COURSE.

Professor.—Henry E. Roscoe B.A., Ph.D., F.R.S.

Senior Assistant.—Mr. C. Schorlemmer, F.C.S.

Junior Assistant.—Mr. T. E. Thorpe, Ph.D.

The aim of this course is to make the student practically acquainted with Chemical Science, to enable him to conduct analysis and original research, and to fit him for applying the science to the higher branches of Art, Manufactures, and Agriculture. To accomplish this, an attendance of not less than four days per week during three whole sessions is as a rule necessary. It is very advisable that each Laboratory Student should attend or should have attended the course of Lectures on Theoretical Chemistry.

The College Laboratory will be open for students daily from 10.30 a.m. until 5 p.m., except Saturdays, when it will be closed at 1.30. The Laboratory is closed from 1.15 until 2, for dinner.

The Laboratory is fitted with every convenience for the prosecution of practical chemistry, all branches of qualitative and quantitative analysis, and original research.

Each student is provided with a separate working table, set of tests, fuel, water, and gas, free of expense; but he is required to find his own apparatus, a few of the more expensive reagents, and the chemicals required for his experiments. Other apparatus or instruments of a more expensive description may be obtained on loan from the Laboratory Steward, subject to regulations to be prescribed by the Professor.

Fees for the Session.—Students working six days per week, £21; ditto, four days, £17 17s.; ditto, three days, £13 13s.; ditto, two days, £9 9s.; ditto, one day, £5 5s. Students entering the Laboratory Class at or after Christmas, for not less than two days per week, will be charged two-thirds of the fees for the whole session.

Special Fees for Shorter Periods.—For six months, six days per week, £17 17s.; five months, ditto, £15 15s.; four months, ditto, £13 13s.; three months, ditto, £10 10s.; two months, ditto, £7 7s.; one month, ditto, £4 4s.

Lectures on the methods of Qualitative and Quantitative Analysis, intended to supplement the instruction in Practical Chemistry, will be given by Mr. Schorlemmer, on Mondays, from 4 to 5 p.m.

First year's Laboratory Students are recommended to attend and answer the written exercises and the *viva voce* questions given in this class. Fee, £1 11s. 6d.

Chemical Calculations.—In this class, instruction and special practice is given, by Mr. Schorlemmer, on Wednesday, from 4 to 5 p.m., in the methods of Chemical Calculations, serving as supplementary to the Lecture and Laboratory Courses. Fee, £1 1s.

The Lectures on Chemistry in Owen's College are recognised by the University of London for its Medical Degrees, by the Royal College of Surgeons, and by the Apothecaries' Hall.

EVENING CLASSES.

Chemistry.

Professor H. E. Roscoe, B.A., Ph.D., F.R.S.

Lecture Class (First Course—The Non-Metallic Elements).—Monday, from 8.35 to 9.35 p.m.

Lecture Class (Second Course—The Metals).—Mr. T. E. Thorpe, Ph.D. Friday, from 8.35 to 9.35 p.m.

Lecture Class (Third Course—Organic Chemistry).—Mr. C. Schorlemmer, F.C.S. Friday, from 7.30 to 8.30 p.m.

Laboratory Courses of Practical Chemistry.

Professor Roscoe, F.R.S., and Mr. Schorlemmer, F.C.S.

Junior and Senior Divisions.—Monday, from 6 to 8.30 p.m.

Pharmaceutical Course.—Monday from 6 to 8.30 p.m.

COLLEGE OF MEDICINE, NEWCASTLE.

(IN CONNECTION WITH THE UNIVERSITY OF DURHAM).

Education in Pharmacy.—The Council of the College have added a Lectureship on Pharmacy to those at present existing. The proposed curriculum for Students in Pharmacy will consist of attendance on Lectures on Botany, Materia Medica, Chemistry, and Pharmacy. The Lectures on the two former of these subjects will be delivered in the summer, and those on the two latter in the winter session of study.

Lecturer on Chemistry.—Mr. A. Freire-Marreco.

Monday, Wednesday, Thursday, and Friday, at 4 p.m.

EVENING COURSES.

Chemical Physics.—Every Monday, at 7.30 p.m.

Inorganic Chemistry.—Every Wednesday, at 7.30 p.m.

Practical Pharmacy.—B. S. Proctor. Every Tuesday, at 7.30 p.m.

This course will include—General Processes and Physics applied to Pharmacy—Pharmacopœial Processes, and the most important recent improvements in Pharmaceutical preparations—Dispensing operations—Testing and the Test Solutions of the Pharmacopœia. The course will be illustrated, whenever practicable, with apparatus, experiments, and processes in operation.

Practice of Chemistry.—The Laboratories are open daily throughout the year from 10 to 5 o'clock. Non-Medical students can attend Laboratory practice and receive Instruction in Analysis.

Students attending the Laboratory practice and Lectures on Chemistry, who have passed the Durham Registration Examination, or any Examination in Arts recognised as its equivalent, will be registered on the books of the College as Matriculated Students in Chemistry.

Fees.—Perpetual ticket for Pharmacy Course, £6 6s (this applies only to Students at present engaged in Pharmacy, and who enter before October, 1871). Separate Courses of Lectures (each), £4 4s. Laboratory Practice, 6 days per week—Three months' ticket, £9 9s; six months' ticket, £16 16s.; twelve months' ticket, £31 10s. Special arrangements for shorter attendances. These fees admit to all the courses in Chemistry. For a certificate in Chemistry, 10s.

SHEFFIELD.

Mr. W. Baker, F.C.S. Laboratory for Theoretical and Practical Chemistry, 46, High Street, Sheffield.

SCHOOL OF CHEMISTRY,

1, SURREY STREET, SHEFFIELD.

Mr. A. H. Allen, F.C.S., delivers a Course of Thirty Lectures on Inorganic Chemistry, in connection with the Science and Art Department.

Day and Evening Classes for Analytical Chemistry.

SHEFFIELD SCHOOL OF MEDICINE.

During the Winter Session, Mr. A. H. Allen, F.C.S., will deliver a Course of Forty-five Lectures on Chemistry.

SCOTLAND.

UNIVERSITY OF EDINBURGH.

Professor of Chemistry.—Dr. A. Crum Brown, F.R.S.

ROYAL COLLEGE OF PHYSICIANS AND SURGEONS, EDINBURGH.

Lecturer on Chemistry.—Dr. Stevenson Macadam, F.R.S.E.

The Courses of instruction in Chemistry include its applications to Medicine, Agriculture, and the Industrial Arts; and they qualify for the University of Edinburgh, and other Universities; the Royal Colleges of Physicians and Surgeons, the Navy, Army, and Indian Medical Service, and the other Medical and Public Boards.

The Lectures on Chemistry commence on Wednesday, November 3rd, and continue to be delivered daily during the five months of the Winter Session. The Lectures form a complete Course; the New Nomenclature and Notation are employed throughout, and special Lectures in Technological Chemistry are given. Tutorial Class Examinations are held during the Session, and Excursions are arranged for visiting the principal Chemical Manufactories.

The Instructions in Analytical Chemistry are conducted in the Laboratories at Surgeons' Hall, which are now open daily, under the personal superintendence of Dr. Macadam, for the instruction of gentlemen in Chemical Analysis, and the prosecution of researches in Manipulative Chemistry.

The Prelections in Practical Chemistry are also conducted in the Laboratories at Surgeons' Hall. The subjects

selected for Examination are those with which Medical Students are specially called upon to exhibit a practical acquaintance.

Fees.—Lecture, £3 5s. (University Graduation, £4 4s.); Practical Chemistry (University, &c.), £3 3s.; Analytical Chemistry, £2 per month, £5 for three months, or £10 for six months.

ANDERSONIAN UNIVERSITY, GLASGOW.

Professor of Chemistry.—Dr. Penny, F.R.S.E., F.C.S., &c.

1. Systematic Course of Lectures and Demonstrations on Chemistry, for Medical Students, Manufacturers, Civil Engineers, Agriculturists, &c. Daily, except Saturday, from 12 to 1, commencing 27th of October and terminating in April, £2 2s.

The object of this Course, which comprises upwards of 100 Lectures, is to convey to the student a thorough knowledge of the principles of Chemistry, and the applications of the science to Medicine, Manufactures, Agriculture, &c.

Certificates of attendance on these Lectures are received by the Royal College of Physicians of London and Edinburgh; by the Royal Colleges of Surgeons of England, Ireland, and Edinburgh; by the Faculty of Physicians and Surgeons of Glasgow; by the Army, Navy, and East India Boards; and by the Apothecaries' Halls. They also qualify for Graduation in the University of London, &c.

2. Instruction in the various branches of Practical Chemistry, and Analysis in the Laboratory. Daily, from 10 to 4.

After the usual preparatory training, the attention of the Student is specially directed to the examination and analysis of Minerals, Products of Commerce and Manufacture, Manures, &c., and, when desired, to Original Research.

3. The Private Laboratory for Commercial and Mineral analyses and assays, and for consultations and special investigations. Open daily, from 10 to 5, throughout the year.

4. Evening Course of Popular Lectures on the General Principles of Chemistry, and its application to the various branches of the Useful Arts. On Fridays, at 8.30.

Students attending this Course have the privilege of competing for the Prizes and Certificates offered by the Society of Arts, and the Government Department of Science and Art.

5. Evening Course of Instruction in Practical Chemistry and Analysis. On Thursday, from 7 to 9.

6. Summer Course of Practical Chemistry for Medical Students. Three months, commencing in May, £2 2s.

Young's Chair of Technical Chemistry.—This new Chair, which has been founded by Mr. James Young in connection with the Andersonian University, has been accepted by Mr. W. H. Perkin, F.R.S. We hear that the Laboratory will be opened in January next, and will accommodate about forty students.

UNIVERSITY OF GLASGOW.

Professor of Chemistry and Practical Chemistry.—Dr. Thomas Anderson, F.R.S.E.

GLASGOW MECHANICS' INSTITUTION.

Lecturer on Chemistry.—Dr. R. Carter Moffat.

1. Course of six months morning Lectures, qualifying for the various Medical Examinations, and also suited to the requirements of Manufacturers, Civil Engineers, &c. Daily, at 10. Begin 25th October.

2. Day and Evening Experimental Classes are held in the Laboratory, by Dr. R. Carter Moffat. Hours, from 10 till 4, and 7 till 9.

In these Classes, Students are instructed individually, and not as members of a class, so that every facility is given for the thorough attainment of the various principles and methods in Analysis, &c. Students may enter at any time; and the Classes are suitable for beginners as well as for advanced pupils. All are supplied with Apparatus, &c., and they personally perform their own Experiments. Those desiring it may take up, on entering, any department they choose—as, for example, the Analysis of Substances for Trade purposes, or investigations relative to the Improvement of certain Manufacturing Processes, and the Discovery of New Materials useful in the Arts, &c.

3. Popular Evening Lectures, every Monday, at 8.30, for six months.

4. Medical Students' Practical Class in Summer, commencing May 3rd. £2 2s.

GLASGOW VETERINARY COLLEGE.

Professor of Chemistry and Materia Medica.—Dr. R. Carter Moffat.

The Session will commence on Monday, October 25th, 1869.

IRELAND.

DUBLIN.—TRINITY COLLEGE.

Professor of Chemistry.—Dr. Apjohn, F.C.S.

The Lectures will commence on Wednesday, November 2nd, at 2 o'clock, and be continued each Tuesday, Thursday, and Saturday.

ROYAL COLLEGE OF SURGEONS, DUBLIN.

Professor of Chemistry.—Dr. Barker.

The Professor receives operating pupils into the Chemical Laboratory.

QUEEN'S COLLEGE, BELFAST.

Professor of Chemistry.—Dr. Andrews.

QUEEN'S COLLEGE, CORK.

Professor of Chemistry.—Dr. Blyth.

QUEEN'S COLLEGE, GALWAY.

Professor of Chemistry.—Dr. T. H. Rowney.

A Laboratory for Practical Instruction is attached to all the Queen's Colleges. The usual Practical Course for the Medical Boards is given in the summer.

ROYAL COLLEGE OF SCIENCE FOR IRELAND, STEPHEN'S GREEN, DUBLIN.

This College supplies, as far as practicable, a complete course of Instruction in Science, applicable to the Industrial Arts. The Subjects of Instruction are:—Pure and Applied Mathematics, Descriptive Geometry and Mechanical Drawing, Mechanism, Theoretical and Applied Chemistry, Chemical Analysis, Physics, Botany, Zoology, Geology and Paleontology, Mineralogy, Mining, Machinery, Surveying, and Agriculture.

Professor of Theoretical Chemistry.—W. K. Sullivan, Ph.D., V.P.R.I.

Professor of Analytical and Applied Chemistry.—R. Galloway, F.C.S.

Assistant Chemist.—Wm. Plunkett, F.C.S.

A Course of Lectures on Inorganic and Organic Chemistry is delivered by Dr. Sullivan three times a week during the session. Fee for the entire course, £2.

A Course of Lectures on Technological Chemistry is delivered by Mr. Galloway twice a week during the session. Fee for the course, £2.

The Chemical and Metallurgical Laboratories, under the Direction of Mr. Galloway, are open every week day during the session, except Saturday. Instruction is given in the different branches of Analytical Chemistry, including Assaying, and in the methods for performing Chemical research. Each student is taught, not in class, but separately and independently; and he is supplied with a separate working table, with reagents, fuel, water,

gas, and the larger and more expensive apparatus. Fee, for the session of nine months, £12; or for three months, £5; or for one month, £2.

Students have access to the extensive Library of scientific books in the College, and have the privilege of borrowing the books.

There are four Royal Scholarships, of the value of £50 each, yearly, with free Education, including Laboratory Instruction, tenable for two years; two become vacant each year; they are given to students who have been a year in the College. There are also nine Exhibitions attached to the College, of the yearly value of £50 each, with free Education, including Laboratory Instruction, tenable for three years; three become vacant each year. These are awarded at the annual May Examinations of the Science and Art Department.

A Diploma of Associate of the College is granted at the end of the three years' Course.

The Session commences on Monday, October 4th.

ON SPIRIT MADE FROM RICE.

By JAMES BELL, Esq.

THERE has always been a difficulty experienced in producing from rice a spirit free from a pungent odour. An impression prevailed that the pungency was due to the presence of some compound ether generated during the process of fermentation; but how or why it was produced in the fermentation of a saccharine extract prepared from rice, and not in that obtained in the ordinary way from other materials, was a problem which appeared difficult of solution.

In the course of manufacture of spirit from rice, sulphuric acid is the agent employed for converting the starch of the rice into glucose, and this process is conducted in a close wooden vessel under steam pressure at a temperature ranging from 216° to 230° Fahr. It has been observed that when the process of saccharisation was conducted at a temperature approaching 230°, the spirit obtained was more pungent than if the lower temperature had been observed. It has also been remarked that the pungency of the spirit was less in proportion as the rice was purified or freed from the husk.

Being desirous to investigate this subject, I undertook the examination of a sample of rice spirit which was placed at my disposal, and which had been made from rice that had been only partially freed from the husk, and though it appeared that the temperature during the process of saccharisation was maintained at about 216° Fahr., the spirit was very pungent.

The spirit was found, on the application of a slight heat, to freely reduce ammoniacal nitrate of silver, but without depositing the metal in a specular form; and a very small quantity sufficed to instantly decompose a solution of a permanganate.

When a portion of the spirit was treated in the cold with caustic potash and allowed to stand for a few hours, the pungency rapidly disappeared, and there was simultaneously produced a dark brown resinous substance soluble in alcohol and ether. The spirit recovered by distillation from the alcoholic alkaline solution was free from acrid odour, and gave the normal reaction with the mercury compounds for ethylic alcohol.

The addition of a very small quantity of the acid sulphite of sodium to the spirit, rapidly destroyed the pungent odour, and the alcohol obtained afterwards by distillation was unobjectionable in quality.

These reactions, it will be seen, pointed directly to the presence of an aldehyde, and in order to identify it, a portion of the spirit was introduced into a stoppered bottle, and treated in the cold with moist oxide of silver and left in contact therewith for several days. At the end of this time, there was a slight deposit of the metal on the glass, as well as other evidence that a quantity of the oxide had been reduced. To obtain the oxidised product, the excess of oxide of silver was removed by filtration and the silver salt in solution exactly decomposed with hydrochloric acid. The precipitate of chloride of silver was then filtered off, and the liberated acid neutralised with baryta and the spirit distilled. The distillate obtained was destitute of pungent odour, and the spirit was commercially pure.

The baryta salt which formed the residue in the retort was decomposed with sulphuric acid, and the liberated organic acid separated from the insoluble sulphate by distillation. The acid thus obtained proved to be acrylic, which had been produced from acrylic aldehyde by oxidation, and consequently, it was to the presence of this aldehyde that the pungent odour of the spirit was due.

There can hardly be a doubt that it is during the process of saccharisation that the fatty substances contained in the rice are decomposed; and that the acrolein is immediately thereupon produced by the action of the sulphuric acid upon the glycerine; and this view would seem to be borne out by the fact stated above, that a variation in the steam pressure in conducting the process of saccharisation affected the quantity of the acrolein produced.

It is well known that fats in a state of emulsion are in a condition to be readily acted upon by chemical reagents and to be decomposed, and it is not improbable that the conditions in this case are favourable to the action of the sulphuric acid upon the fatty substances in the rice, and in effecting their decomposition.

A sample of the rice from which the spirit was prepared was found to contain 0·62 per cent of fats, and assuming that the whole of the glycerine contained therein was converted into acrylic aldehyde, and that 65 per cent of starch was actually utilised in the production of ethylic alcohol, every thousand grains of the latter would contain one grain and a-half of the aldehyde.

The fact has long been known that rice spirit contained some compound which possessed the property, like acetone, of dissolving and keeping in solution certain compounds of mercury which are insoluble in pure alcohol and in water; and that before the absence of wood naphtha in rice spirit could be established by the ordinary chemical tests, it was necessary to distil the spirit once or twice from caustic potash.

The sample of rice spirit in question possessed the property of preventing the precipitation of the mercury compounds in an eminent degree, but the spirit after the complete separation of the acrylic aldehyde gave the normal reaction for pure alcohol.

To test the solvent power of acrolein for the mercury compounds, a small quantity of the aldehyde was prepared, and it was found to possess the property of preventing the precipitation of the ammonium compound of iodide of mercury in an alkaline solution, to nearly the same extent as acetone; and a very minute quantity of it was sufficient to impart a pungent odour to pure alcohol, similar to that possessed by the rice spirit.

MISCELLANEOUS.

Artificial Light.—The German chemist Landsberg says that artificial light contains 90 per cent of calorific rays, while sunlight contains only 50. To the number of these rays he attributes the disagreeable sensation produced upon the eyes by artificial light. By passing it through alum or mica, the calorific rays are interrupted, and the light rendered more agreeable and less injurious.

The Humboldt Centenary.—On the 14th of September, 1769, was born Alexander von Humboldt. According to the *Moniteur Belge* of this date, 1869, there is a plan on foot at Berlin to found and establish a Humboldt Palace, wherein would be united together the libraries of all the literary and scientific societies existing at Berlin, all of which would have their meeting rooms in that palace also.

St. Bartholomew's Hospital and College.—

The Winter Session will commence on Friday, October 1.

Students can reside within the Hospital walls, subject to the College Regulations.

For all particulars, concerning either the Hospital or College, application may be made, personally or by letter, to Mr. Morrant Baker, the Resident Warden; or at the Museum or Library.

St. Bartholomew's Hospital and College.—

CLASSES for the UNIVERSITY OF LONDON.

MATRICULATION EXAMINATION.

There will be Two Classes held at St. Bartholomew's Hospital in each year, for the convenience of gentlemen preparing for the Matriculation Examination at the London University—from October to January, and from March till June. Provision will be made for teaching all the subjects required, as follows:—

(1) Classics, French, English, Modern Geography, and English History—Malcolm Laing, M.A., Trinity College, Cambridge.
(2) Mathematics and Natural Philosophy—P. J. Hensley, M.D., Cantab., Fellow of Christ's College, Cambridge, Tutor to the Hospital.
(3) Chemistry—A. Matthiessen, F.R.S., Lecturer on Chemistry to the Hospital.

Fee for the Course of Three Months .. 10 guineas.
Fee for (1) or (2) .. .. 5 guineas.
Fee for (3) .. .. 2 guineas.

PRELIMINARY SCIENTIFIC EXAMINATION.

A Class in the subjects required for the preliminary Scientific Examination will be held from January to July, and will include all the subjects required, as follows:—

Chemistry—A. Matthiessen, F.R.S.
Botany—Rev. G. Henslow, M.A., Cantab., F.L.S., Lecturer on Botany to the Hospital.
Zoology and Comparative Anatomy—W. S. Church, M.D. Oxon., Lecturer on Comparative Anatomy to the Hospital; late Lee's Reader in Anatomy at Christchurch, Oxford.
Mechanical and Natural Philosophy—P. J. Hensley, M.D., Cantab.

Fee to Students of the Hospital .. .. 6 guineas.
Fee to others .. .. 10 guineas.
Fee for any single subject .. .. .. 3 guineas.

Further information may be obtained on application, personally or by letter, to the Resident Warden of the College, St. Bartholomew's Hospital.

University of Aberdeen.—Chancellor, His

Grace the Duke of Richmond. *Vice-Chancellor and Principal*, the Very Rev. P. C. Campbell, D.D. *Lord Rector*, M. E. Grant Duff, M.A., M.P.

FACULTY OF MEDICINE—SESSION 1869-70.

WINTER SESSION, Commencing on Wednesday, October 27.

Anatomy—Professor Struthers, M.D. 11 a.m. £3 3s.
Practical Anatomy and Demonstrations—Professor Struthers and the Demonstrator. 9 to 4, and 2 p.m. £2 2s.
Chemistry—Professor Brazier. 3 p.m. £3 3s.
Institutes of Medicine—Professor Ogilvie, M.D. 4 p.m. £3 3s.
Surgery—Professor Pirrie, C.M., F.R.S.E. 10 a.m. £3 3s.
Practice of Medicine—Professor Macrobin, M.D. 3 p.m. £3 3s.
Midwifery and Diseases of Women and Children—Professor Inglis, M.D. £3 3s.
Zoology, with Comparative Anatomy—Professor Nicol, F.G.S. 2 p.m. £3 3s.
Medical Logic and Medical Jurisprudence—Professor Ogston, M.D. 9 a.m. £3 3s.

SUMMER SESSION, Commencing on the First Monday of May.

Botany—Professor Dickie, M.D. 9 a.m. £3 3s.
Materia Medica (100 Lectures)—Professor Harvey, M.D. 3 and 4 p.m. £3 3s.
Practical Anatomy and Demonstrations—Professor Struthers and the Demonstrator. 9 to 4, and 2 p.m. £2 2s.
Practical Chemistry—Professor Brazier. 10 a.m. £3 3s.
Zoology, with Comparative Anatomy—Professor Nicol. 11 a.m. £3 3s.

Matriculation Fee (including all dues) for the Winter and Summer Sessions, £1. For the Summer Session alone, 10s.

Royal Infirmary—Daily, at Noon. Perpetual Fee to Hospital Practice, £6; or, first year, £3 10s., second year, £3.

Clinical Medicine—Drs. Harvey and Smith. £3 3s.
Clinical Surgery—Drs. Keith and Pirrie. £3 3s.

General Dispensary, and Lying-in and Vaccine Institution—Daily. Eye Institution—Daily. Royal Lunatic Asylum—Clinical Instruction is given for Three Months in the year.

The Regulations relative to the Registration of Students of Medicine, and the Granting of Degrees in Medicine and Surgery, may be had of Dr. Macrobin, Dean of the Faculty of Medicine.

Full information regarding the Classes and Degrees in the Faculties of Arts, Law, and Divinity, and in regard to Bursaries and Scholarships, will be found in the University Calendar, published by Messrs. Wyllie and Son, Union Street Aberdeen, by post, 1s. 8d.

Medical Education.—St. Mary's Hospital

MEDICAL SCHOOL, Paddington, will open on October 1st, 1869. In addition to the usual courses, special instruction is provided in Operative Minor Surgery and Bandaging, Ophthalmic, Aural, and Dental Surgery, Comparative Anatomy, Histology, and Pathology; all of which are taught practically by demonstration as well as lecture. For prospectus, apply to

W. B. CHEADLE, M.D., Dean of the School.

St. George's Hospital Medical School.—

The WINTER SESSION will commence on Friday, 1st October, with an Introductory Address by Dr. WADHAM, at 2 p.m., in the Hospital.

Consulting Physicians—Dr. Wilson, Dr. Bence Jones, Dr. Pitman.
Physicians—Dr. Fuller, Dr. Barclay, Dr. John Ogle, Dr. Wadham.
Assistant-Physicians—Dr. Dickinson, Dr. William Ogle.
Physician-Accoucheur—Dr. John Clarke.
Consulting-Surgeons—Mr. Cæsar Hawkins, Mr. Cutler, Mr. Tatum.
Surgeons—Mr. Hewett, Mr. Pollock, Mr. Henry Lee, Mr. Holmes.
Assistant-Surgeons—Mr. Rouse, Mr. Pick.
Ophthalmic Surgeon—Mr. Henry Power.
Orthopædic Surgeon—Mr. Brodhurst.

A Maternity Department and Departments for Ophthalmic and Dental Surgery are arranged in connection with the Hospital School.

LECTURERS.

Descriptive and Surgical Anatomy—Mr. Rouse.
Physiology and General Anatomy—Dr. Wm. Ogle.
Chemistry—Dr. Noad, F.R.S.
Medicine—Dr. Barclay.
Psychological Medicine—Dr. Blandford.
Surgery—Mr. Holmes.
Ophthalmic Surgery—Mr. Power.
Orthopædic Surgery—Mr. Brodhurst.
Operative Surgery—Mr. Rouse.
Pathology and Morbid Anatomy—Dr. John Ogle.
Midwifery—Dr. John Clarke.
Materia Medica—Dr. Dickinson.
Forensic Medicine—Dr. Wadham.
Dental Surgery—Mr. Vasey.
Botany—Mr. Child, F.L.S.

Clinical Lectures by the Physicians and Surgeons every week.

A Medical Tutor is appointed to superintend the studies of the pupils, and hold periodical examinations.

On payment of one hundred guineas at entrance, a Pupil becomes perpetual to the Hospital Practice and all the Lectures.

Compounders pay forty guineas on admission, forty guineas for the second year, and ten guineas for each subsequent year, until their payments shall have reached one hundred and ten guineas, when they become perpetual pupils.

Gentlemen may enter separately to Medical or Surgical Practice, or to any single course of Lectures.

Dental pupils are admitted on payment of £45.

The Pupils attending the Practice of the Hospital will be divided into classes among the Physicians and Surgeons in rotation, and each of them will be required to act as Clinical Clerks and Dressers to the Medical Officer to whom they are attached.

Special Demonstrations of Skin Diseases and Lectures on Public Health will form part of the course of Lectures on the Practice of Medicine; and Students will be required also to attend the separate courses of Lectures on Pathology and on Psychological Medicine.

In connection with the Lectures on Surgery, Demonstrations will be given on the Use of the Laryngoscope. A separate course of Lectures on Diseases of the Eye, with Demonstrations of the Use of the Ophthalmoscope, will be given, as well as Lectures on Orthopædic Surgery, with Illustrations of Deformities and their Treatment. Attendance on each of these courses will be required of Surgical Pupils.

In the Maternity Department, special Clinical Instruction will be given on Diseases peculiar to Women, and Practical Instruction in Vaccination to those who require certificates of proficiency.

House-Physicians and House-Surgeons are selected from among the senior Students according to merit, without further payment beyond a small sum paid to the Hospital for board.

The offices of Obstetric Assistant, Curator of the Museum, Medical and Surgical Registrars, and Demonstrator of Anatomy, with salaries of from £50 to £100 attached to each, are held out for competition annually. The William Brown Exhibition of £40 per annum, tenable for three years, is bestowed after a competitive examination. Clinical Prizes are offered annually by Sir Benjamin Brodie and Dr. Acland. Sir Charles Clarke's "Good Conduct" Prize; the Thompson Medal, and the Johnson Memorial Prize, are also to be competed for each year. A general examination of all the Students is held at the end of the Summer Session, and Prizes and Certificates of General Proficiency are given to the most deserving.

Further information may be obtained from Dr. Barclay, the Treasurer, or Mr. Holmes, the Dean of the Medical School, and from any of the Lecturers and Medical Officers of the Hospital.

New Kennington Institute.—The Popular

Evening Lectures and Practical Classes in CHEMISTRY will re-commence on the 1st of October, under the direction of Dr. MUTER.

Tickets to be had of W. Baxter, Hon. Sec., 182, Lower Kennington Lane.

THE CHEMICAL NEWS.

Vol. XX. No. 513.

ON MICROSCOPICAL MANIPULATION.*

By W. T. SUFFOLK, F.R.M.S.

The object of the present series of articles is to place my own practice before beginners in microscopical science, for although there are a vast number of existing works on the microscope, many of them are of a popular nature and addressed to those who seek in the microscope a means of recreation rather than of scientific research. My wish is to supply simple and practical directions to aid the student, giving very much in detail such processes as are but little mentioned in books, and which are more usually learned by seeing the instrument in the hands of an experienced person; but as this is an advantage not accessible to every one, it would seem that there is still a want, which it is my hope that this and succeeding papers will help to supply, and prepare the student to consult with profit more elaborate treatises.

I have thought proper, therefore, to devote this article to the consideration of the instrument we have to work with. No workman is any the worse for a knowledge of the contents of his tool-chest; in fact, he will be far better qualified for making use of the appliances he possesses by knowing their construction.

Microscopes vary much in their details of construction, each maker having an instrument for which he claims its own especial merit. For convenience sake, the general plan of structure may be described as consisting of a tube containing the optical portion, capable of a sufficient range of motion to and from a support for the object to be examined, known as the stage, beneath which is placed a mirror, provided with the necessary adjustments for reflecting light upwards through the aperture in the stage.

The plans employed for supporting the tube containing the lenses, or "body," are two in number; in one, that adopted by Messrs. Beck and a few other makers, the body is supported by the greater part of its length, and runs in groove of peculiar form, which effectually prevents the detrimental movement known as "twist." In the other mode, the one used by Messrs. Ross, Powell and Leland, and the majority of opticians, the body is attached to the extremity of the cross-arm, the rack work moving up and down in a tube attached to the trunnions which carry the instrument between the two uprights connected with its base. This last plan of construction involves the use of a greater weight of metal and a more careful disposition of it to secure stability than where the body is supported in the former manner, but when skilfully made there is no practical objection to its employment.

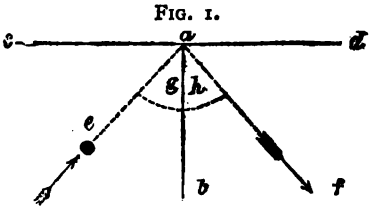
Dr. Carpenter speaks highly of the first mode, which is also approved of by Dr. Bowerbank: my experience is decidedly in its favour, my own instrument so constructed having been exposed to more than ten years' severe wear, and having had no substantial repairs during that period.

The part of the microscope I wish to direct attention to in the first instance, is the body and its contents. A combination of lenses called the object glass is screwed to the bottom of the tube, and another called the eye-piece, is placed at the top. For the sake of simplicity, the binocular arrangement will be for the present omitted, the instrument being supposed to have but a single body. In order that the use of the glasses contained in this tube may be understood, I must direct attention in the first place to some of the properties of light.

A *ray* of light, which is a very arbitrary term, may be considered, for the present purpose, as a small cylinder of light—a thing which has no real existence in nature, but will serve well for the purpose of demonstration. It is very much what the line is in mathematics.

Should this ray of light fall upon a polished surface which is not capable of allowing it to go through, or, in other words, an opaque polished surface like a bright plate of metal, *c*, *d* (Fig. 1), if the ray of light, *b*, *a*, falls upon that surface perpendicularly, it will be sent back by the same course through which it came down. On the contrary, should the ray of light *c*, *a*, fall obliquely, it will

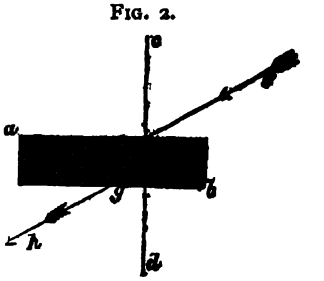
Fig. 1.



be reflected at an angle, *b*, *a*, *f*, equal to that *e*, *a*, *b*, at which it fell upon the reflecting medium. This angle of incidence, *e*, *a*, *b*, will be equal to the angle of reflection, *b*, *a*, *f*. Now this principle is made use of in our commonest means of illumination,—the mirror under the stage by which the light from a lamp or other source of light at one side or in front of the microscope, or in any other convenient place, is directed through the axis of the instrument. In the subsequent papers I shall say more about the application of the reflective principle. This is the only instance to be noticed at present.

Now, supposing that the ray of light falls upon a transparent material (a plate of glass, for example, a substance more dense than air), should the ray, *c*, *d*, fall upon this plate of glass, *a*, *b* (Fig. 2), perpendicularly,

Fig. 2.



it passes it straight through without any alteration taking place; but should the ray of light, *e*, *f*, fall obliquely, it will no longer pass through in the same direction, but will be bent towards the perpendicular,

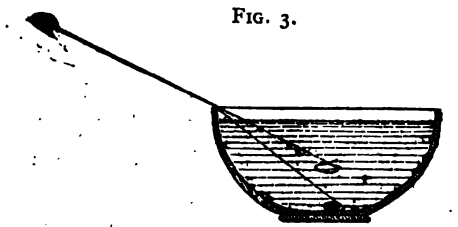
* The substance of a course of lectures delivered to the members of the Quekett Microscopical Club, January—April, 1869.

c, *d*, in a greater or less degree according to the density of the medium, as at *f*, *g*, and is bent again upon its emergence into the rarer medium at *g*, towards *h*.

The amount of "refraction," as this bending is called, would be much less with water than it would be with glass, and it would be greatest of all in the diamond, other substances refracting in intermediate degrees.

The effect of refraction is familiarly illustrated by the well-known phenomenon of objects immersed in water appearing to be nearer the surface than they really are, a pool appearing to be only three or four feet deep, when in reality it is nearer six or eight. This may be readily demonstrated by placing a stick or other object in a basin of water (Fig. 3); the stick

Fig. 3.



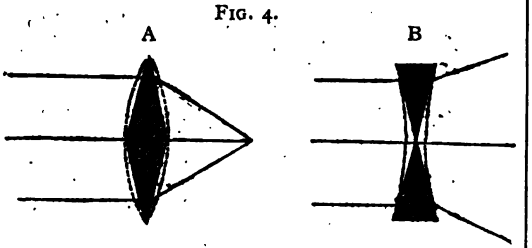
will appear bent where it enters the water; a coin or other object will appear to be at a much less depth than it actually is.

It is owing to refraction that we are able to make use of lenses, which give us the power of bending rays of light and turning them about in any way that may be required.

Lenses are circular pieces of glass or other transparent material capable of refracting light, and having curved surfaces, either convex or concave.

The action of a lens upon a ray of light will be best understood by reference to Fig 4. For the sake of

Fig. 4.



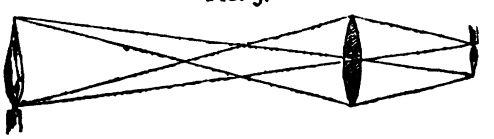
simplicity the dotted curved lines representing the section of the lenses may be considered as straight lines, as shown in the diagram.

It has been shown (Fig 2) that when a ray falls obliquely it is refracted, but that when it falls at right angles with the refracting medium it suffers no refraction. The central ray in both A and B passes straight through without refraction; in A the inclination of the surfaces is such that the rays passing above and below the centre line converge at a point called the focus. The lens, B, being thickest at the margin, the effect is just the reverse; the rays are dispersed, and do not come to a focus but diverge, as if they proceeded from a point on the opposite side of the lens, called the virtual focus. These concave lenses do not magnify, but are used in microscopes and other optical instruments, for purposes to be hereafter mentioned: the most familiar instances to be cited of their use are as the eye-glass of an opera-glass or Galilean telescope, and as spectacles for short-sighted persons.

Lenses may be made with one side worked to a plane surface and the other either convex or concave, such lenses are known as plano-convex and plano-concave lenses; their respective powers are about half those of lenses of similar and double curvatures. There are also lenses convex on one surface, and concave on the other; these are called meniscus lenses; the curves may be so proportioned that they have either the power of convex or concave lenses, according as they are thickest in the middle or at the edge; they have, moreover, some properties peculiar to themselves which are turned to good account by skilful opticians.

The formation of images is one of the most valuable properties of convex lenses, and one taken advantage of in the construction of optical instruments. If a convex lens is held at the distance of its focal length in front of a sheet of paper or other white surface, an inverted picture more or less distinct will be seen of objects that may be before it, such as a window or candle flame. This is illustrated by the diagram Fig. 5, representing a candle flame on the left hand, from the apex of which two rays diverge, the lower

Fig. 5.



one reaching the lower edge of the lens and the upper one its centre. Rays proceed from each point of the flame to every part of the surface of the lens, but, for the sake of clearness, only two are here represented. After passing through the lens they converge; the same takes place with the rays proceeding from the lower part of the flame, which also pass through the lens. The result is the formation of an inverted image, the size of which and its distance from the lens are dependent upon the distance of the object and the focal length of the lens.

The greater the distance of the object, or "anterior focus," the shorter will be the distance of the image, or "posterior focus." The commonest example may be taken from the operations of the photographer, who, if he wants to take a small portrait, will place the sitter at a great distance from the camera, if, on the contrary, he desires a large figure, he will bring his model nearer; in the former case the posterior focus of the camera will be shorter than in the latter, which is shown by the camera requiring to be lengthened when the model is brought near to it.

Besides the use of lenses to form images, they are also employed as magnifiers, and constitute the simplest form of microscope. Most naturalists and microscopists are provided with some little contrivance of this kind either attached to the watch chain or carried in the pocket,—either one or more lenses suitably mounted, or the Stanhope lens. In all these simple microscopes no image is formed, so that the principle upon which a magnified view is obtained is different. The idea of the magnitude of an object is formed entirely by the space which it occupies upon the retina of the eye. It is quite irrespective of its actual size; or, to express it in mathematical language, an object is large or small in proportion as it subtends a great or small angle with respect to the eye.

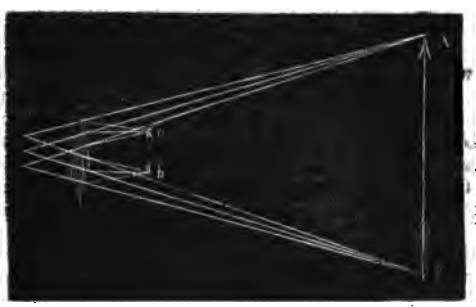
The eye has a certain power of adjusting itself to

view objects at different distances, but there is a limit to the distance of distinct vision. It varies from five to ten inches in different persons. An object cannot be distinctly seen nearer than either one or other of these distances, or some intermediate point. Now optical science supplies a means of overcoming this difficulty. An object apparently enlarged by being brought nearer to the eye, becomes indistinct, because the pencils of rays proceeding from it diverge too much to be brought to a focus on the retina by the lens of the eye.

The optical instrument most closely resembling the eye is the camera obscura. When the rack is run out to its full extent and the body is drawn out as far as it will go, and the object is still too near to be focussed distinctly, the position is precisely that of the eye with an object too close to it for distinct vision.

The remedy with the camera, supposing that no more focussing space could be obtained, would be to shorten the focus of the lens; that is, use one of greater refractive power. The same thing must be done in the case of indistinct vision, by interposing a convex lens and so increasing the convergent power of the lens of the eye; the object, hitherto too near the eye, *a*, *b*, is thus rendered visible and clearly defined, but with this remarkable difference, that it appears not to be the image of the object placed near the eye, but of a larger object, A, B, at the distance of distinct vision. No crossing of the rays takes place, and consequently the image is not inverted.

FIG. 6.*



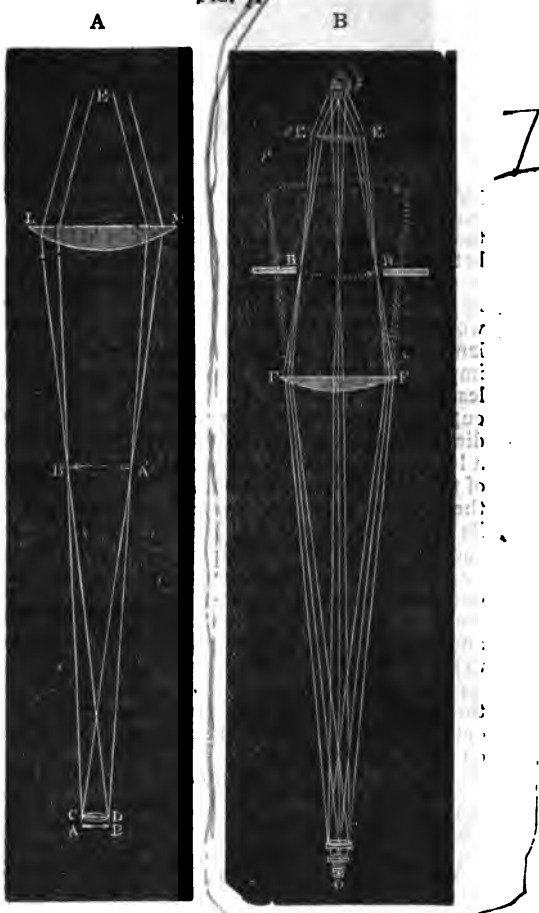
The hand magnifier is an extremely useful instrument, but many persons find great trouble in using it to advantage, especially when it is of short focus and high power. A trifling hint about its use may be of value.

Hold the object in the left hand, either in the fingers or with forceps, and, placing the left hand against the right which is holding the lens, look through the magnifier and adjust the focus. The view is usually most distinct when the eye is in one focus of the lens and the object in the other; the two hands being held in contact move together and prevent that tremor which would be apparent, especially with high powers, if the hands were kept apart, and which unsteadiness prevents any accurate view of the object being obtained. Single lenses, when their diameter exceeds that of the pupil, possess the property of bringing light to the eye and rendering the object clearer than it would be without such assistance. This may be proved by looking at print or other suitable object in a bad light and noticing how much the magnifier aids by its light-collecting power.

Single lenses are mounted on stands of various kinds, and then they become what are called single or simple microscopes. The older observers had no other instruments. These may consist of many lenses, while the compound microscope may be made with as few as two; but then they act upon the principle that no image is formed, but the object is rendered visible at a shorter distance than it could be without optical aid. Single microscopes are still in use for dissection and other purposes where only a low power is required. And various contrivances have been adopted by which both eyes may be used and much fatigue saved in protracted operations.

The compound microscope differs from the simple instrument just mentioned in an image being formed and again magnified by being viewed with another lens or eye-piece (Fig. 7).

FIG. 7.



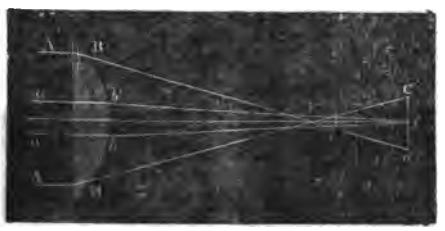
From what has been said before respecting the formation of images, it is evident if a lens of short focus is used and an object placed before it, the image will be formed at a great distance behind it and be much enlarged; if instead of viewing this image directly, as in the camera obscura, it is viewed with a suitable lens, another enlargement takes place. Such an instrument might be constructed with only two lenses, as in the diagram Fig. 7, A, but a microscope so made would of course be a very imperfect instrument; indeed it would in almost every point be inferior in its performance to that of a simple lens, principally because the eye lens magnifies all the

* Figs. 6, 7, 8, and 10 are taken from "The Microscope and its Revelations," by W. B. Carpenter, M.D. (Churchill).

imperfections of the image formed by the small lens or object-glass. These imperfections are chiefly caused by the spherical and chromatic aberrations of the object-glass, and also in some degree by those of the eye-piece.

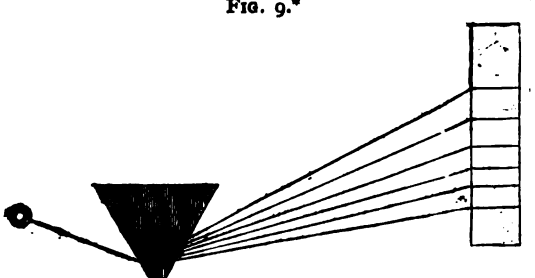
Theoretically, convex lenses bring parallel rays to a point called the focus, at a distance from the lens dependent upon the radii of their curved sides; practically, this is not the case; the rays passing through the marginal portion of the lens come to a focus at a shorter distance from it than those which pass through or near its centre (Fig. 8). Those

Fig. 8.



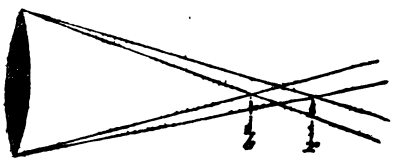
passing through intermediate portions converge to some part between these two points; the result is that indistinct images are formed at various points between F and *f*, Fig. 8, no well-defined figure being seen anywhere. Could lenses be made having an hyperbolic or elliptic section, the spherical aberration would be corrected, but the difficulties of making lenses of such figures are so great as to be considered impossible in practice. Spherical aberration may be lessened by reducing the aperture of the lens, by cutting off the marginal portion by means of stops or diaphragms; but any great use of this means causes a loss of light very detrimental to the performance of the instrument. Advantage may also be taken of the position in which the lens is placed and also of its figure; the spherical aberration of some lenses, such as plano-convex and meniscus, is much affected by the way they are placed, being much greater in one position than other. Much may be done by placing the glasses in their most favourable position and using suitable curves: as a striking example, take to pieces a photographic lens and observe the curious forms adopted in its construction. The details of these corrections are rather a matter for the practical optician, and are unsuitable for an elementary treatise on the microscope.

Fig. 9.*



Chromatic aberration is caused by the unequal refraction of the constituents of a ray of light. If a ray be bent by passing through a glass prism, instead of the ray appearing on the other side as white light it will be decomposed, owing to the unequal capability of bending which the rays possess; the red ray is bent least, the yellow more, and the blue and violet most of all (Fig 9). This also takes place when light is caused to pass through a lens (Fig. 10). The blue ray

Fig. 10.



being the most refrangible comes to a focus nearest to the lens at *b*; the red ray being the least refrangible will not converge until it reaches *r*; the yellow, green, &c., rays come to a focus at intermediate points, so that a series of images surrounded by fringes of their respective colours would be formed at various points between *b* and *r*, such coloured margins rendering the definition extremely defective. Chromatic aberration may be lessened by the use of stops, cutting off the marginal portion of the lens, but at the sacrifice of a great quantity of light and the impairing of some of the most valuable qualities of the glass for microscopic purposes. Fortunately, a means has been found of almost entirely correcting chromatic aberration. Different kinds of glass vary not only in their refractive power but also in the degree in which they disperse the coloured rays, and, by combining lenses of suitable forms and materials, the error of one lens is so neutralised by the opposite error of the other that the combination as a whole is nearly free from the production of colour, or becomes, as it is termed, achromatic. For the practical application of this valuable fact, we are indebted to the elder Dollond, who constructed telescopes on this principle towards the end of the last century. The object glass of the microscope was not improved until many years afterwards.

Owing to the very divergent condition of the rays proceeding from a minute object placed near the lens of a microscope, the construction of an achromatic object-glass is much more complex than the combination employed in other optical instruments. High powers contain as many as three combinations of compound lenses placed behind each other, the careful adaptation of which requires the greatest skill on the part of the optician, and necessarily causes objectives of large aperture and great perfection to be very costly. A valuable series of papers by Mr. F. H. Wenham on the construction of object-glasses for microscopes will be found in the *Monthly Microscopical Journal*, vol. I., pp. 111, &c.

So perfectly was the correction of the chromatic and spherical aberrations effected, that it was found that even the covering of the object to be viewed with a thin plate of glass or mica rendered the image sensibly indistinct: fortunately the defect was no sooner discovered than the late Andrew Ross applied a simple remedy; some alteration was made in the disposition of the correcting media, and the front combination allowed a small range of motion backwards and forwards, which is usually regulated by a graduated collar, the use of which it will be well to explain, as, although it is to be found in most works on the microscope, it seems to be generally overlooked. Makers differ a little in the details of their arrangement for this correction, but there will always be found some mark indicating when the object-glass is corrected, for viewing an uncovered object. Focus

* Hardwich's "Photographic Chemistry," p. 173 (Churchill).

carefully for distinct vision, with the glass so arranged, and then, taking hold of the collar, turn it round until a view is obtained of dust that may be resting on the upper surface of the cover of the slide; if the object is now focussed by the use of the fine adjustment, the correction for the thickness of the cover glass will be found to be very perfectly made, and as the collar is usually graduated, the number may be noted on the slide for future use, as it is constant with the same object and eye-piece, and also for the same thickness of cover-glass.

The eye-piece usually employed in the microscope in combination with achromatic object-glasses is that invented by Huyghens, a Dutch astronomer (Fig. 7, B), and consists of two plano-convex lenses (E E and F F), with their plane sides towards the eye; this eye-piece, although not achromatic, when used with object-glasses slightly "over-corrected," renders the instrument achromatic as a whole. The optical principles involved are far too complicated to find a place in the present paper.

The power of the instrument may be greatly varied by using a series of eye-pieces of different power, and if the corrections of the object-glass are perfect, and its angular aperture sufficient to admit a large amount of light, great advantage may be derived from the use of a short or "deep" eye-piece; but as the magnifying power of the eye-piece exaggerates every defect of the image, it is only with good object-glasses that this means of increasing the power is available. A very deep eye-piece is of value in testing the quality of an objective, as it causes defects which may not be apparent with lower powers to become very marked.

The power of the instrument is greatly influenced by the length of the tube or body, and were it not for the inconvenience of excessive length, this would probably be the least objectionable way of increasing the magnifying power, but a very long tube renders manipulation difficult, on account of its removing the hands to an uncomfortable distance from the stage and illuminating apparatus. Most microscopes have a sliding tube in the body known as the draw-tube, by which the length can be increased to the extent of four or six inches at pleasure.

(To be continued.)

PRELIMINARY NOTE ON A NEW CORNISH MINERAL.

By Professor CHURCH, M.A.

DURING a recent visit to Cornwall, I purchased from Mr. Talling, of Lostwithiel, some specimens of a dark brown, amorphous mineral which had been recently found by him. These prove to be an unrecognised silicate of iron. Here are, in brief, the characters of the new species:—

Hardness, 2·75; specific gravity, 1·74. Amorphous, reniform, fissured, dark brown. Streak, pale rust-brown. Fragile; fracture, irregular conchoidal. Blowpipe—in closed tube, much water, having slight permanent acid reaction; on charcoal, decrepitates, and becomes black; partially fuses in outer flame to a black bead, in inner to a red-brown. Boiled in acids, leaves a siliceous skeleton.

This mineral gives, on analysis, the following percentages:—

Water	10·51
Silica	36·39
Ferric oxide	52·94
	99·85

The mineral also contains 0·82 per cent of P_2O_5, and traces of magnesia. It loses 29 per cent of water *in vacuo*, and only 0·54 per cent more at 100°. The analyses were made with the substance dried at 100° C.

The numbers above agree with the expression—

$$5Fe_2O_3,9SiO_2,8H_2O,$$

which demands 53·74 per cent Fe_2O_3, 36·58 per cent SiO_2, and 9·68 per cent H_2O; but many considerations point to the simpler formula, $Fe_2O_3,2SiO_2,2H_2O$, which demands—

	Theory.	Experiment.
$2H_2O$	11·39	10·51
$2SiO_2$	37·98	36·39
Fe_2O_3	50·63	52·94
	100·00	99·85

The chief discrepancy between theory and experiment concerns the iron, which is greater than it should be. This arises from three causes—(1) Traces of the iron exists as a ferrous salt in the mineral; (2) the percentage of Fe_2O_3 includes 0·82 per cent of P_2O_5; (3) it is difficult to separate the haematitic matrix from every portion of the mineral taken for analysis. The causes which have raised the iron percentage have also been amongst those which have reduced the silica and water percentages below their theoretical amounts.

The new mineral, which I shall name on a future occasion, has been mistaken for beraunite: it accompanies pyrite, chalybite, quartz, black haematite, and cronstedtite.

ON THE SUPPOSED ACTION OF LIGHT ON COMBUSTION.*

By CHARLES TOMLINSON, F.R.S., F.C.S.

THE popular idea that "light puts out the fire," is so fixed, that probably no conclusions drawn from actual experiment are likely to disturb it, especially if they be adverse to the notion. It is a matter of daily experience, people say, that, if the fire is nearly out, and you put a screen before it, or draw down the blind, or close the window-shutters, it will immediately begin to revive. It is generally forgotten that a fire that looks dull, or "out," in a well lighted room, will appear to be in tolerable condition in the same room when darkened. It only requires to be "put together" to make it burn up, and it might have been done so just as well in the light.

Experiments on this subject are not easy to make, on account of the many disturbing causes. In an old volume of the "Annals of Philosophy," is an account of some experiments by Dr. M'Keever, who took two portions of green wax taper, each weighing 10 grains, and ignited both at the same moment. One piece was placed in a dark room, at 67° F.; the other was exposed to broad sunshine, at 78° F.

In five minutes { The taper in sunshine lost .. 8½ grs.
" darkened room lost 2½ "

The taper, divided into inches, was also burnt in the coloured portions of the solar spectrum, when it was found that the time required to burn two inches of taper varied as follows:—

	Mins.	Secs.
In the red ray it took	8	0
In the green	8	20
In the violet	8	39
In the verge of the violet ..	8	57

The conclusion is, that the solar rays, in proportion to their intensity, have the power of retarding, to a con-

* Read before the British Association, Exeter Meeting, Section B.

siderable extent, the process of combustion; and it is supposed that the chemical rays act, in some way, on the portion of oxygen about to combine with the fuel, so as to delay, if not prevent, combination.

Supposing, in these experiments, the taper was so uniform, that one inch contained precisely the same quantity of matter as another inch, the time occupied in burning was too short to justify so important a conclusion as Dr. M'Keever arrived at, whether the results were taken by measure or by weight.

Everyone engaged in photometrical observations must be aware of the difficulty of getting rid of disturbing causes and perplexing results. In comparing candles of the same make, the light is affected, both in quantity and economy, by a number of small circumstances, such as the warmth of the room, the existence of slight currents of air, the extent to which the wick curls over in burning, and so on. In testing the quality of gas, the standard candle defined by Act of Parliament is a sperm candle of six to the pound, burning at the rate of 120 grains per hour. From such a standard, we get the terms "twelve candle gas," "fourteen candle gas," &c. Mr. Sugg, in his "Gas Manipulation," has pointed out some of the difficulties in obtaining a uniform standard candle. The wick does not always contain the same number of strands; they are not all twisted to the same degree of hardness; the so-called sperm may vary in composition—one candle containing a little more wax than another, or variable quantities of stearine or of paraffin; the candle may have been kept in store a long or a short time; the temperature of the store-room may have varied considerably, and the temperature of the room in which it was burnt may have been high or low. All these circumstances affect the rate of combustion, and the illuminating power of candles, irrespective of the action of light, if such action really exist.

I have lately had a good opportunity of testing this action at the works of Price's Patent Candle Company, at Battersea. Under the direction of Mr. Hatcher, the accomplished chemist of the Company, the greatest possible care is taken to ensure identity of composition and illuminating power in candles of the same name. There has lately been an extensive series of experiments on the photometrical value of sperm candles, during which, at my request, Mr. Hatcher was good enough to note the rate of combustion of such candles in a darkened room, and also in broad daylight, and even in sunshine.

In the first observation, three hard and three soft candles were burned, each for four hours, in a dark closet. A similar set of candles, taken from one and the same filling, were burned, during the same time, in open daylight, partly in sunlight. The average consumption per hour of each candle was as follows:—

Sperm, in the dark	.. .. ..	134 grs.
Ditto, in the light	.. .. ..	141 ,,
No. 2 composites	In the dark ..	133 grs.
	In the light ..	140 ,,

It must be noticed that the temperature in the light was 72°, and in the dark 71°; moreover, in the light there was a much greater motion of the air than in the dark closet. Both these circumstances would operate in producing a larger consumption of candle.

In a second trial with No. 2 composites, the results were:—

In the dark	..	140 grs. each candle.
In the light	..	134 ,, ,,

In a third trial, also with No. 2 composites, the results were:—

In the dark	.. ..	131 grs.
In the light	.. ..	129 ,,

In these two trials, the flames were protected, as far as possible, from currents of air; and, in a third trial, the temperature, both in the light and in the dark, was nearly equal.

The fourth trial was made on a bright, sunshiny day, with hard sperm candles, which are less affected by variations of temperature than the composites. The results were:—

In the dark (temperature, 81°), 544 grs., or 136 grs. per hour.

In the light (temperature, 84°), 567 grs., or 142 grs. per hour, nearly.

It is evident that, in this case, the increase of temperature caused by the bright sunshine led to an increased consumption of material.

It will be seen that, in the first and fourth trials, there is a greater consumption of material in the light than in the dark; and in the second and third trials, the consumption is greater in the dark than in the light; but, in any case, the difference is so small—amounting only to from 2 to 7 grains per hour—that it may fairly be referred to accidental circumstances, such as difference in temperature, in currents of air, and in the composition and make of the candles; the final conclusion to which I am led being that the direct light of the sun, or the diffused light of day, has no action on the rate of burning or in retarding the combustion of an ordinary candle.

SOME EXPERIMENTS WITH THE GREAT INDUCTION COIL AT THE ROYAL POLYTECHNIC.*

By JOHN HENRY PEPPER, F.C.S., Assoc. Inst. C.E.

The Large Induction Coil.

The length of the coil from end to end is 9 feet 10 inches, and the diameter 2 feet; the whole is cased in ebonite; it stands on two strong pillars covered with ebonite, the feet of the pillars being of a diameter of 22 inches. The ebonite tubes, &c. are the largest ever constructed by the Silver Town Works.

The total weight of the great coil is 15 cwts., that of the ebonite alone being 477 lbs.

The primary wire is made of copper of the highest conductivity, and weighs 145 lbs.; the diameter of this wire is 0·0925 of an inch, and the length 3770 yards. The number of revolutions of the primary wire round the core of soft iron is 6000, its arrangement being 3, 6, and 12 strands.

The total resistance of the primary is 2·201400 British Association units, and the resistances of the primary conductors are respectively—For three strands, 0·733800 B.A.U.; six, 0·366945 B.A.U.; twelve, 0·1834725 B.A.U.

The primary core consists of extremely soft straight iron wires 5 feet in length, and each wire is 0·0625 of an inch in diameter. The diameter of the combined wires is 4 inches, and the weight of the core is 123 lbs.

The secondary wire is 150 miles in length; it is covered with silk throughout, and the average diameter is 0·015 of an inch.

The total weight of this wire is 606 lbs., and the resistance 33,560 B.A. units. The length of the secondary coil is 50 inches, and the insulation throughout is calculated to be 95 per cent beyond that required. The secondary wire is insulated from the primary by means of an ebonite tube of ¼ an inch in thickness and 8 feet in length.

The length of the secondary coil is 54 inches, the diameter is 19 inches, and without the internal ebonite tube containing the primary wire and iron core it is a cylinder 19 inches in diameter and 6 inches thick.

The condenser, made in the usual manner with sheets of varnished paper and tinfoil, is arranged in six parts,

* Abstract of a paper communicated to the Royal Society, by J. P. Gassiot, F.R.S.

each containing 125 superficial feet, or 750 square feet of tinfoil in the whole.

A large and substantially made contact breaker, detached from the great coil and worked by an independent electro-magnet, was constructed and worked very well with a comparatively moderate power of 10 or 20 large Bunsen's cells; when, however, the battery was increased to 30 or 40 cells, it became unmanageable.

A Foucault break, with the platinum amalgam and alcohol above it, was now tried, and answered very much better than the ordinary contact breaker; there was no longer any burning or destruction of the contact points, although the great power of the instrument appeared to cause continued decomposition in the water of the alcohol placed above the platinum amalgam; and every now and then the spirit was violently ejected, probably by explosion of the mixed gases taking place in the amalgam, in which they collected in bubbles; the alcohol took fire constantly, and had to be extinguished. A large and very strong glass vessel (in fact, an inverted glass cell belonging to a bichromate battery) was bored through, and the neck fitted into a cap with cement, a thick wire covered with platinum being inserted in the botton; the platinum amalgam was poured on this, and over it a pint or more of alcohol; the contact wire was also very thick and pointed with a thick stud of platinum, and, being attached to a spring, contact was easily made and broken. Explosions did not occur, flashes of light could be seen between the amalgam and the alcohol, and the height of the column of the latter prevented the forcible ejection of the spirit, which no longer took fire. The break was used for eight hours in a continuous series of experiments.

The Bunsen's battery used in the experiments was made with the largest porous cells that could be obtained, and each cell contained about one pint of nitric acid.

Some experiments were tried with the battery arranged for intensity, and used with the complete condenser of 750 square feet of tinfoil and 1500 square feet of paper. At first five cells were used, and these gave a spark 12 inches in length. The number of cells were gradually increased until 50 were in operation, when a spark from 28 to 29 inches in length was obtained.

In order to ascertain whether any variation in the size of the condenser would affect the length of the spark, a number of experiments were tried; and it was found that when half the condenser was used the spark increased in length up to twenty cells, but not after.

Experiments were now tried to ascertain whether any increase in the length of the spark could be obtained by arranging the battery and the primary coil for *quantity*, but no material advantage was obtained by this arrangement; even where three groups of cells were connected a decrease in the length of the spark is observed when compared with the 45 or 50 cells arranged for intensity, the difference being as 20 to 28.

The spark obtained from the large coil is thick and flame-like in its appearance, and therefore it will be alluded to as the "flaming spark."

When the discharging point and circular plate are brought within 6 or 7 inches of each other, the flaming nature of the spark becomes still more apparent.

Two light yellow flames curving upwards appear to connect the opposite poles. If a blast of air from powerful bellows is directed against a flaming spark, the flaming portion can be blown away and increased in area, and thin wiry sparks are now seen darting through it, sometimes in one continuous stream, at another time divided into three or more sparks, all following the direction in which the flame is blown.

The flaming spark is very hot, and if passed through asbestos (supported on an insulating pillar), quickly causes the latter to become red-hot.

When powdered charcoal is shaken from a pepper-box into the flaming spark in a vertical line and in considerable quantities, the greater part of the light is obscured, and the whole form of the flaming spark presents the appearance of a black cloud with a line of brightly ignited particles fringing the bottom parts. If the charcoal is dusted through in small quantities, each particle becomes ignited, like blowing charcoal into a hydrogen flame.

When the flaming spark is directed on to a glass plate upon which a little solution of lithium chloride is placed, the latter colours the flame upwards to the height of 3 or 4 in the most beautiful manner; and if the point of the discharge is tipped with paper, or sponge moistened with a little solution of sodium chloride, the two colours (the yellow from the salt, and the crimson from the lithium) meet each other, a neutral point being found about halfway, and thus illustrating apparently the dual character of electricity, and that + passes to − electrical, and *vice versâ*.

The flaming spark can be obtained in perfectly dry air.

Whilst passing through common air, if blown against a sheet of damp litmus-paper, the latter is rapidly changed red. In order to ascertain whether the acid product was nitric acid, the flaming spark (9 or 10 inches in length) was passed through a tube connected by a cork and bent tube with a bottle containing distilled water, from which another tube passed to the air-pump; on drawing the air slowly over the spark, and passing the former into the bottle, nitric acid was obtained in large quantities, so much so that it could be detected by the smell and taste as well as by the ordinary tests. The popular notion that nitric acid is always produced during a thunder-storm would therefore appear to be correct. To determine the effect of a cooling surface on the flaming spark, a hole 1¼ inches in diameter was bored through a thick block of Wenham Lake ice, and the spark passed through the air in the tube of ice; no change took place, and the spark was still a flaming one.

When the spark was received on the ice, it lost its flaming character, and became thin and wiry, spreading out in all directions.

If the discharging wires were tipped with ice, the spark was always flaming when any thickness of air intervened between them. Even over the ice, if the spark passed a fraction of an inch above the surface, it was always a flaming one, but changed to the thin spark when the point of the discharging wire was thrust into the ice.

If one of the discharging wires of the great coil is brought to the centre of large swing looking-glass and the other wire connected with the amalgam at the back, the sparks are thin and wiry, arborescent, and very bright; the crackling noise of these discharges being quite different from that of the heavy thud or blow delivered by the flaming spark.

When the discharging wire is brought close to the flame of the looking-glass, or if a sufficient thickness of air intervenes, the spark again becomes flaming; or, as sometimes occurs, if the discharging wire is placed about 5 inches from the frame, the spark is partly flaming and partly wiry, *i. e.*, when it impinges on the glass.

The spectrum is a continuous one with the sodium-line.

When the blast of air is used, and the wiry sparks made apparent, then the nitrogen line appears.

The flaming spark has been ascribed by some experienced observers to the incandescence of the dust in the air, and especially sodium chloride.

To ascertain whether the "flaming spark" could be obtained with a small number of cells, the large Bunsen's battery was reduced to three cells, and it was found that no appreciable spark could be produced when the whole primary wire was used with less than five cells.

By reducing the length of the primary wire, and using the four divisions separately, with five cells the spark was wiry, and varied from 4½ inches to 6½ inches; with ten cells it was wiry, and varied from 8½ to 9½; in the latter the spark was slightly flaming. With fifteen cells the spark was slightly flaming, and varied from 10 inches to 11½ inches. With 20 cells a flaming spark varying from 11½ inches to 12½ inches was obtained.

When the two wires from the secondary coil are placed in water, no spark is perceptible, even when the wire was brought very close together, until they touch.

If the negative wire is passed through a cork, on which a glass tube (a lamp glass) is fixed containing a depth of 5 inches of water, and the positive wire is brought within half an inch of the surface of the water in the tube, it becomes red-hot, and if drawn further away from the surface the upper part of the tube is filled with a peculiar glow or light abounding in Stokes's rays.

The experiments with the vacuum tube, and especially Gassiot's cascade, are, as might be expected, very beautiful. When a coal-gas vacuum tube of considerable diameter, and conveying the full discharge from the secondary coil, is supported over a powerful electro-magnet axially, the discharge is condensed and heat is produced.

If placed equatorially, the heat increases greatly, and when the discharge is condensed and impinges upon the sides of the glass tube, it becomes too hot to touch, and if the experiment was continued too long the tube would crack.

The enormous quantity of electricity of high tension which the coil evolves, when connected with a battery of forty cells, is shown by the rapidity with which it will charge a Leyden battery.

Under favourable circumstances, three contacts with the mercurial break will charge 40 square feet of glass.

On one occasion a series of twelve large Leyden jars arranged in cascade were discharged; the noise was great: and each time the spark (which was very condensed and brilliant) struck the metallic disk, the latter emitted a ringing sound, as if it had received a sharp blow from a small hammer.

The discharges were made from a point to a metallic disk; and when the former was positive the dense spark measured from 18¼ to 18¾ inches, and fell to 8¼ inches when the metallic plate was positive and the point negative.

Variations of the Leyden-jar experiments were tried by connecting the coil worked by a quantity battery of 25+25 cells with six Leyden jars arranged in cascade, and the spark obtained measured 8¼ inches.

The same six jars connected with the coil, when the fifty cells were arranged continuously for intensity, gave a spark of 12 inches of very great density and brilliancy.

NOTICES OF BOOKS.

Arithmetical Exercises for Chemical Students. By C. J. Woodward, B.Sc., Lecturer on Chemistry and Physics, Midland Institute, Birmingham. Birmingham: The Educational Trading Company (Limited). London: Simpkin, Marshall, and Co.

We have received, under the above title, a series of ten very neatly printed cards, enclosed in a case. Instead of "Exercises for Chemical Students," it would have been better to write Students of Chemistry.

The author very properly and truly states that, in almost all examination papers on the subject of chemistry, there are introduced questions involving considerable arithmetical calculation. Each card of this series contains all the data necessary for working the problems, and certain questions, which may be looked upon as *type* questions, are worked out in full. The subjects include—(1) the metric system of weights and measures; (2) conversion of thermometer scales—correction of gases for pressure and temperature; (3) specific gravity; (4) formula of a body being given, required either its percentage composition, or the quantity of any constituent a given weight of it will contain; (5) percentage composition of a compound being given, required its empirical formula; (6) quantity of material to yield, liberate, or produce a given weight of a substance; (7) required the bulk of a substance produced in certain decompositions, or, conversely, the volume of a substance necessary to effect certain decompositions; (8) combinations and decompositions of bodies in the gaseous form; (9) the crith and its uses; thermal units (by "crith" is understood the weight of 1 litre of hydrogen at 0° C., and 760 m.m. Barometer); (10) specific, atomic, and latent heat.

Very opportunely, these cards have been published at the moment that the courses of lectures are commenced at the various schools in the kingdom. A careful perusal justifies us, we think, in recommending these cards to all students of chemistry and physics; and a number of teachers will also find them a very useful addition to their library-table. As far as perusal goes, we have no fault to find with this work; and its very moderate price, especially considering the large amount of highly useful information contained in ten duodecimo cards, holds out a good inducement for students who really desire to obtain, within a very small compass, a permanently-useful pocket companion to purchase this work.

MISCELLANEOUS.

Death of the Master of the Mint.—With sincere regret, we learn that Professor Thomas Graham, F.R.S., Master of the Mint, died on Thursday night, the 16th inst., at his residence in Gordon Square. Mr. Graham succeeded Sir John Herschel at the Mint in April, 1855, and was, at the time of his decease, in his sixty-fourth year. He was born at Glasgow, on the 20th of December, 1805. He was the son of a Glasgow merchant, and was educated at the Grammar School and the University of that city, and afterwards spent some years in Edinburgh. He returned to Glasgow, where he distinguished himself as a practical chemist, and was elected Professor in the Andersonian Institution. In 1837, he was appointed Professor of Chemistry in University College, London, and, in 1855, he was appointed Master of the Mint. To the duties of this office he applied all his varied scientific knowledge, and, at the same time, devoted himself to original investigations in his favourite science. To him we are indebted for the discovery of the laws of the diffusion of gases, the diffusion of liquids, and the new method of separation known as dialysis. More recently, his analysis of an aërolite, which he found to be partly composed of hydrogen, afforded an interesting confirmation of the results obtained by spectrum analysis as to the constitution of heavenly bodies. His "Elements of Chemistry" is a standard work, and has had a large circulation both in England and Germany, the German translation being edited by Professor Otto, of Brunswick. In 1836, Mr. Graham became a Fellow of the Royal Society. In 1848, he was elected a Corresponding Member of the Academy of Sciences of the Institute of France; and, in 1855, the University of Oxford conferred upon him the honorary degree of D.C.L. The loss of the deceased *savant*, who was a bachelor, will be very seriously felt in the scientific world and also at the establishment of which he was the head, where he has rendered eminent service to the nation at large by the introduction of many great improvements.

The Whitworth Scholarships.—The following candidates have been reported to the Science and Art Department as entitled to the ten Whitworth scholarships of £100 a-year each:—William H. Greenwood, aged 23, engineer, student at the Mechanics' Institution, Manchester, 143 marks; Thomas A. Hearson, aged 23, engineer, student, Royal School of Naval Architecture, 137 marks; John Hopkinson, B.Sc., aged 19, student at Cambridge University, 134 marks; Thomas S. Elgood, aged 24, mechanical engineer, Leicester, and Owen's College, Manchester, 127 marks; George A. Greenhill,

aged 21, student at Christ's Hospital School and Cambridge University, 116 marks; John R. Brittle, aged 23, engineer, student at Sir Walter St. John's School, Battersea, 113 marks; Thomas W. Phillips, aged 23, student at British School, Millwall, and Royal College of Science, Dublin, 100 marks; Richard Sennett, aged 21, engineer, student at the Royal School of Naval Architecture, 98 marks; Robert B. Buckley, aged 21, engineer, student at Merchant Taylors' School, 97 marks; Charles E. Leeds, aged 23, B.A. (Oxon.), student at Oxford University, 96 marks.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

In accordance with the generally expressed wishes of our friends and readers, we have effected arrangements to enable us to give, under the above heading, notices of EVERY CHEMICAL PAPER IN THE WORLD, *as soon as possible after publication. Whenever possible, these notices will appear in the form of carefully prepared, although necessarily brief, abstracts; as respects papers either too long or too abstruse to render condensation possible, their titles will be chronicled; and in all cases accurate reference will be made to the original publication. The two half-yearly volumes of the* CHEMICAL NEWS, *with their copious indices, will therefore be equivalent to an English edition of the "Jahresberichte," with the additional advantage of keeping the readers week by week on a level with the latest advances of science.*

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus des Séances de l'Académie des Sciences, August 30, 1869.

This number contains the following original papers bearing upon, or more or less relating to, chemistry and allied sciences:—

Antidote of Nicotine.—M. Armand.—The author proposes that the deleterious effects of the use of tobacco should be counteracted, if not entirely annihilated, by moistening tobacco, while undergoing the various preparations and fermentations, previous to its delivery to the consumer, with a strong infusion, or other preparation, of watercresses, since the author has discovered that this vegetable contains principles which, without destroying the peculiar aroma of tobacco, destroy the deleterious effects of nicotine.

Action of Hydrate of Potassa upon the Sulphuretted Derivatives of the Carbides of Hydrogen.—M. Berthelot.—The author has studied the action of fusing caustic potassa upon the sulphuretted derivatives of some hydrocarbons which are not decomposed by water or alkalies at 100°. The soda-salt of hydrethylosulphuric acid, $C_4H_9S_2O_6$, is readily decomposed, and the result is the formation of pure ethylen and an alkaline sulphite—

$$C_4H_9NaS_2O_6+KHO_2=C_4H_4+H_2O_2+S_2KNaO_6.$$

Formenosulphate of soda, $C_2H_3NaS_2O_6$, should, by analogy, have yielded methylen, C_2H_2; but an excess of potassa decomposes the formenosulphate of soda, yielding hydrogen and carbonate and sulphite of alkalies—

$$C_2H_3NaS_2O_6+3KHO_2=C_2K_2O_6+S_2KNaO_6+3H.$$

With a relatively small quantity of potassa, a very volatile methylsulphide is formed, which, in many respects, is like methylic mercaptan. The author has extended his researches over a large number of equally complex compounds as those already alluded to; but, to be well understood, it would be required to quote a very large number of complicated formulæ; we therefore refrain from further abstraction of this paper.

Synthesis of Acetic Acid from Acetylen by a New Method.—M. Berthelot.—After referring to a now well-known method for the conversion of acetylen into acetic acid, devised by this author some time ago, the author now communicates another, and easier method—to wit, the heating of protochloride of acetylen, either with aqueous potassa solution up to 230°, or heating with an alcoholic solution of potassa up to 100°, for about ten hours. When the perchloride of acetylen is heated with an alcoholic solution of potassa up to 100°, glycolic acid is formed; and when the same perchloride is heated with aqueous potassa up to 230°, oxalic acid is formed.

September 6, 1869.

This number opens with a report on the practice of—

Heating Wines in order to Improve and make the same Keep Better.—M. Pasteur.—The contents of this paper are only interesting to wine growers. It appears, however, that the cautious heating of wine (on the large scale, and before it has reached maturity) not only improves its quality, but has the effect of making it keep better, and render fit for transport on long journeys, and by sea, such brands of French wines as are otherwise not suitable, on account of their rapid deterioration.

Detailed Account of the Spectrum of the Sun's Spots.—Rev. Father A. Secchi, S.J.—This indefatigable *savant* gives in this paper a very precise and fully detailed description of this difficult subject, which, however, since it is treated in a strictly astronomical style, we do not further allude to.

Nature of Aniline Green.—MM. A. W. Hofmann and Ch. Girard.—The authors treat, in this memoir, the following subjects:—*What is iodine green?* is a question first answered by stating that it is a secondary product, which is formed during the manufacture of the colouring matters generated by the methylation and ethylation of rosaniline, and known in commerce as Hofmann's violets. The preparation of iodine green (more correctly, green produced by iodine) is next treated at length; the preparation of this substance in crystallised state is then fully described. The composition of this green is—

$$C_{52}H_{52}N_6OI_2=\left\{\begin{matrix}H_{18}\\C_{20}(CH_3)_2\end{matrix}\right\}N_2\left\{\begin{matrix}CH_2I\\CH_2I\end{matrix}\right\}H_2O.$$

This memoir is a very lengthy and exhaustive monograph on this subject not well suited for further condensation.

Thermochemical Researches on the Substances formed by Double Decomposition.—MM. Berthelot and Longuinine.—This memoir, divided into several chapters, is too much filled with a very large number of figures, without which this paper cannot be well understood, and, therefore, we regret that we can only here quote the title of a highly scientific memoir wherein the authors have laid down the results of a long series of carefully-made experiments.

Bulletin de la Société d'Encouragement pour l'Industrie Nationale, No. 200, August, 1869.

Leaving the papers relating to mechanics, steam engineering, and watchmaking, met with in this number, we notice the conclusion of a very lengthy, yet very excellent, monograph on—

Truffles.—M. Chatin.—The chemical composition of these cryptogamic vegetables has been investigated at even so early a period of the infancy of chemical analysis as the year 1803, and at various epochs after that year, such investigations have been especially conducted in France. The latest researches on this subject have been recently made, and are quoted by the author, as well as the analysis made by M. Payen. From these we learn that the *Agaricus campestris*, the edible mushroom, contains, in 100 parts:—Water, 91·010; nitrogenous matter and traces of sulphur, 4·680; fatty matter, 0·396; cellulose, dextrin, sugar, and mannite, 3·456; saline matter, 0·458, among which there is a very large proportion of phosphoric acid. Genuine truffles contain 76·60 per cent of water and 23·40 per cent of solid matter, including 7·16 per cent of nitrogen; upon 100 parts, the ash of truffles contains 27·40 phosphoric acid, and 28·34 potassa; the quantity of phosphoric acid contained in the ash of truffles growing in the neighbourhood of Nérac amounts to 33·5 per cent. This paper contains valuable information on the cultivation of truffles, on the bibliography of this subject, and on the commercial importance of a vegetable which, at first sight, one would hardly credit to yield, to fifty departments of France, a sum of nearly 16,000,000 francs yearly. The author states that these vegetables are highly nutritious, and that, when taken at meals in lieu of butcher's meat, they are readily enough digested, provided they are properly cooked, for which purpose the author gives the necessary directions.

Estimation of the Quantity of Non-Saponified Fatty Matter contained in Soap.—Dr. Bolley.—Dry the soap at 100°, in order to eliminate, as much as possible, any water it contains. Treat the soap, after having been previously reduced to thin shavings, or powder, if possible, with rectified benzol, or petroleum naphtha. Boil the soap for several hours with this fluid placed in a retort, and take care to pour back into that vessel any of the hydrocarbon which distils over. Next filter the liquid, and evaporate on a water-bath. 11·3 grms. of Marseilles soap (this is made with inferior kinds of olive oil and soda) treated in this manner left a residue, on evaporation, weighing 0·145 grm., or 1·2 per cent; this quantity consisted of the non-saponified fatty matter, and a very small quantity of soap which had been dissolved. On igniting the residue just mentioned, it left 0·002 grm. of ash, equal to 0·13 per cent of the soap submitted to analysis.

Bulletin de l'Académie Royale des Sciences, des Lettres et des Beaux, Arts de Belgique, No. 6, 1869.

This number contains the following original papers relating to chemistry:—

Researches concerning the Isomerism of the Salicylic Series.—M. Henry.—The chief object of this lengthy memoir is the study of the action of pentabromide of phosphorus upon a number of salicylic compounds. Considering the existing analogy between pentachloride and pentabromide of phosphorus, the conclusion seemed justifiable that these two bodies would act in the same manner upon aldehyde and salicylic acid. The author's researches have proved that, instead of this supposition being correct, the pentabromide behaves as if it were free bromine, giving rise to the generation of bromated organic compounds only.

Researches concerning the Ethereal Derivatives of the Acids and Polyatomic Alcohols.—M. Henry.—The author gives a review of his experiments on the chloride of ethylglycollyl, obtained by the action of terchloride of phosphorus upon ethylglycollic acid. The author's aim was to apply that chloride, in order to produce several diglycollic combinations which would have been interesting for the elucidation of isomerism in general; this aim has not, however, been attained by the author at present.

Researches on the Derivatives of Phenyl-Acetic (α Toluic) Acid.—Dr. Radziszewski.—This memoir, like the two foregoing, of which the headings were mentioned, does not admit of suitable abstraction. This second portion of a monograph on this subject is divided into nine separate sections, and contains a complete and exhaustive review of a lengthy series of complex compounds derived from phenyl-acetic acid, $C_6H_5—CH_2—CO(OH)$.

The American Journal of Science and Arts, July, 1869.

This number contains the following original papers:—

Charles Grafton Page.—A biography of this deceased philosopher, who has been, for a series of years, one of the foremost scientific investigators of the Union.

Hortonolite, a New Member of the Chrysolite Group.—Messrs. Brush and Blake.—The mineral alluded to has a dark yellowish green colour on the fresh fracture, and a vitreous to resinous lustre; hardness, 6·5; sp. gr., 3·91. Before the blowpipe in the closed tube no change takes place; in the open tube, and on charcoal, the mineral becomes dull and magnetic, and fuses in the platinum forceps; with borax and salt of phosphorus it yields the reaction for iron and silicic acid, and with soda for manganese. The pulverised mineral forms, with hydrochloric acid, a gelatinous mass, and is almost completely decomposed. Average composition, in 100 parts:—Silica, 33·59; protoxide of iron, 44·37; protoxide of manganese, 4·35; magnesia, 16·68; lime, a trace; potash, 0·39; loss on ignition, 0·29. A spectroscopic examination of the concentrated chlorhydric solution showed sodium, potassium, and calcium lines only.

Effect of Atmospheric Air, when Mixed with Gas, in Reducing its Illuminating Power.—Messrs. B. Silliman and A. Wurtz.—The results arrived at by the authors may be summarised as follows:—For any quantity of air less than 5 per cent, mixed with gas, the loss in candle power due to the addition of each 1 per cent is a little over 6-10ths of a candle (0·611 exactly); above that quantity, the ratio of loss falls to half-candle power for each additional 1 per cent up to about 12 per cent of air; above which, up to 25 per cent, the loss in illuminating power is nearly 4-10ths of a candle for each 1 per cent of air added to the gas. With less than one-fourth of atmospheric air, not quite 15 per cent of the total illuminating power remains, and with between 30 and 40 per cent it totally disappears.

Formation of Sugar in the Liver.—Dr. Barker.—A physiologico-chemical essay.

Aurora at Toronto, Canada.—Mr. Kingston.

Qualitative Separation of Cobalt and Nickel.—Mr. F. W. Clarke.—As is well known, ferricyanide of potassium precipitates cobalt and nickel from their solutions. The cobalt precipitate is of a deep reddish brown colour, while the nickel compound is of a dirty yellowish brown. The nickel ferricyanide is readily soluble in ammonia and in solution of cyanide of potassium, while the corresponding cobalt compound is absolutely insoluble in either. It is a noteworthy fact that the previous presence of either ammonia or potassium-cyanide entirely prevents the precipitation of cobalt by the ferricyanide; the solution, when ammonia is present, merely assuming an intense blood-red colour. It is always best to employ ammonia to dissolve the nickel precipitate, since the presence of a cyanide renders the subsequent detection of that metal rather difficult. The author proceeds, as follows, in an analysis:—To the slightly acid solution containing the two metals, first an excess of chloride of ammonium is added; this causes the cobalt precipitate, which otherwise would run through the filter, to fall in a denser state, and also of much darker colour, often nearly black. The ferricyanide of potassium is then added, until the precipitation is complete, and afterwards strongly agitate with a considerable excess of ammonia. Upon filtering, all the cobalt remains upon the filter, being recognised by the characteristic colour of the precipitate, and the nickel is readily detected in the filtrate by means of ammonium-sulphide. This process is merely offered, the author states, as a convenient means of detecting cobalt and nickel in presence of each other in ordinary analyses.

Wollongongite, a remarkable Hydrocarbon found in the Wollongong District of the Illawarra Coal Field, N. S. Wales.—Mr. Silliman.—This remarkable substance occurs five miles inland, and forty miles south of Sydney, in cubical blocks, without lamination, extremely tough, and resounding like hard wood under the blows of the hammer. Hardness, 2·5; sp. gr., 1·04 to 1·49; lustre, resinous; colour, greenish black and brownish black; tasteless; insoluble in alcohol, ether, or benzol; slightly soluble in sulphide of carbon; heated in a test-tube, it does not melt, decrepitates and distils a copious flow of oil of a yellow colour and heavy odour, giving off much gas; it is readily kindled, in thin splints, by a match, burning with a brilliant flame and much smoke. Analysis in platinum crucible yields:—Volatile matter, 82·5 per cent; fixed carbon, 6·5 per cent; ash, 11·00 per cent.

Estimation of Carbonic Acid.—Mr. S. W. Johnson.—Since the woodcut added to this paper is absolutely required for it to be clearly understood, we do not abstract it here.

Journal für Gasbeleuchtung, July, 1869.

We notice from this number the following papers and communications of more general interest:—

Effect of Illuminating Gas upon Vegetation.—Dr. Poselger.—The author of this paper deserves the thanks of a great public for his energy in determining, by positive experiments, that the death of fine trees growing along the streets and promenades of many, especially continental, towns, is not due, as has been too often asserted, to the effects of leakage in gas mains. From the author's experiments, made with trees and shrubs, it is a settled point that no damage can accrue to the trees, nor their growth interfered with, by any quantity of gas which may escape in the soil and find its way to their roots. Moreover, the author points out that no care is taken at all with the trees, as regards keeping the soil covering the roots, so as to admit of air permeating freely; that too often that soil becomes as hard as rock; and that, in very many cases, the filthy habit of using trees, especially if so thick as to admit of a man hiding behind it, instead of urinals, contributes largely to the destruction of fine old trees. The leakage of gas, or the laying down of mains near the roots, has nothing to do with this destruction; other causes influence the decay of trees, but with these we do not further occupy ourselves.

Brief Abstracts from the Reports of the Meeting of German Gas Engineers and Gas-Works' Managers held at Coburg at the end of May.—*Analysis of Oberursefer Oxide of Iron.*—This material is applied for the purification of gas, and was found to consist principally of 36·5 per cent of a siliceous sand, 38 per cent of Fe_2O_3, and 11·7 per cent of Mn_3O_4. The material known as Mannheim oxide of iron contains 98 per cent of Fe_2O_3, and small quantities of lime and sand. *Report of the Committee on Photometry.*—This paper contains a description of a series of experiments made at Frankfort-on-the-Maine, with the view to enable the gas-works' managers throughout Germany and some adjoinining countries to adopt a general plan of making photometrical tests of the gas they manufacture. From this report, we learn that the use of glycerine, instead of water, in wet gas-meters is attended with some danger, owing to the fact that, after a length of time, the glycerine appears to attack the metal working parts of the meter, and give rise to leakage. The quantity of gas consumed last year in Paris amounts to 138,797,911 cubic metres; this figure has to be multiplied by 35·3165 to convert it into English cubic feet.

Les Mondes, August 19, 1869.

This number contains:—

The Electrical Machine of Holtz.—Dr. P. J. Kaiser, the celebrated astronomer and physicist, of Leyden University, and his equally eminent colleague, Professor Ryke, have been not only experimenting with this instrument, but have very much improved its construction, and thereby largely increased its efficacy. We regret that we cannot enter into details on this subject, owing to the fact that, for the proper understanding the woodcut annexed to the original would have to be reproduced.

Theoretical and Practical Studies on the Divers Processes in Use for the Purification (Defecation) of Beet-Root Saccharine Juice by means of Lime and Carbonic Acid.—M. Feltz.—This paper treats, at length, on a subject of considerable importance to the parties more immediately interested, beet-root sugar manufacturers. There is added to it a very precise description of the different methods of estimating the quantity of lime contained in the clarified juice, and, also, divers processes for the quantitative estimation of the organic matters, other than sugar, contained in the said juice. The paper is too long, however, for useful abstraction, and is to be continued in following numbers of this periodical.

We learn from this number that two scientific men of great name in their time have died at an advanced period of life—Prof. Purkinge, of Prague, died on the 24th of July last, aged eighty-two years; Dr. Carus, of Dresden, born in 1789, died also a few weeks ago.

August 26, 1869.

This number contains the following original article:—

Theoretical Chemistry.—M. Maumené.—The author's chief object is to prove that chemists should avail themselves of the author's "Théorie Générale de l'Action Chimique"; and, in order to exhibit it, the author refers to M. Schutzenberger's recent discovery of hydrosulphurous acid. Hydrosulphite of soda, $NaO.S_2O_3H$, when exposed to heat, after having been carefully dried, yields a little water, sulphur, and sulphurous acid, and leaves a residue consisting of sulphate and sulphuret of sodium. The author of this paper puts the question, Why hydrosulphite of soda should give, under the influence of heat, all the products just enumerated? Why should we not have a more simple action? as, for instance—

$$NaO.S_2O_2H = NaO.SO_3 + HS,$$

or—

$$= NaO.SO_3 + HO + S.$$

Every impartial chemist will at once admit that not one of the hypotheses at present current in the science of chemistry can serve to explain this. My theory exhibits precisely why these more simple actions cannot take place, and why all the bodies observed to be formed by M. Schutzenberger, must of necessity be formed. When a salt is submitted to the action of heat, the acid and base of that salt only constitute, during the action of the heat, a simple mixture acting by equal weight. For one equivalent, E, of one of these two bodies (that is to say, that which has the highest equivalent), the number, n, of the equivalents, E', of the other body (that the equivalent of which is the lowest) is expressed by the general formula—

$$n = \frac{E}{E'}$$

We have, therefore, in the present instance—

$$n = \frac{57(S_2O_2H)}{31(NaO)} = 1·84$$

that is to say, that the equivalent of the acid S_2O_2H, at the moment that the heat becomes strong enough to cause its dissociation from the soda, acts upon 1·84, say, nearly two equivalents of soda. We have, therefore—

$$2NaO + S_2O_2H = NaO.SO_3 + NaS + HO.$$

This first action is followed by a second; one-half of the acid was free; it has, by itself, been exposed to the action of the heat, and gave—

$$S_2O_2H = SO_2 + S + HO.$$

The total result of the decomposition is, therefore, the sum of the equals—

$$2NaO.S_2O_2H = NaO.SO_3 + NaS + SO_2 + S + 2HO,$$

as observed by M. Schutzenberger.

Cosmos, August 21, 1869.

This periodical contains, among other interesting matter :—

Description of the Self-Registering Instruments used at the Kew Meteorological Observatory.—Messrs. R. and J. Beck.—The editor of this paper states that, since these well-known eminent instrument makers are amongst his subscribers, he has been favoured with the excellent woodcuts and description given by the makers of the instruments.

Discovery of Coal.—On the eastern shores of the Caspian sea, abundant seams of coal have been found. The steam-ships navigating on that sea have hitherto used wood as fuel, which had to be carried far away from the Ural mountains, at great cost. The coal is of very good quality. More than forty years ago, the late A. von Humboldt stated his belief that coal would be found in this region at no great depth under the surface of the ground, since this entire locality abounds in naphtha.

Pharmaceutische Zeitschrift für Russland, May, June, and July, 1869.

These three numbers of this periodical have been published simultaneously, and are, therefore, taken together. The leading article, commenced in the May number, and continued through the two others, is a lengthy monograph on the following subject :—

Best Method of Preparation and Constitution of Hyoscyamine, and the relation this Alkaloid bears to the Quantity of Nitre (Nitrate of Potassa) contained in the Plant wherein the Alkaloid occurs.—M. Thorey.—The author divides this paper into three sections, respectively headed—On the preparation of hyoscyamine; the constitution of that substance; and its relation to the quantity of nitre the plant which yields it contains. The preparation of this alkaloid is described by the author with full details, as given by the very large number of chemists and pharmaceutists who have worked on this subject. Among the various methods of preparation of this alkaloid devised by the author, we notice the following :—50 grms. of *Semina hyoscyami nigri* (common henbane) are ground to powder, exhausted with 150 grms. of alcohol (85 per cent strength), and the alcoholic tincture concentrated by distillation, one-half of the bulk of the alcohol being distilled off. The residue left in the retort is next mixed with water, filtered, reduced, by evaporation, to about 30 grms., and then again filtered. The filtrate is mixed with a solution of caustic potassa, after having been previously heated to 40°, next treated with chloroform, the chloroformic solution washed with water, until that fluid runs off quite clear, and the solution thus obtained evaporated to dryness, leaving 0·0835 grm. of a yellowish mass smelling like tobacco. This mass is re-dissolved in weak hydrochloric acid, filtered, carefully saturated with caustic potassa, again treated with chloroform, this solution again washed with water, and, at last, left to spontaneous evaporation over sulphuric acid, yields well-crystallised hyoscyamine. The alkaloid thus obtained is a quite pure, colourless substance, of bitter taste, readily soluble in dilute alcohol, in ether and chloroform, in benzine and amylic alcohol, and dilute acids. Among its characteristic chemical reactions, belongs a red amorphous precipitate, with the double iodide of bismuth and potassium; a yellow precipitate, gradually verging on blue, when left standing with phospho-molybdate of soda; a flocculent yellow precipitate with chloride of gold, which, after a time, becomes crystalline; a deep kermes red colouration with aqueous solution of iodine; and an amorphous yellowish grey precipitate with tannic acid. During his researches on this subject, the author has discovered that henbane contains, in addition to hyoscyamine and saltpetre, a peculiar resinous substance, and an acid. The resinous material is remarkable, since it contains nitrogen, its percentical composition being—C, 67·67; H, 8·772; N, 3·508; O, 20·05. As regards the constitution of hyoscyamine, the author says it is, at present, not easily possible to control the statement made by M. Kletzinsky, that this alkaloid should be the nitrile of santonate of ammonia. The question, What relation the hyoscyamine bears to the quantity of saltpetre contained in the plant which yields it? is treated at great length; but it is difficult to give any brief *résumé* of these researches, which are recorded in several tabulated forms full of figures. All parts of the henbane contain a considerable quantity of nitrate of potassa; and it appears that, while that quantity varies at various periods of the growth of the plant, so, also, varies the quantity of hyoscyamine contained in the various parts of the plant. The quantity of hyoscyamine contained in the leaves of the plant dried at 110°, and taken before the blooming period, varies from 0·023 to 0·208 per cent. The seeds contain from 0·048 to 0·160 per cent of hyoscyamine.

The Saline Deposits of Turkestan.—M. Palm.—The author says that he was sent on a long journey through a very little frequented portion of the Asiatic part of the Russian empire, and that, during that time, he studied especially those saline deposits which are not chiefly composed of common salt, known by the German name of *salz-steppen*. The first deposit alluded to in this paper is met with near Fort Perowski, and consists of alternate layers of a saline mass and fine white sand, impregnated with a salt soluble in water. As instances of the composition of this salt, we quote the following analysis from this paper:—Percentical composition—NaO, 42·4; SO_3, 54·8; water, 2·0; sand, 1·0. Sulphate of soda, 47·215; common salt, 2·719; water, 48·50; sand, 1·566; formula—

$$NaO,SO_3 + 8\,aq. + 1\text{-}14th\ eq.\ NaCl.$$

Sulphate of soda, 57·26; common salt, 10·18; water, 35·56; formula—

$$10(NaO,SO_3) + 2(NaCl) + 9HO.$$

The author describes, very minutely, these deposits, and a number of others, stating that several millions of tons of sulphate of soda are deposited in this far away region, inhabited only by a few Nomadic tribes, and by the Cossacks, who do duty along the great roads as a military police.

Very Black and Very Cheap Ink.—M. R. Voigt.—Take 12 ozs. of extract of logwood, 1½ lbs. of best nutgalls, 1 lb. 6 ozs. of dried sulphate of iron (*sulphas ferri ustum*), 1 lb. 1½ ozs. of senegal gum, 1 oz. of commercial sulphate of copper, ½ a drachm of corrosive sublimate, and 45 lbs. of water. The nutgalls, previously ground to a coarse powder, are macerated for four days with 12 lbs. of previously well boiled, and afterwards quite cooled, water, taking care to place the mixture in a cool place. The extract of logwood is also dissolved by itself in 12 lbs. of the same water; the previously dried sulphate of iron is dissolved by itself in 5 lbs. of that water; the sulphate of copper is, also, separately dissolved in ½ a lb. of water. The quantity of corrosive sublimate is, likewise, separately dissolved in 4 lbs. of the said water, while the gum is dissolved in 9 lbs. of that same fluid. Each of these solutions should be filtered, either through a very fine hair sieve, or through linen; and, after that, the solutions should be mixed together in the same order as they are here enumerated. The ink thus obtained should be bottled, and the bottles, after having been well corked, kept in a cool place. 1 lb. of this ink can, according to this author, be had for the low price of 6 kopéiks (about three farthings).

Comparative Study on the Characteristics of the Halogens and their Combinations, and especially, also, on Hyperiodic Acid.—Dr. Ferrein.—This monograph contains the history of the halogens (chlorine, bromine, iodine, fluorine), treated at length, from the earliest days of Lavoisier and Scheele up to the present time. The essay is too lengthy for any useful abstraction.

On Mercurialin.—M. Reichardt.—The preparation of this substance from the *Mercurialis annua* is given at great length; it is a complicated process, requiring great nicety of manipulation. Mercurialin is an oily fluid, at first colourless, but readily becoming brownish tinged by the action of heat, as well as by simple contact with air; it is an alkaloid, exhibiting a strongly alkaline reaction to test paper. The formula of mercurialin, as deduced from its salts, is C_8H_9N. The author has studied a series of the salts of this substance, most of which salts crystallise, and some are capable of forming well-defined double salts.

Steam-Boiler Incrustations.—M. E. Wiederhold.—The author states that the hardest incrustations of this kind are formed when the quantity of carbonate of lime amounts to from 20 to 25 per cent of the entire mass. He has found, by an experience extending over several years, that some kinds of clay, among these, the substance known as *kieselschiefer* (a peculiarly fatty clay), when suspended in the water contained in steam-boilers, prevent the particles of carbonate and sulphate of lime dissolved in the water, even if the latter is very hard, to cling together, and become fixed to the sides of the boilers, forming there a hard incrustration. A series of experiments, made on purpose, and continued for a sufficient length of time to yield a reliable result, has fully proved that the addition to the feed-water of the steam-boilers of fatty clays, especially the kind known as fuller's earth, entirely prevents boiler incrustations, even where, of necessity, very hard water has to be used as feed water. A loose, soft mud is deposited as soon as the motion of the water, due to the boiling, ceases on cooling. This mud readily runs off on opening the sludge-valve of the boiler.

Zeitschrift für Chemie, von Beilstein, No. 14, 1869.

This number contains only two original papers :—

Reduction-Products of Mononitroazoxybenzol.—G. A. Schmidt.—It appears that the author had been engaged with researches on this subject some eight years ago, but had not then gone very deeply into it. Meanwhile it was taken up by various other experimenters, and among them, also, M. Alexejeff, who wrote and published a monograph on this subject in the Russian language. This circumstance induced the author to resume his work; and he proceeds with the reduction of the nitroazoxybenzol as follows :—One part, by weight, of that material is dissolved into ten parts of strong and boiling alcohol. While boiling temperature is kept up, there is gradually added a strong alcoholic solution of sulphide of ammonium, in small quantities of from 2 to 3 c.c. at once, and this is continued until all nitroazoxybenzol is dissolved, and none of it appears to crystallise out on a few drops being taken out of the boiling fluid as a test and cooled down. The formation of aniline and β phenyldiamin is in this way entirely prevented. To the liquid, after having been decanted from the precipitated sulphur, a mixture of weak spirit and excess of hydrochloric acid is added, whereby muriate of amidoazoxybenzol is formed; this is a solid substance, exhibiting crystalline form, and possessed of a violet-blue colour and metallic lustre. When to these yet impure crystals is added a little ammonia and weak spirit, there is obtained

a golden yellow-coloured crystalline mass, insoluble even in boiling water, but readily soluble in alcohol and ether; this pure material fuses at 127°. This muriate, or hydrochlorate, yields, on being treated with excess of ammonia, the amidoazoxybenzol, a solid substance fusing at 138·5°, composed according to the formula $C_{12}H_9(NH_2)N_2O$, nearly insoluble in cold water, a little soluble at the boiling point of that fluid, and readily soluble in strong alcohol, ether, and benzol.

On Trinitroazoxybenzol.—G. A. Schmidt.—When azoxybenzol is treated with a mixture of nitric and sulphuric acids, a trinitro product is obtained. The author mixed, in a flask, 20 grms. of azoxybenzol with 200 grms. very strong nitric, and 100 grms. of concentrated sulphuric acids. The azoxybenzol dissolves without giving off red vapours (but, becoming very hot, the mixture is to be poured into cold water immediately), and yields a bright yellowish crystalline mass, glued together by a resinous product. After having rubbed up with some water, and placed on a filter, washed, and dried, the resinous matter is dissolved, and thereby the trinitroazoxybenzol obtained as a crystalline powder, insoluble in water, very difficultly soluble in alcohol and ether, and readily soluble in benzol. It is best purified by re-crystallising it from nitric acid of 1·38 sp. gr., wherein it is readily soluble on being boiled, and crystallises on cooling. It fuses at 152°, solidifies at 140°, and explodes rather sharply when heated more strongly. Formula, $C_{12}H_7N_3O_7$. The resinous matter referred to contains binitroazoxybenzol, or isomeric substances, researches about which still occupy the author.

PATENTS.

2501. J. Baur, New York, U.S.A., "Improvements in the manufacture of steel."—August 21, 1869.

NOTES AND QUERIES.

Solid Chloride of Carbon.—Could you kindly inform me of the method for preparing the solid chloride of carbon mentioned in the CHEMICAL NEWS (vol. xx., p. 130)? Could it be made from the tetrachloride of carbon?—H. BUTT.

Sulphate of Ammonia and Sulphuric Acid.—Can any of your readers inform me of a ready commercial method of determining the percentage of ammonia in sulphate of ammonia, and also tell me the readiest way to find out if pyrites has been used in the preparation of vitriol?—A. Z.

Gas Furnace.—Will any of your readers inform me if it is practicable, by means of an ordinary chimney draft, and gas from the main, to get up a white heat within a cylinder of some 2 ft. diameter and 4 ft. high (the cylinder would be fitted inside with objects for flame to strike against)? if so, I should feel much obliged.—J. C.

Simple Experiment Shewing that Air Possesses Weight.—Heat a little water in a flask until the air is purged out, and, while in this state, cork tightly, and set aside to cool. When cool, balance carefully in a good balance, or even ordinary scales; then remove the cork to admit air, and again weigh (including cork): the additional weight of air admitted into the flask will be sufficient to sensibly turn the scale.—W. NETTLETON, Huddersfield.

Terra Alba.—In answer to "Terra Alba," this article is not an artificial product, but the finest quality of gypsum stone that can be had, carefully ground to a powder. It is made principally in Derbyshire, and at Leith; it is used for many purposes; it never varies in quality, except according to the quality of the stone it is made from. There is an artificial terra alba, sold under the name of pearl hardening, and which is chemically the same, made by precipitation, under the patent of M. Jullien. It contains a larger quantity of water than the natural article. If it is too much dried, it is liable to lose part of its water of crystallisation, and, on addition of water, to set hard like plaster. If your correspondent applies to me, through you, I will give him every information he needs.—NEMO.

Octylic Alcohol.—In reply to your correspondent G. P. Clark, I beg to inform him that the best method of preparing octylic alcohol from castor-oil is the following:—Dissolve one part of caustic potash (or soda, which will do quite as well) in a small quantity of water, add two parts of castor-oil, and heat this mixture in a large iron pot until all frothing ceases, and a smell of mushrooms is given off. Introduce the solid mass thus obtained into the still, and conduct the distillation as quickly as possible. To purify the crude alcohol, it has to be rectified several times over fused caustic potash, the portion boiling below 200° C. only being collected. Besides higher boiling products, hydrocarbons having a lower boiling point are also present, and are easily removed by fractional distillation. Instead of using castor-oil, castor-oil soap may be used, which has first to be heated with caustic alkali, in an open vessel, as described above.—C. SCHORLEMMER, Owen's College, Manchester, September 11th, 1869.

TO CORRESPONDENTS.

*** It is our pleasing duty to accord our best thanks to those gentlemen who have so kindly acceded to our request in sending us the necessary information respecting the Chemical and Medical Schools for our Students' Number.

J. Cabitt.—You will find full particulars on the subject you name in Watts's "Dictionary of Chemistry," vol. v., p. 276.

L. W. Longstaff.—Dr. Roscoe's new work on spectrum analysis, published by Macmillan, is the most complete work on the subject.

W. Carslon.—Consult "Annaire Almanach de Commerce, de l'Industrie, de la Magistrature, et de l'Administration, ou Almanach des 500,000 adresses (Didot-Bottin), 72e année, 1869." You can see this work at the library of the Patent Office, and possibly at one of the libraries, or the French Consulate Office in Edinburgh.

W. Seddon.—(1) A number of works on this subject have been published; amongst them we may name "A Treatise on Coal and Coal Mining," by W. W. Smyth, M.A., F.R.S., &c. (Virtue); "Coal and Coal Oil," by Eli Bowen, Philadelphia, U.S. (Burat La Houille, Paris): several editions of this work have appeared. (2) Galvanic batteries are made so cheaply by philosophical instrument makers that it is scarcely worth while to make them; but any work on natural philosophy will give you sufficient information about their construction.

Vol. XX. No. 514.

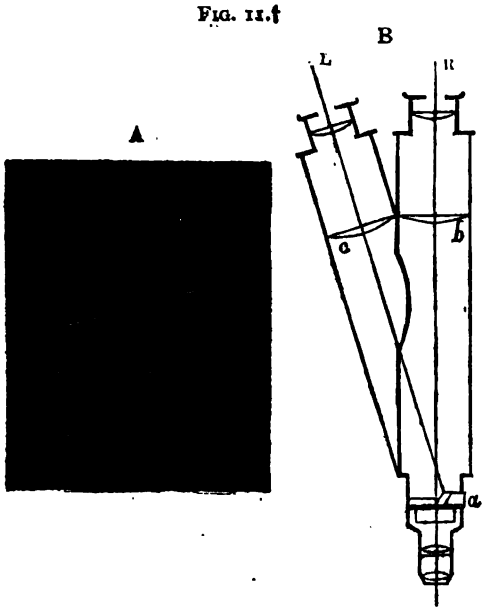
ON MICROSCOPICAL MANIPULATION.*

By W. T. SUFFOLK, F.R.M.S.

(Continued from p. 149.)

A description of the compound achromatic microscope can, at the present time, hardly be considered complete without some mention of binocular instruments. The binocular principle had been applied to opera glasses with great success for many years. More recently the invention of the stereoscope and its great popularity drew increased attention to the subject of binocular vision, but until a few years ago no attempt seems to have been made to adapt the principle to microscopes. Owing to the short focal length of microscopical objectives, the use of two convergent instruments would of course be impracticable; the only resource was to divide the pencil proceeding from the object-glass and convey half to each eye. The earlier attempts resulted in the

Fig. 11.†



production of pseudoscopic instruments; that is, the relative positions of the object viewed were reversed projections, being represented by depressions and the contrary. This was found to be caused by the rays of light being conveyed to the wrong eyes, the right side of the image entering the right eye, and the left the left eye, the effect being that of a wrongly mounted stereoscopic picture. It was found necessary that the right-hand image should be conveyed to the left eye, and *vice versa*, to produce a stereoscopic effect; this was accomplished by M. Nachet of Paris, and Mr. Wenham by different methods, each having their respective merits. As Mr. Wenham's is most in use in this country, I will briefly describe it. A four-sided prism of peculiar form (Fig. 11, A) is placed in the body of the microscope, just behind the posterior combination of the object-glass (Fig. 11, B, *b*), which, when in position, it half covers. An additional body, L, is joined at a slight inclination to the left-hand side of the instrument, and the two bodies are furnished at their upper extremities with draw-tubes, which supply the means of making an adjustment for the varying distance between the eyes of different persons. The image formed by the left-hand half of the objective passes up the straight tube to the right eye without being in any way interfered with by the prism; the right-hand image falls on the prism, is twice reflected, and passes into the left-hand inclined tube, and in this simple manner the crossing of the images from the two sides of the objective is effected, only one-half of the pencil suffering any reflection at all, besides giving the great advantage of instantly converting the instrument into a monucular by simply withdrawing the prism. It is only due to Mr. Wenham to mention that he has, with most praiseworthy liberality, granted free and unconditional use of his valuable invention to the public.

The binocular arrangement of Mr. Wenham cannot be used with advantage with objectives of less than half an inch focal length, but several arrangements have been constructed by which both eyes can be employed in high power observations, the most noteworthy of which has been brought forward by Messrs. Powell and Lealand. This instrument does not produce any stereoscopic effect, but nevertheless greatly diminishes the fatigue of protracted observations. A still more perfect adaptation has been constructed by Mr. Wenham, in which the light in each tube has been more nearly equalised than in preceding instruments.

The stereoscopic binocular offers many advantages over the monocular instrument, not the least of which is the saving of the fatigue to the eyes from which most persons suffer in a greater or less degree when using one eye for observation. Did the binocular arrangement do no more than this it would be a great boon, but it has the valuable property of enabling the observer readily to estimate the amount of elevation and depression of the surface he is viewing, and accurately to determine the relative position as to depth of the various parts of the tissue under observation. The discoveries which we owe to this improvement of the microscope have been numerous and valuable; among the earliest were some interesting observations on the circulating system of the tadpole, by Mr. W. U. Whitney (*Trans. Micros. Soc. Lond.*, vol., x., 1862, p. 1; and vol. xv., p. 43). Several also by the late Richard Beck; among them the re-discovery of the aperture in the fang of the spider figured by Leeuwenhoek (Hoole's English Translation, vol. i., Pl. 2, fig. 19) (*Science Gossip*, 1866, p. 201).

By a slight variation of the form of the prism, Mr. Crouch has succeeded in constructing a microscope which can, by merely shifting the position of the prism, become stereoscopic or pseudoscopic at pleasure. This modification of the binocular will probably be of value in confirming certain doubtful points of structure, by giving a reversal of the parts in relief.

Further particulars respecting the construction of

* The substance of a course of lectures delivered to the members of the Quekett Microscopical Club, January—April, 1869.

† "The Microscope and its Revelations," by W. B. Carpenter, M.D., Figs. 19 and 20 (Churchill).

the microscope and the optical principles involved will be found in the "Microscope and its Revelations," by Dr. Carpenter, and "Manual of Natural Philosophy" by Mr. Charles Brooke.

The microscope being a costly instrument, it is necessary that great care should be taken to preserve it from injury. When out of use it should be returned to its case or may be conveniently covered with a large shade or bell-glass. The eye-pieces should be carefully cleaned, as dust upon them becomes very apparent. The object-glasses, if kept in their boxes when out of use, will seldom require much cleaning; dust on the object-glass only causes a slight loss of light, but does not make itself visible. The best material for cleaning lenses is a piece of very soft wash-leather from which all dust has been beaten out; it should be kept in a large pill-box when out of use to preserve it from dust and grit, and should on no account be used for any other purpose, such as cleaning the brass-work of the instrument. Should the object-glasses require anything beyond mere dusting, they should be placed in the maker's hands as they are liable to injury if taken to pieces by inexperienced persons.

The sources of light for the purposes of observation will need a few remarks. When it can be procured, daylight is in every respect to be preferred to artificial sources of illumination, as by it alone can colours be perfectly seen and distinguished, and daylight observations are far less fatiguing than those made by lamp-light. Direct sunlight should be avoided, and, if possible, the light taken from a white cloud. But in towns, as the sky is seldom visible, and, moreover, few persons have much time to observe by daylight, it becomes important to seek for a good source of artificial light.

Gas has been used by many microscopists; it has the disadvantage of giving out a large amount of heat, and the quality of the light is inferior to that obtained from most other sources; its sole advantage is its convenience, as it is always ready for use, and requires no trimming, as is the case with lamps.

Well constructed lamps burning colza oil give a light of good and pure quality, although not as intense as those presently to be described. The best oil lamp I have used was obtained from Mr. Pillischer, and was only abandoned for the very intense camphine lamp. Oil-lamps require great care in trimming and cleaning, otherwise they will not burn well.

The mineral oils (paraffin, belmontine, &c.), when of good quality, and consumed in properly constructed lamps, are among the best of the microscopist's means of illumination. The quality of the light is good, and there is very little trouble required in keeping the lamp in good working order. The glasses, as in all lamps, should be kept clean, otherwise much light is lost, and to obtain the best possible effect the lamp should be trimmed each time of using, although it will burn very well two or three times without any attention. The best way of obtaining a good oil is to try small samples from various shops, and when a good one is found keep to its use. The burner exercises a very great influence upon the light, so great that in a series from various makers it would hardly be supposed that they were burning the same oil. The burners of American make supplied by Mr. Collins with the Bockett microscope lamps (Fig. 12), are some of the best that I have met with. This lamp has recently been improved by the adaptation of a metal chimney which is not liable to breakage, and also has the advantage of protecting the eyes of the observer from the light.

The best light of all for those who do not mind the slight amount of trouble attending its use is obtained from the combustion of camphine or highly rectified spirits of turpentine in a small lamp, especially constructed for the purpose by Mr. W. Young. The light is much whiter and more intense than that of any other lamp; owing to this quality the flame can be very much reduced in size, and most of the heat of a large lamp avoided, a matter of importance where the lamp is often placed near and below the face of the observer.

Camphine, when not used quickly, should be kept in small bottles, filled up to the neck, and closely corked, and kept in a cool place—a wine-cellar answers admirably. For the small consumption of the microscope lamp the bottles should not exceed four or five ounces, as the spirit rapidly deteriorates by exposure to the air both from evaporation and the absorption of oxygen, which renders it liable to clog the wick and reduces its illuminating power. The wick should be cut very exactly to a level, far more carefully than would be required for oil or paraffin, the least uneven point rendering the lamp liable to smoke. No more camphine than is likely to be consumed should be placed in the lamp; if there is more than is needed it should be allowed to burn itself out, or be thrown away, and the wick allowed to burn dry, otherwise the lamp is liable to become clogged, and burn badly. Should any part of the lamp become incrusted with a resinous deposit, it must be cleaned with methylated spirit; care should be taken that none of the air passages are obstructed. Although these precautions may seem troublesome, they really are not so to persons willing to acquire the habits of neatness so necessary to those who would make good microscopists; and the slight extra trouble is amply compensated by the superior purity and intensity of the light and its extreme cleanliness, it being perfectly free from greasiness or disagreeable smell. As the lamp is always kept empty it is very convenient for carrying about when it is necessary to make observations away from home.

Fig. 12.

The illuminating apparatus commonly supplied with microscopes consists of the mirror below the stage, and a condensing lens either attached to the instru-

ment or, as is to be preferred, on a separate stand. Other apparatus will be described in subsequent chapters.

The mirror is used for illuminating objects by directing light through them from beneath the stage, and is the usual, although not always the best, means of lighting an object, as it is one which we are unaccustomed to, and, without special precautions, is likely to lead into error. The mirror is capable of being moved out of the axis of the instrument, and light may be directed very obliquely upon the object, which is sometimes advantageous.

The condensing lens is used to concentrate light upon the object from above, and, when it can be employed, it is always preferable to commence an observation in this way rather than by means of transmitted light, as it accords more closely with our every-day way of viewing objects: it is not our usual custom to hold up a substance we wish to examine and try to look through it, but we generally allow the light to fall naturally upon it. If a plano-convex lens, or "bull's-eye," be used as a condenser, it is necessary to be careful which side is turned to the source of light, otherwise it may be used in a position causing a great amount of spherical aberration and consequent loss of light. A plano-convex condenser should always have its curved side turned to the source of light when used for concentrating light upon an object. When used for rendering divergent rays, such as those of a lamp, parallel, which is often required when using apparatus hereafter to be described, the bull's-eye should be placed with its flat side to the lamp and at about the distance of its focal length.*

The beginner is recommended to commence his observations by endeavouring to procure a good and brilliant illumination with the condensing lens, looking at any easily procured objects, such as fragments of paper, feathers, sand, &c.; a hummingbird's feather or wing of a butterfly is particularly useful, as either of them presents very different appearances, according to the direction of the illuminating pencil, the iridescent colours of the first and the imbricated structure of the second not being seen unless the light is made to fall in the proper direction. The light should be moved or the object turned round, and the varied appearances carefully noted. This precaution should be adopted with all objects viewed by reflected light.

In commencing observations by transmitted light, the student may profitably examine air-bubbles in water, easily procured by shaking up a little very weak gum-water in a bottle, and also globules of oil in water, of which milk furnishes a good and readily-procured example. A little of each of these should be placed on a separate slide, covered with a thin glass and examined by transmitted light, the air-bubbles with an inch objective; the milk may probably require a ½ or ¼.

The leading characteristic of the air-bubble is its broad black margin when examined by transmitted light. If the laws of refraction are considered, it will be evident that a bubble of air in water will act precisely as a double concave lens, Fig. 4, B, and by its dispersive power scatter the rays of light, especially at the part where its power is greatest—the margin. The same effect may be produced, on a large scale, by holding to the light two plano-concave lenses of glass with their hollow sides placed together; this will almost exactly represent the air-bubble in water, differing only in the glass having a greater refractive power than the water in the microscopic slide, and dispersing the light rather more powerfully.

The oil globules of the milk exhibit a brilliant spot of light in their centre when slightly beyond the focus of the microscope; this is owing to their being more refractive than the surrounding medium: their action is that of double convex lenses, Fig. 4, A, and the bright spot is an imperfect image of the source of illumination, which is rendered visible when the focus of the microscope coincides with that of the globule, which will be when the instrument is slightly above the focus for distinct vision of the globule.

These appearances should be carefully studied and remembered, as bubbles of air are among the most frequent of the instrusive substances to be met with during microscopical observations; cells filled with oil and globules of oil are also of frequent occurrence in tissues. Besides these, the student should make himself acquainted with the microscopical appearance of fibres of cotton, wool, flax, &c., hair of cats and other animals, all of which are frequently found in the dust of our apartments, and of course in our microscopical preparations, unless more than ordinary care is taken to prevent their intrusion, so that it is well to know them that they may not be mistaken for characteristic portions of the substance under observation, a not unlikely error on the part of inexperienced observers.

A sample of dust from the walls of an office in the Bank of England, where it had accumulated for more than ten years, consisted of about one-half cotton fibre, probably derived from abrasion of paper; the remainder consisted of fibres of wool and flax in small quantities, and soot and grit; molecular motion was apparent when examined in water with a power of 400 diameters. An interesting paper "On the Microscopical Examination of Dust" was read by Mr. J. B. Dancer before the Literary and Philosophical Society of Manchester, January 26th, 1869.

(To be continued.)

* Each lecture was followed by a practical demonstration, during which various objects, &c., were examined and processes in manipulation carried on under the superintendence of the lecturer and assistants. Much of the subject-matter of these demonstrations will be incorporated with the text; such portions as cannot be so given will be added at the end of the various chapters.

ON THE

DETERMINATION OF CRYSTALLISED SUGAR.

By JAMES BELL, Esq.

Two processes for the determination of crystallised sugar have been proposed, one by M. Dumas, and the other by M. Payen. Both methods are based on the insolubility of crystallised sugar in alcohol saturated with refined white sugar, while inverted and uncrystallised sugars are supposed to be soluble therein.

These two processes, while differing in many important particulars, are essentially the same in the method followed in liberating the crystallised sugar, which consists in mechanically washing out, by simple agitation, the inverted and uncrystallised portion. This method of operation may be adapted for the analysis of superior qualities of sugar, but it is not applicable to low descriptions, such as "jaggery" and "concrete," or to mixtures of sugar and treacle.

In the analysis of "jaggery" and "concrete," &c., simple agitation in the test liquor is not sufficient to dissolve out, and remove the whole of the inverted and un-

crystallised sugars, and liberate the crystallised portion. When the proportion of inverted and uncrystallised sugars present is tolerably large, the sample possesses a considerable degree of tenacity, and, it is not practicable, by simple agitation, to reduce it into that minutely divided state which is essential to admit of the solvent power of the test liquor being brought into full action; and in practice, in order to effect a complete disintegration of the sugar, it is necessary to operate in a mortar, and to gently rub the sample in the test liquor with a pestle.

The alcohol employed in both Dumas's and Payen's processes is of a strength of 85°, or a little under 50 over proof strength, and, prior to saturation, there is added to the alcohol five per cent of acetic acid, for the purpose of decomposing and dissolving any salts of lime, &c., that may be present.

Before submitting the sample to the action of the test liquor, M. Payen removes the "2 or 3 per cent" of moisture it contains by "absolute alcohol." It is obvious that this could not be done with samples containing large percentages of treacle, such as those to which the process hereafter described is applicable, as the "absolute alcohol" could not abstract the water from them, on account of their viscidity, and even if it were possible for it to do so, the reduction in strength would be so considerable that the alcohol would have a very appreciable solvent action.

The strength of the alcohol has a very important influence upon the accuracy of the result, and, while it is desirable to keep the strength as high as possible, that the alcohol may be readily saturated with a small quantity of crystallised sugar, and that a slight reduction in strength will not materially increase its solvent power, it is, on the other hand, essential that the alcohol should be of such a strength that the proportion of the test liquor used for washing the sample will be sufficient to dissolve the whole of the inverted and uncrystallised sugars present.

Alcohol, at the higher strengths, has a very limited solvent power for sugar; but its power for dissolving the sugar increases in a greater ratio than its reduction in strength. For example, at a temperature of 60° Fahr., 100 grains of alcohol by measure of the respective strengths of 62·6, 55·7, and 49·6 over proof dissolve 0·52, 1·34, and 2·94 grains of crystallised sugar respectively. It will thus be seen that, from 62·6 to 55·7 over proof, a reduction in strength of 6·9°, the solvent power of the alcohol is increased by only 0·82 of a grain, or 0·12 of a grain for each degree of reduction in strength, while from 55·7 to 49·6 over proof, a reduction in strength of 6·1°, the solvent alcohol is increased 1·60 grains, or 0·26 of a grain for each degree of reduction, being more than double the ratio of the increase from 62·6 to 55·7 over proof.

In like manner, the solvent power of alcohol for inverted sugar increases with its reduction in strength, but not in an increasing ratio, as in the case of crystallised sugar; on the contrary, the ratio of increase appears to be a diminishing one.

It is necessary to bear these facts in mind in selecting alcohol of the most suitable strength for preparing the test liquor. If the alcohol be of a very high strength, the result will show a higher percentage of crystallised sugar than is known to be present; but, on the other hand, if the alcohol used be of a very low strength, there will not only be considerable difficulty in fully saturating it with cane-sugar, but the result will be a much less proportion of crystallised sugar than there should be.

This may be illustrated by the following results obtained from experiments, made upon the same mixture of refined sugar and treacle, with test liquors prepared from alcohol at each of the strengths specified.

		Percentage of crystallised sugar.
1.	Alcohol of 40 over proof gave	49·20
2.	„ 56 „ „	54·49
3.	„ 63 „ „	64·70

The result obtained in No. 2, by alcohol of 56 over proof strength, is within a few tenths of the quantity of crystallised sugar known to be present. The large excess in No. 3 is doubtless due to the very limited solubility of inverted and uncrystallised sugars in alcohol of that strength, and the consequent difficulty of dissolving the whole of these sugars in a given number of washings, and thus liberating the crystallised portion. In No. 1 there is a considerable deficiency, which is probably due to the water in the sample having increased the solvent power of the alcohol at that strength in a greater ratio than in the other cases at the higher strengths. The additional quantity of crystallised sugar, however, which the reduced test liquor dissolves, is not, as a rule, in proportion to the reduction which the quantity of moisture in the sugar would make in the strength of the alcohol, a circumstance which is due to the fact that the time the test liquor and the sugar are in contact is too short to allow the former to become completely saturated.

After making a variety of experiments, it soon became obvious that the most suitable strength of alcohol to be used for preparing the test liquor lay between 50 and 56 over proof; but that it could not be absolutely affirmed that alcohol of any particular strength was applicable to the analysis of all descriptions of sugar, ranging from the finer qualities down to molasses.

To ascertain the relative value of alcohol at the strengths of 56 and 50 over proof for preparing the test liquor, a mixture was made, consisting of 60 parts of purified white sugar and 40 parts of treacle; and experiments were made on the mixture with saturated alcohol at each of the strengths named, with the following results:—

	Percentage of crystallised sugar.
Alcohol of 56 over proof gave	59·12
„ „ 50 „ „	57·72

Thus, with alcohol of a strength of 56 over proof, there was a loss of 0·88 of crystallised sugar; but, with the alcohol of 50 over proof, the loss amounted to 2·28 grains, or nearly 2½ per cent more than in the case of the alcohol of the higher strength.

The test in this case was very rigid, and, upon this ground, as well as from a slight loss which must inevitably occur in manipulation, the loss of the 0·88 of crystallised sugar with the alcohol of 56 over proof strength may be accounted for. With refined sugar, it is not only difficult to obtain an intimate and uniform mixture of the crushed crystals and treacle, but the crystals remain exposed, as it were, to the immediate action of the first portion of the test liquor, which acquires increased solvent power from the additional moisture which it takes up from the sugar.

The sample of treacle employed in the preparation of the mixture was found to contain 3·35 per cent of salts and other impurities insoluble in the test liquors; and, in calculating the results, an allowance was made for the proportion of insoluble matter contained in the quantity of treacle used in the experiments.

To determine whether a test liquor prepared from alcohol of a strength of 56 over proof would give uniform results with mixtures of crystallised and inverted sugars in all proportions, mixtures were made of treacle and raw sugar, varying from 10 to 90 per cent of each; and the several mixtures were submitted to careful analysis, and the same conditions observed in every instance. Three analyses were made of each mixture, and also of the raw sugar, and a mean of the results taken.

The raw sugar used was of medium quality, and gave 84·69 per cent of crystallised sugar. The treacle employed was the same as that used in the experiments referred to above; and, in each instance, the proper allowance was made for the proportion of salts and other impurities insoluble in the test liquor.

The mean results of the analyses made of the respective mixtures were as follows:—

					Percentage of crystallised sugar by calculation.	Percentage of crystallised sugar by experiment.	Loss. Gain.
90 parts of sugar and	10	of treacle			76·22	75·80	0·42
80	,,	,,	20	,,	67·75	67·84	0·09
70	,,	,,	30	,,	59·21	59·71	0·43
60	,,	,,	40	,,	50·81	51·44	0·63
50	,,	,,	50	,,	42·34	43·65	1·31
40	,,	,,	60	,,	33·87	36·01	2·14
30	,,	,,	70	,,	25·40	28·01	2·61

From the results of the experiments, it will be seen that, as the percentage of treacle is increased (the percentage of moisture being also thereby proportionately increased), the residue, contrary to what might have been expected, indicates a small but gradually-increasing excess over the percentage of crystallised sugar known to be present. This cannot be due to the salts and other impurities in the treacle which are insoluble in the test liquor, for they, as before stated, have already been allowed for. It is highly probable that it is caused by the increasing viscidity of the mixtures and the consequent difficulty of the alcohol, limited in quantity, and approaching nearer and nearer to its saturating point for inverted and uncrystallised sugars, in effecting the liberation of the crystallised portion.

The results obtained in the analysis of the mixtures containing 80 and 90 per cent of treacle respectively were considerably in excess of the quantity of crystallised sugar present; and it was obvious that the test liquor was inapplicable to the analysis of mixtures containing so large proportions of treacle.

The results accord very well with the theoretical percentages of crystallised sugar in the mixtures down to 50 per cent, but, from this point, the results are not so satisfactory as could be wished.

In the analysis of samples of sugar or mixtures of sugar and treacle in which the proportion of inverted and uncrystallised sugars amounts to upwards of 50 per cent, a test liquor prepared with alcohol of a slightly lower strength than 56 over proof is more suitable, and gives more accurate results; in fact, by gradually reducing the strength of the alcohol, and employing a fresh test liquor as the scale is descended, practically accurate results may be obtained down to the lowest mixture, consisting of 90 parts of treacle to 10 of sugar.

The mode in which the analyses were conducted may be shortly described. To alcohol of the proper strength, excess of finely-powdered purified white sugar was added, and the mixture was agitated for two or three days, and, as required for use, the clear saturated liquid was drawn off. 100 grains of the sample were then gently rubbed in a mortar with 200 fluid grains of the saturated alcohol, and the washings thrown upon a filter previously counterpoised with another filter. The operation of washing was repeated nine times, with the like quantity of fluid grains, the sugar in the mortar being gradually transferred to the filter, so that, when the 2000 grains of the test liquor were used, the whole of the sugar had been transferred to the filter. The counterpoised filter and that containing the crystallised sugar were then dried in a water-bath, and the difference in the weights, after allowing for the salts, &c., present in the treacle, and insoluble in the test-liquor, gave the percentage of crystallised sugar in the sample.

My best thanks are due to Messrs. Helm and Stokes for the valuable assistance which they rendered me in making the experiments connected with this investigation.

Permanent White, which is necessary in the manufacture of ultramarine, may be formed by adding to the washing waters of that dye sufficient chloride of barium to render the liquid no longer turbid. The precipitate, which is heavy, and falls quickly, may be deprived of a bluish tint by depositing a portion first, with which the ultramarine held in suspension also settles.

ON THE ACETIC DERIVATIVES OF HYDROCARBONACEOUS SUBSTANCES.

By MM. SCHUTZENBERGER and NAUDIN.

ACETIC anhydride reacts easily upon many immediate organic principles, playing the part of polyatomic alcohols. The total transformation of bodies into acetic derivatives is thus quickly effected, the degree of substitution varying according to the temperature and the quantity of the anhydride. Here are the results of my experiments.

Acetic Celluloses.—The cellulose (Swedish paper or cotton) was heated to 180° in a closed vessel with six or eight times its weight of acetic anhydride. It dissolved into a thick syrup, which, when poured into water, precipitated white flakes of triacetic cellulose—

$$C_6H_7(C_2H_3O)_3O_5,$$

insoluble in water, alcohol, or ether; soluble in concentrated acetic acid; easily saponifiable by alkalies, with regeneration of cellulose. Whatever the duration of the heating process or the excess of anhydride employed, no higher limit was reached. Cellulose is, then, a triatomic alcohol—

$$\left.\begin{matrix} C_6H_7O_2 \\ H_3 \end{matrix}\right\} O_3$$

On employing but two parts of anhydride, and heating to only 150°, the cotton swelled without dissolving, by reason of the simultaneous production of diacetic and monoacetic ethers, which could not be separated.

Starch and Dextrine.—Starch, when heated to 140° with excess of acetic anhydride, swelled greatly without dissolving. The mass, when washed with water, yielded a white, amorphous substance, insoluble in water, alcohol, ether, and acetic acid; not turned blue by iodine, and saponifiable by caustic alkalies, with regeneration of starch, turning blue by iodine. It represents triacetic starch $C_6H_7(C_2H_3O)_3O_5$. If the mixture of starch and acetic acid be heated to 160°, the swelled mass will dissolve, yielding an amber syrup. This, when poured into water, precipitates a white, amorphous matter, insoluble in water, alcohol, and ether, but soluble in glacial acetic acid. It is easily saponified by alkalies, with separation of dextrine. Its composition is the same as the preceding, and represents triacetic dextrine obtained directly by the action of the anhydride upon dextrine. The degree of substitution of the third order cannot be passed; those inferior were not examined, on account of the difficulty of distinguishing them. Starch and dextrine act, therefore, as triatomic alcohols.

Glycogene.—Glycogene, when heated at 155° with excess of acetic acid, swells without dissolving. The mass, washed in water, gives an amorphous, white product, insoluble in water (even warm), and in alcohol, ether, and acetic acid. It is saponified by alkalies, with regeneration of glycogene. It represents the maximum of saturation, and is triatomic—$C_6H_7(C_2H_3O)_3O_5$.

Gum Arabic.—This substance, when heated with about two parts of acetic anhydride to 150° for some hours, swells without dissolving. The mass, washed first with boiling water and then with alcohol, leaves an amorphous white powder, insoluble in boiling water, and saponified by alkalies, with regeneration of soluble arabin. It represents diacetic arabin, $C_6H_8(C_2H_3O)_2O_5$. By employing an excess of 6 to 8 parts of acetic anhydride, and heating to 180° for five or six hours, a triacetic derivative is obtained, similar in its properties to the preceding one: this is the highest degree of substitution.

Inuline.—This yields, under the same conditions, a saturated, triacetic derivative, soluble in water, of a bitter taste, and melting, at about 110°, into a syrup which solidifies into a vitreous, transparent, and colourless mass. It is easily saponified by alkalies, with regeneration of a white body, insoluble in water, and which melts below

100°. Thus, cellulose and its isomers of the formula $C_6H_{10}O_5$ all give saturated derivatives of the third degree, easily distinguishable from each other by their character of solubility and the nature of the products generated by saponification.

Acetic Derivatives of Sugar.—The action of acetic anhydride on sugar is vigorous: the reaction begins at the instant when the acid boils, and ends of its own accord in a few moments, with great development of heat. The sugar was heated for twenty-four hours at 170° with large excess of anhydride. Alkalies could not here be used for decomposition on account of their ulterior action upon sugar, but it was easily effected by water only at 160°.

Acetic Glucose.—One part of dry glucose, heated to the boiling point of the acetic anhydride with 2½ parts of the latter, in an open vessel, gives a lively reaction, ending in a few moments. The product, when suitably purified, is solid, colourless, and of a bitter taste. It is soluble in water, alcohol, ether, and acetic acid, and melts below 100°. Its analysis corresponds with the formula for diacetic glucose, $C_6H_{10}(C_2H_3O)_2O_6$. This substance, when again heated to 140° with about twice its weight of anhydride, yields a second solid derivative, distinguished from the first by its slight solubility in pure water. It dissolves in water containing acetic acid, in alcohol, and ether, and represents triacetic glucose. This latter, maintained at 160° for twenty-four hours with a large excess of anhydride, changes into a saturated product very similar to the preceding, but differing by its insolubility in water charged with acetic acid. The acetic liquid, poured into water, yields a viscous precipitate, which is washed with water, again dissolved in alcohol containing bone-black, filtered, and evaporated to dryness. Its composition, which is ascertained by combustion and estimation of the acetyle, is that of tetracetic glucose, wanting a demi-molecule of water, and answers to the formula $C_{12}H_{14}(C_2H_3O)_8O_{11}$. The more simple formula, $C_6H_6(C_2H_3O)_4O_5$, may, perhaps, be employed, but it does not tally so well with the results of the analysis. Under these conditions, glucose undergoes a partial dehydratation. Cane-sugar yields, under similar circumstances, a saturated derivative, undistinguished in character or composition from the preceding. (The rotatory power was not studied).

Lactine, heated to 140° with acetic acid, dissolves entirely. The liquid, when poured into water, yields a viscous precipitate, which quickly becomes powdery. Acetic lactine softens at about 52°; its composition corresponds with the formula $C_{12}H_{14}(C_2H_3O)_8O_{11}$, or $C_6H_6(C_2H_3O)_4O_5$.—*Comptes Rendus.*

ON THE

OXIDATION OF PHOSPHORUS

AND THE

QUANTITY OF PHOSPHORIC ACID EXCRETED BY THE KIDNEYS IN CONNECTION WITH ATMOSPHERIC CONDITIONS.*

By J. MOFFAT, M.D., F.R.A.S., F.G.S.

FROM results deduced from observations on the luminosity of phosphorus in connection with atmospheric conditions for a period of six years, it appears that periods of phosphorescence and ozone periods commence, continue, and terminate under the same atmospheric conditions; that phosphoric ozone is formed only when phosphorus is luminous, and that increase of temperature and low atmospheric pressure are favourable to luminosity, while low temperature and high atmospheric pressure are unfavourable to it.

While the readings of the barometer are increasing and the wind is veering towards the N. points of the compass, phosphorescence diminishes in brilliancy and ozone in quantity; and, while the polar current continues, the barometer attains its maximum, the wind veers from N. to E., phosphorus becomes non-luminous, and ozone disappears. If, when the wind has veered to the E., the barometer readings begin to decrease, the wind sets in from points by S., phosphorus becomes luminous, and ozone appears; and, while the south or equatorial current continues, the barometer readings fall to a minimum, the wind veers from S. to W. points, phosphorescence becomes brilliant, and ozone is in maximum quantity. Liquid and gaseous bodies, when in contact with phosphorus in a non-luminous state, become phosphorated, and they, under suitable conditions, become phosphorescent and ozonised, the temperature at which phosphorescence takes place varying with the pressure of the atmosphere.

As venous blood contains phosphorus (phosphorated fat), which, in coming in contact with the oxygen of the air during respiration, is converted into phosphoric acid (the blood, perhaps, being ozonised at the same time), and combines with the alkalies and earths in the *liquor sanguinis*, and forms phosphates of soda, magnesia, and lime, it appeared to me not unreasonable to suppose that the quantity of phosphorus oxidated and phosphates formed in the system, and eliminated from it through the kidneys, is in some degree determined by the pressure and temperature of the atmosphere, and the state of the weather generally.

With a view to ascertain the quantity of phosphoric acid excreted by the kidneys, I tested the urine of a healthy man daily for twelve months. The quantity of urine evacuated in twenty-four hours was measured daily, and the quantity of phosphoric acid in one ounce of it ascertained. The man was of abstemious habits; his food seldom varied in kind or quantity. It consisted of tea, bread-and-butter, eggs, animal food, rice, oatmeal, and milk. The two articles in excess were bread and milk; of the latter he took at least 3 pints daily. The readings of the barometer and thermometer, the quantity of atmospheric ozone, and the direction of the wind, were recorded daily. The results were deduced monthly, and tabulated as below.

TABLE I.

Showing the Mean Daily Quantity of Phosphoric Acid Excreted by the Kidneys when—

The barometer was				Temperature was		Ozone was		Phosphorus was		The wind was			
Increasing.	Decreasing.	Above 30 in.	Above 29 in., below 30 in.	Above 28 in., below 29 in.	Increasing.	Decreasing.	Present.	Absent.	Luminous.	Non-luminous.	N. to E.	E. to S.	S. to W.	W. to N.
grs.	grs.	grs.	grs.	grs.	grs.	grs.	grs.	grs.	grs.	grs.	grs.	grs.	grs.	grs.
58·8	62·8	53·6	57·5	67·5	62·4	61·4	62·0	56·0	60·0	57·0	56·8	59·5	62·0	61·4

From these results, then, it would appear that the maximum quantity of phosphoric acid excreted from, and in all probability formed in, the system occurs with the conditions of the equatorial or south and ozoniferous current of the atmosphere, and that the minimum quantity occurs with the conditions of the polar or north and non-ozoniferous current. The results of the observations for each month were similar to those in the table, with the exception of March and May. In March, there were 2 grains more of daily mean with increasing than with decreasing readings of the barometer; and, in May, the quantities were equal for both sets of readings. The range of the barometer, for March and May, was 1·247 in. only; while, for August and November, the range was 1·532 in.; and the difference in the quantities of phosphoric acid excreted was a daily mean of 12 grains more with decreasing than increasing readings. When the

* Read before the British Association, Exeter meeting, Section B.

range of the barometer for the month is above 1·5 in., the difference in the two sets of readings is 6·8 grains more with decreasing than increasing readings; and, when the range is less than 1·5 in., the mean difference between the two sets of readings is 3·4 grains more only for decreasing than increasing readings.

During the months from October to February (both inclusive), that is, during the months in which the temperature of the air is owing more to atmospheric than solar influence, a piece of phosphorus was kept in a dark cellar. It was examined daily, and the quantity consumed or oxidised was ascertained monthly. The results are given in the following table:—

TABLE II.

Showing that, when the Mean Monthly Reading of the Barometer was—

Between	The quantity of phosphorus oxidised was	The mean daily quantity of ozone was	The No. of ozone days was	The mean daily quantity of phosphoric acid excreted was
in.	grs.			grs.
29·0 and 29·5	41·3	2	18	62·5
29·5 ,, 30·0	20·0	1	8	55·6

From this, it would appear that the amount of phosphorus oxidised in the air and the amount oxidised within us depends upon similar atmospheric conditions. The readings of the barometer which lead to the issuing of cautionary (Admiral Fitzroy's) telegrams are, of course, decreasing.

I have observed that 94 per cent of the telegrams are accompanied by the commencement of periods of phosphorescence. Atmospheric ozone invariably appears or increases in quantity with them. The mean daily quantity of phosphoric acid excreted by the kidneys on the day before the telegrams is 65·3 grains; and, on the day of it, 63·9 grains; giving a mean of 64·6 grains, which is 3½ grains daily above the mean.

The diseases which accompany the meteorological changes which appear to lead to the foregoing results I leave for future discussion.

Hawarden, July, 1869.

NOTICES OF BOOKS.

Field's Chromatography, or Treatise on Colours and Pigments as used by Artists. A new edition, re-written by THOMAS W. SALTER, F.C.S. London: Winsor and Newton, 38, Rathbone Place. Pp. 435; 8vo.

WE have, unfortunately, too many examples of the disastrous effects which ensue from the use of certain colours by artists who are unaware of their nature and durability. Many a grand and immortal work of art has suffered irretrievably from the fading of some paints, and the blackening of others, and the effects of damp and impure air upon others. Sometimes colours slowly react upon each other: sometimes bright lead colours pass, in the course of years, into the dingiest of greys, ultimately becoming almost metallically black from the sulphur of the air by which they are surrounded. Now, with all this in view, the appointment of a Lecturer on chemistry to the Royal Academy of Arts has been more than once seriously discussed, and we may hope that, sooner or later, will be carried into effect. In the same direction, and tending to remove such like conflictions of chemical with artistic lore, is Field's "Chromatography;" and we are happy to welcome a new and revised edition of it. Fortunately, its reviser, Mr. Salter, is a chemist; so that artists have already within their grasp a certain application of chemical knowledge to the usages of their craft.

In the preface to this new edition, Mr. Salter informs us that the work has been entirely revised and re-written, "the notices of colours have been considerably extended, their chemical and artistic properties more fully dilated on, and many new pigments of the utmost importance described." Mr. William Winsor was engaged upon the revision of this work at the time of his death, and his *collaborateur* regrets that the intimate knowledge of colours which Mr. Winsor possessed can no longer be applied to the purposes of the revision.

The "Chromatography" is divided into three parts—Part I. "On Colours and Colouring;" Part II. "On Colours and Pigments generally;" Part III. "On Colours and Pigments individually."

In the first chapter, an infinitely too brief history of the prominent phases in painting is given, and allusion is made to the early works of the Egyptians and Greeks. There are, it is asserted, in reality, but three schools of painting—the *Material*, the *Sensible*, and the *Intellectual*. "Modern art, as founded upon the *intellectual* school of the ancient Greeks, became grand, scientific, and severe in the practice of Michael Angelo and Leonardo de Vinci; graceful, beautiful, and expressive in Raphael, Correggio, Dominichino, and Guido; and, aiming at *sensible* perfection, it attained harmony of colouring and effect in the works of Titian and Tintoret; but it sunk into grossness and sensuality while perfecting itself *materially* among the Flemish and Dutch." This is indeed a sweeping survey, so sweeping that no mention is made of the French or Spanish schools. We would not ask it for ourselves, for it is so recently that anything like an English school of painting—and that a mongrel and a bastard offspring—has arisen, that we can well make no demands for recognition; but surely, in the above statement, the name of Fra Angelico de Fiesole should come in between Raphael and Correggio; nay, we know not whether he should not be placed at the head of those painters who brought art to its culminating point in regard to the graceful, the beautiful, and the divine. What shall we say to those glorious angels, with wings sprinkled with golden stars, who are ascending jubilantly upon the purple clouds which curl at their feet? Or what shall we say to the serene and infinitely majestic and calm S. John, seated upon the outspread wings of an eagle? The art of to-day is as far behind the art of that day as the science of to-day is in advance of the science of that day. We always think that picture must have reference to Fra Angelico in which we see a monk who, seated in front of his painting, has fallen asleep over his work, while an angel, taking the brush from his fingers, continues that which he has left undone.

Passing on now to the third chapter, which commences Part II., we find some very useful definitions; for example, "By mixing his colours with white, the artist obtains his *tints*. By mixing colours with colours, he produces compound colours, or hues; and, by mixing colours or tints with black, he gets *shades*." Colours themselves are divided into five classes; the Neutral, the Primary, the Secondary, the Tertiary, and the Semi-Neutral. Neutral colours are *black*, *white*, and *grey*. Primary colours are *yellow*, *red*, and *blue*. Secondary colours are *orange*, *green*, and *purple*. Tertiary colours are *citrine*, *russet*, and *olive*. Semi-neutral colours comprehend all the combinations of primary, secondary, and tertiary colours, with the neutral black.

In regard to the "durability and evanescence of pigments," we have a good deal of useful information in chapter 4. The organic colours are most easily affected by light and air; compounds of lead, mercury, and copper by air containing sulphuretted hydrogen. Many colours are altered by the action of lead pigments, and others, again, by ferruginous pigments; finally, the vehicles and varnishes with which colours are mixed often act deleteriously upon the colours.

No less than seven-eighths of the work are devoted to colours and pigments individually considered; and we have here a long list of colours, with an account of their composition and general qualities: let us take the fol-

lowing as an example of the mode of description here employed:—"Burnt carmine is the carmine of cochineal partially charred, until it resembles, in colour, the purple of gold, for which, in miniature and water-painting, it is substituted. It is a magnificent reddish purple, of extreme richness and depth, eligible in flower painting and the shadows of drapery. As it is generally impossible, however, to alter the nature of a pigment by merely changing its colour, burnt carmine is scarcely more permanent than the carmine from which it is produced. If used, therefore, it should be in a body, and not in thin washes, or as a glaze. Durable pigments are admissible in any form; but semi-stable pigments (gamboge excepted) should only be employed in body."

We are glad to notice that descriptions of new pigments have been introduced; thus we have aureolin, thallium red, tungstate of baryta, viridian, brun de mars, indium yellow, and molybdenum green.

The "Chromatography" cannot but prove most valuable to all who are interested in art; and we cordially recommend it even to that dignified and austere Body which dictates the art taste of the kingdom.

The Chemical Manufacturer's Plant, as Supplied by the St. Helen's Foundry, Lancashire."

This is an illustrated catalogue of various vessels employed in some of the chemical manufactures, notably in the two greater industries, sulphuric acid and soda. Thus we have pyrites' burner frames, nitre pots, decomposing pans, black ash vats, crystallising pans, &c. Some of the decomposing pans described have a thickness of no less than 7 inches at the bottom; the charge of salt is from 5 to 18 cwts.; and the amount of salt-cake decomposed in a pot varies from 1000 to 2700 tons. The "black ash revolving furnace" is also figured, and appears to be replacing the old hand-furnace in Lancashire and elsewhere.

CORRESPONDENCE.

INK.

To the Editor of the Chemical News.

Sir,—In the Chemical News (vol. xx., p. 155) you give M. Voigt's recipe for "a very black and very cheap ink." The objections to it seem to me to be these—(1) It involves a number of unnecessarily troublesome processes; (2) it requires the use of sulphate of copper, which leads to the deposit of copper on steel pens, and so makes them useless; (3) it prescribes corrosive sublimate, which is not good for little boys, who will suck their pens; (4) it recommends logwood, which gives a brownish tone to ink.

For any one who wishes to make his own writing-ink, I do not know an easier or better method than that adopted by the late Professor Daniell, of King's College. He put into a stone-ware jar 1 gallon of soft water, ½ lb. of bruised nut-galls, and next day 6 ozs. of green vitriol, 6 ozs. of gum arabic, and 4 or 5 drops of kreosote. The bottle was then corked, and left in a corner of the room for two or three weeks, so that, once in two days, or so, it might remind the owner that it wanted a good shaking. After this, it was left a few days, and then the clear liquor was decanted off for use. This formed a very black, a very cheap, and, what is more, a very durable ink.

I have letters from Professor Daniell written with such ink a quarter of a century ago, and from Snow Harris (who used the same ink), of the same date, and they form a good written character of this useful black servant.—I am, &c.,

O. T.

September 25th, 1869.

MISCELLANEOUS.

Discovery of Bismuth Ore.—On an estate belonging to M. Carnac, near Balhannah, South Australia, a very valuable lode of bismuth has been found, while some miners were seeking for copper ore. Since bismuth has very much increased in price, and is increasingly in demand, this discovery is a highly welcome one.

Incrustations in Boilers may be prevented by introducing raw potatoes, which cause all solid matters to be precipitated at the bottom of the boiler in a fine powder, leaving the sides perfectly free. The experiment was tried with an engine of 8-horse power, into the boiler of which ten kilogrammes of potatoes per week were introduced through the safety-valve. Every week, when the fires were extinguished, the deposit was removed previous to the introduction of a fresh supply of potatoes. On examining the boiler after fourteen consecutive months of work, no traces of incrustation were perceptible; the appearance of the plates was blackish and slightly greasy, and the corners of the joints were in the same state as when first made. Refuse leather-cuttings from the tanneries will answer the purpose equally well.—*Annales de Génie Civil.*

Electro-Plating of Paper or other Fibrous Material.—The *Druggist's Circular* says—"A mode has been devised for depositing copper, silver, or gold, by the electric process, upon paper, or any other fibrous material. This is accomplished by first rendering the paper a good conductor of electricity without coating it with any material which will peel off. One of the best methods is to take a solution of nitrate of silver, pour in liquid ammonia till the precipitate formed at first is entirely dissolved again; then place the paper, silk, or muslin for one or two hours in this solution. After taking it out and drying well, it is exposed to a current of hydrogen gas, by which operation the silver is reduced to a metallic state, and the material becomes so good a conductor of electricity that it may be electro-plated with copper, silver, or gold, in the usual manner. Material prepared in this manner may be employed for various useful and ornamental purposes.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

In accordance with the generally expressed wishes of our friends and readers, we have effected arrangements to enable us to give, under the above heading, notices of every chemical paper in the world, *as soon as possible after publication. Whenever possible, these notices will appear in the form of carefully prepared, although necessarily brief, abstracts; as respects papers either too long or too abstruse to render condensation possible, their titles will be chronicled; and in all cases accurate reference will be made to the original publication. The two half-yearly volumes of the* Chemical News, *with their copious indices, will therefore be equivalent to an English edition of the "Jahresberichte," with the additional advantage of keeping the readers week by week on a level with the latest advances of science.*

Note. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus des Séances de l'Académie des Sciences, September 13, 1869.

This number, an unusually small one, contains, among its most remarkable communications, the startling intelligence that the manuscripts and signatures, about which M. Chasles has made so much fuss, are nothing but the work of a clever forger, who, by dint of study and perseverance, has been enabled to carry on a very successful, but, happily, now interrupted, business. M. Dumas read a small portion of a lengthy memoir on the—

Spectrum of the Solar Spots, as observed by the Rev. Father Secchi, S.J.—This paper, and the following, on the—

Constitution of the Luminous Spectra (M. Lecoq de Boisbaudran) are too lengthy, on the one hand, and too concisely written, on the other, to admit of any useful abstraction.

Researches on the Nature of the Products of Fermentation of Glycerine produced by Microzymas.—M. Béchamp.—The author briefly reviews the labours of M. Redtenbacher on this subject, stating that that chemist had transformed glycerine, after addition of beer yeast, into propionic acid. The author of this paper has applied to his researches a mixture consisting of pure glycerine, 250 grms.; chalk, from Sens, full of well and lively-moving microzymas; hashed mutton, quite fresh, and previously washed with cold water, 30 grms.; cold water, 3000 c.c. This mixture has been kept at a temperature of from 35° to 40° for several months. The chief results obtained by the author are, that propionic, butyric, caproic, and valeric acids are formed most abundantly; among the gaseous products, carbonic acid, hydrogen, and nitrogen are found as result of this fermentation.

September 20, 1869.

This number contains the following original papers relating to chemistry or sciences allied thereto:—

Preparation of Nitrogen.—Mr. Calvert.—The author suggests that a mixture of hypochlorite of lime and sulphate of ammonia be made in the following manner:—200 c.c. of an aqueous solution of hypochlorite of lime, containing 5·14 of hypochlorous acid, to which is added 1·146 of sulphate of ammonia, previously dried at 220°; nitrogen gas is immediately given off, even without the application of heat, but it is better to apply heat very gently. The author observes, further, that all nitrogenised animal matters (such as albumen, fibrin, gelatine, silk, feathers, and skin) yield, when mixed with a solution of hypochlorite of lime, especially when heat is applied, a large quantity of nitrogen and carbonic acid. Ulterior researches on this subject are promised.

Researches on the Microzymas of the Blood and on the Nature of Fibrin.—MM. Béchamp and Ester.—This is, strictly speaking, a physiological paper. It is somewhat curious to learn that the coagulation of blood should be due to the juxtaposition and agglutination of minute globules (not the blood corpuscles) and that these globules should be microzymas, and capable of effecting the saccharification of the starch.

Heat Emitted from the Moon.—M. Marié-Davy.—According to the very accurate researches and experimental observations of this author, the heating power of the rays of the moon is incapable of raising the one-millionth part of a degree the temperature of a very sensitive air-thermometer covered with lampblack. This result disagrees with the results obtained by Lord Rosse, when he made observations on this subject.

New Kind of Gunpowder.—M. Brugère.—The author mixes 54 parts of picrate of ammonia and 46 parts of nitrate of potassa; on burning off, this mixture only leaves carbonate of potassa. The following formula explains the reaction:—

$$C_{12}H_3(NO_4)_3NH_4O_2+2(KO,NO_5)=10CO_2+6N+6H+2(KO,CO_2).$$

The author states that this powder presents the following advantages over ordinary powder:—It is more homogeneous, and its effects are consequently more regular; it is far less hygroscopic; it is more effective for equal weights; and it leaves far less solid matter on combustion. The residue left after combustion does not affect metals, since it is only carbonate of potassa; this powder hardly emits any smoke at all, and what little is emitted is devoid of smell. The author recommends a mixture of 25 grms. of picrate of ammonia, 67 grms. of nitrate of baryta, and 8 grms. of sulphur, as an excellent substitute for Bengal light, and as suitable for signal and port lights, and use in theatres, since hardly any smoke is emitted and no unpleasant smell given off, while the light is very brilliant, slow burning, and yields a beautiful greenish tinge.

Annalen der Chemie und Pharmacie, July, 1869.

This number contains the following original papers:—

New Mode of the Formation of Nitro-Prussides. — M. Stüdeler.—The author begins this monograph by a lengthy description of the manner in which he ascertained the composition of the orange-coloured precipitate which ensues when a solution of cyanide of potassium is added to a solution of a proto-salt of iron. The quantitative estimation of the proportions of the proto-salt of iron and of the cyanide of potassium were found to be in relation as 3 : 4, or 4 : 5; the formula for the orange-coloured precipitate alluded to is, accordingly, Fe_3Cy_5K. In order to test the accuracy of this formula, the author tried to convert the orange-coloured precipitate into a nitro-prusside, according to this schematic formula—

$$Fe_3Cy_5K+NO.OK=FeO+Fe(NO)Cy_5K_2.$$

The result of experiment confirmed the correctness of the author's opinion; but the reaction was not found to take place so simply, for, instead of the formation of protoxide of iron and nitro-prusside of potassium, there is formed magnetic oxide of iron and the nitro-prusside; the formation of the nitro-prussides without acids is, therefore, the author's discovery. The orange-coloured precipitate above alluded to is converted into nitro-prusside by being treated with nitrite of potassium, best, after that orange-coloured body has become oxidised, by exposure to air. A portion of this paper is devoted to the discussion of the correctness of the formula generally adopted for nitro-prussides, and due to Gerhardt's researches on this subject.

On Anisaldehyde.—Dr. Rossel.—The author first reviews the labours of MM. Cahours, Piria, Canizzarro, Bertagnini, and others, on this subject. The author states that the anisaldehyde is best prepared by mixing 1 part of essential oil of anise, 2 parts of bichromate of potassa, 3 parts o iconcentrated sulphuric acid, and 8½ parts of water. When 100 grms. of the essential oil are operated upon, about 50 per cent of aldehyde is obtained. The raw product, after having been purified, exhibits a nearly colourless fluid, of 1·1228 sp. gr. at 18°; it is readily soluble in alcohol and ether, but not so in water; its reaction is neutral, but, since it oxidises very readily to anisic acid, a few drops of the aldehyde, on exposure to air, become solid, and, at the same time, exhibit acid reaction to test-paper. This aldehyde is composed of $C_8H_8O_2$. The author has succeeded in obtaining several derivatives from this anisaldehyde, among which are anisoine, $C_{56}H_{16}O_4$, a solid substance crystallising in six-sided prisms, hydranisoine, isohydranisoine, desoxyanisoine, and anishumine.

On Diphenyl.—M. Brönner.—While engaged in rectifying a large quantity of benzol, made by the distillation of a mixture of benzoate of lime and slaked lime, there remained in the retort a solid crystalline substance, which was found to be insoluble in water, and readily soluble in ether and in boiling alcohol, from which latter solution it was obtained in a pearly, crystalline mass, fusing at 70·5°, and which, on being submitted to elementary organic analysis, yielded results leading to the formula, $C_{12}H_{10}$—that is to say, the same as the substance M. Fittig obtained by acting with sodium upon monobrombenzol. The reactions of the latter substance, as described by Fittig, and tried by the author of this paper, with the substance obtained by him in the manner above described, agree in all respects; and there is no doubt, therefore, that both materials are identical, and deserve to bear the same name.

Relations existing between Amylen and Oil of Turpentine.—Drs. Bauer and Verson.—The chief leading points of this memoir may be summarised thus:—1st. Two molecules of amylen form one molecule of diamylen—

$$C_5H_{10}+C_5H_{10}=C_{10}H_{20}.$$

2nd. Diamylen and bromine form diamylen-bromide; and this last named substance forms rutylen, when it is treated with an alcoholic solution of caustic potassa—

$$C_{10}H_{20}Br+2KHO=2KBr+2H_2O+C_{10}H_{18}.$$

3rd. Rutylen forms, with bromine, a bromide of rutylen, and this, on being treated with an alcoholic solution of caustic potassa, yields the new hydrocarbon—

$$C_{10}H_{18}Br+2KHO=2KBr+2H_2O+C_{10}H_{16}.$$

$C_{10}H_{16}$ is evidently related to tereben, which, as observed by M. Berthelot, is the "terme commun et stable auquel tous les carbures, $C_{10}H_{10}$, viennent aboutir."

Products of the Action of Chlorous Acid upon Naphthaline.—M. Hermann.—The products obtained by this reaction are—An acid containing chlorine, phthalic acid, the acid potassa salt of a new sulpho-acid, and bichloride of naphthalin. The author describes these products, and many of their combinations, at great length. The formula of the chlorine containing acid is $C_{10}H_7ClO_5$; this acid readily forms salts, most of which crystallise. The bichloride of naphthaline, $C_{10}H_8Cl_2$, is a solid crystalline substance, fusing at 68°, and soluble in alcohol. The new sulpho-acid above named is *Naphthochinonsulpho acid*, the potassa salt of which contains, in 100 parts:—Carbon, 36·73; hydrogen, 1·22; potassium, 12·00; chlorine, 10·87; sulphur, 9·79; oxygen, 29·39. Formula, $C_{10}H_4KClSO_6$.

Specific Heat of Saturated Vapours.—M. J. A. Groshans.—This paper, a very learned essay on this subject, being entirely based upon higher algebra, is not well suited for abstraction.

Some Derivatives from Creosol.—M. Biechele.—The author first reviews the labours of Hlasiwetz, Hugo Müller, Gorup-Besanez, Sobrero, and others, on this subject; and then he describes a series of his own experiments, treating first on creosol-potassium—

$$C_8H_9KO_2+2H_2O.$$

Creosol, obtained by decomposing the salt just named by means of sulphuric acid. The substance thus obtained is, after purifying, a colourless, oily liquid, highly refractive, boiling between 209° and 220°, becoming a solid mass when treated with ammonia, and reducing salts of silver to the metallic state; formula, $C_8H_{10}O_2$. Creosol-sulpho acid.—The result of the action of sulphuric acid upon rectified creosote is a liquid readily absorbing water from the atmosphere; its formula is $C_8H_9O_2.SO_3H$. This acid forms, with baryta, oxide of lead, and potassa, salts readily soluble in water. When chloride of phosphorus acts upon creosote, the chloride of creosol, C_8H_9OCl, is among the products.

Action of Hypochlorous Acid upon Butylen.—M. Lieben.—By this reaction, butylen-chlorhydrin, chlorinated dibutylen-chloride, are obtained; but the very concise description given by the author, of a long series of rather complicated chemical operations, cannot be readily condensed. The formula of chlorinated dibutylen-chloride is—

$$\left\{\begin{matrix}C_4H_8Cl\\C_4H_7Cl.Cl.\end{matrix}\right.$$

Since the oxidation of an alcohol obtained from butylen-chlorhydrin yields acetic acid, the author states as his opinion, based upon his researches, that the alcohol just alluded to is ethyl-methyl-carbinol.

The two remaining papers in this number are taken, one from the *Proceedings of the Royal Society*, the other from the *Comptes Rendus*, and have both been already abstracted in our pages.

August, 1869.

This number contains the following original papers:—

Amines of Xylyl-Alcohol.—Dr. O. Pieper.—Chlorine gas is first passed into boiling xylol, and the chloride so formed is treated at 116°, in sealed tubes, with a strong solution of ammoniacal gas in alcohol. The contents of the tube, after the reaction was finished, was treated with alcohol; and this fluid, along with excess of ammonia, was removed by distillation. The author thus obtained trixylylamine, $(C_8H_9)3N$, a colourless, viscous, oily fluid, specifically lighter than water, not soluble in that fluid, difficultly soluble in alcohol, but readily soluble in ether. Hydrochlorate of trixylylamine, $(C_8H_9)_3N,HCl$, a solid substance, exhibiting perfectly snow-white needle-shaped crystals, not soluble in water and ether, difficultly soluble in cold, but readily in hot alcohol, and fusing at 212°. Bixylylamine, $(C_8H_9)2HN$, a somewhat yellowish coloured oil, exhibiting an alkaline reaction to test paper, specifically lighter than water, insoluble therein, soluble in alcohol and ether, and decomposed if heated above 210°. Xylylamine, $(C_8H_9)H_2N$, also an oily liquid, boiling at 196°, soluble in alcohol and ether, and insoluble in water; it attracts carbonic acid from the air, and solidifies.

Decomposition of Tri- and Bi-Benzylamine by Heat.—Dr. L. Brunner.—The author divides his essay in two parts, treating in the first on the products of distillation of tri- and bi-benzylamine. Among the fluid products is toluol, boiling at 112°. Among the solid

products, dibenzyl, $C_{14}H_{14}$, obtained, after re-crystallisation, in large foliated shiny crystals fusing at 52°; toluylen, $C_{14}H_{12}$, a solid body, fusing at 120°. Among the residues of the distillation, left in the retort, and treated of in the second part of this essay, we notice lophin, $C_{21}H_{16}N_2$, a solid body, crystallising in needle-shaped crystals, fusing between 260° and 270°. When lophin is placed in a current of dry hydrochloric acid gas, and a dry current of carbonic acid gas passed over it, the compound $C_{21}H_{16}N_2HCl$ is formed.

Amines of Chlorinated Benzyl-Alcohol.—M. Berlin.—By a complicated process, described at too great length for any useful abstraction, the author has obtained a series of chlorinated compounds, and combinations of these with other substances. We notice among them—Chlorinated tri-benzylamine, $(C_7H_6Cl)_3N$, a solid substance, soluble in alcohol, and fusing at about 89°. Chlorinated bi-benzylamine, $(C_7H_6Cl)_2HN$; the author discovered no less than four varieties of this base, designated, respectively, α, β, γ, and δ, and studied the salts they form. Chlorinated benzylamine, $(C_7H_6Cl)H_2N$, a colourless liquid, readily soluble in alcohol and ether, but not in water; it attracts carbonic acid from the air, and is thereby converted into a solid substance.

Variable Behaviour of Iodine towards Hydrosulphuric Acid under Divers Conditions, and the Causes thereof.—M. A. Naumann.—This essay treats on the part water (and what the author calls thermochemical action) plays in the reactions between iodine and sulphuretted hydrogen gas. Dry sulphuretted hydrogen and iodine, dissolved in anhydrous sulphide of carbon, do not act at all upon each other; neither does sulphuretted hydrogen act upon solid iodine, or vapours thereof if water is excluded. The greater portion of this essay is not well suited for abstraction.

Researches on Phloron and Cresol, and some of their Derivatives.—A. von Rad.—This is a lengthy monograph on the subject named; the mode of treatment and the concise manner in which it is written make it unsuitable for condensation.

Conversion of Urea into Carbaminic Acid.—M. H. Bunte.—About 8 grms. of nitrate of urea were mixed with absolute alcohol, and heated in a sealed tube, for some hours, at about 130°. The contents of the tube, which had nearly become solid, were dissolved in water, next treated with ether, and, after more purifying, a substance was obtained yielding, on elementary analysis, results leading to the formula $C_8H_7NO_8$. The remainder of this paper is devoted to a lengthy theoretical discussion on the various methods to ascertain the true nature of *substituted* ureas.

Condensed Ureas.—M. Schiff.—The author describes, at great length, a number of compounds which he calls *condensed ureas*, and which are made up according to the general formula—

$$XCH_4N_2O+(X-1)CnHmO-(X-1)H_2O.$$

Since this paper is, *de facto*, an exhaustive monograph on this subject, it is difficult to give any further abstract of the details it contains.

Compounds of Ammonia and Sulphate of Zinc.—M. G. Müller.—The author gives the following results of analysis of compounds of sulphate of zinc and ammonia, percentically:—Oxide of zinc, 30·58; sulphuric acid, 30·18; ammonia, 25·65; water, 13·59. Formula—

$$1ZnO1SO_34NH_62H_2O.$$

Oxide of zinc, 26·91; sulphuric acid, 26·58; ammonia, 22·59; water, 23·92. Formula—

$$1ZnO1SO_34NH_34H_2O, \text{ or } \left(\begin{matrix}SO_2\\Zn\end{matrix}\right\} O_24NH_3\Big)_4H_2O.$$

Recovery of Nitrate of Uranium from the Phosphate of Uranium, and on a Nitro-Phosphate of Oxide of Uranium.—M. Heintz.—Since this paper bears upon a subject of importance to many chemists, and, since it is too lengthy for suitable abstraction, we intend to give it in full at a future period.

Chromate of Oxide of Zinc and Ammonia.—M. L. Bieler.—The author describes, at great length, the preparation of a salt composed, in 100 parts, of—Oxide of chromium, 33·01; oxide of zinc, 26·73; ammonia, 22·44; water, 17·82. This salt is readily soluble in dilute acids, crystallises, is decomposed by water, exhales ammonia constantly, and is, hence, readily and spontaneously decomposed.

Behaviour of Boracic Acid towards Oxide of Copper, Borate of Copper, and Ammonia.—M. Pasternack.—After reviewing the labours on this subject by MM. Tiinnermann and Rose, the author records some experiments made by him in order to settle what compound is formed when a solution of two parts of sulphate of copper, and a solution of one part, by weight, of borax, are mixed, care being taken to pour the latter solution into the former. The mixture was next heated, filtered, and washed with warm water, whereby all the boracic acid was eliminated, and a salt left containing, in 100 parts—Sulphuric acid, 18·65; oxide of copper, 64·65; water, 16·79. To the filtrate obtained was added a fresh quantity of solution of borax, and a salt obtained containing, percentically—CuO, 52·72; B_2O_3, 18·59; H_2O, 28·69. A combination of boracic acid, ammonia, oxide of copper, and water, a true basic salt, had the following percentical composition:—CuO, 20·80; B_2O_3, 35·41; NH_3, 17·20; H_2O, 27·31.

Borate of Zinc and Ammonia.—M. Büscher.—This paper is analogous to the foregoing. The borate obtained consists, in 100 parts, of—ZnO, 20·40; B_2O_3, 35·27; NH_3, 17·13; water, 27·20.

Action of Acids upon Carbylamines.—This paper is not well suited for useful abstraction.

Synthesis of Paramonochlorobenzoic Acid.—M. C. Muller.—The acid just named is obtained in large quantity by the oxidation of chloride of benzol, after having been purified and dried over sulphuric acid. Paramonochlorobenzoic acid is a solid, fusing at 235°, readily soluble in alcohol and ether, but very difficultly soluble in water. Formula, $C_7H_5ClO_2$. Its baryta salt crystallises readily.

New Mode of Formation of Ethylsulphuric Acid.—M. Heusser.—By means of the action of sesquichloride of sulphur upon alcohol, and simultaneous exclusion of oxygen, the author has succeeded, by a method described at great length, in obtaining a baryta compound, $(C_2H_5)Ba''S_2O_8(OH_2)_2$, which is ethyl-sulphate of barium. The paper discusses, at great length, the labours of MM. Carius, Warlitz, and others on this subject.

Nitride of Boron.—M. Darmstadt.—The author finds that this compound of boron and nitrogen can be readily obtained when one part of previously fused and powdered boracic acid, and about two parts of urea, are mixed and heated in a covered porcelain crucible, first more gently, at last to red heat. The fused mass is lixiviated with hot water acidified with a few drops of hydrochloric acid, in order to promote the deposition of the nitride of boron.

Journal de Pharmacie et de Chimie, August, 1869.

This number contains the following original papers:—

Magnetic Oxide of Iron and its Salts.—M. Lefort.—After briefly referring to the labours of M. Fourcroy, and other chemists of comparatively older date, the author describes, at some length, the preparation of the ferroso-ferric oxide of iron in the following manner:—100 grms. of pure sulphate of protoxide of iron is dissolved in a small quantity of distilled water previously freed, by long-continued boiling, from all air; 200 grms. of the same salt are placed in a suitable vessel, containing already 50 grms. of nitric acid and 50 grms. of water. This mixture is heated on a sand-bath, until the whole of the sulphate of iron is peroxidised, and a dark brownish red liquor is obtained, which, after having become quite cold, is added to the solution of 100 grms. of sulphate of iron. The author next proceeds to make a boiling concentrated solution of either caustic potassa or soda, and, while this is kept boiling, the mixed solution of iron salts is cautiously added, drop by drop, to the alkaline liquid. In this manner a very beautiful magnetic oxide of iron is obtained, which, on account of its great density, is easily washed with previously well boiled, and still hot, distilled water. After washing, it should be carefully dried over sulphuric acid. After having been thus well dried, the author found, on analysing it, that its composition corresponds to the formula $FeO+Fe_2O_3+HO$. When dried by means of heat, gradually applied, the water is eliminated, and oxidation at the same time sets in; and when the substance is entirely dry, it is, also, entirely converted into Fe_2O_3. The quantity of water contained in the air dried (over sulphuric acid) magnetic oxide, amounts to 7·20 per cent. The composition of the chloride of this magnetic oxide, a perfectly well-defined salt, is, in 100 parts:—Chlorine, 36·57; iron, 21·66; water, 41·77. Formula, $4Cl3Fe18HO$; or—

$$4Cl\left\{\begin{matrix}Fe\\Fe_2\end{matrix}\right\}+18HO.$$

The author has also succeeded in obtaining a sulphate; but the stability of these salts is, after all, very slight.

Synthesis of Phenol.—M. Berthelot.—The author has combined acetylen with fuming sulphuric acid, thereby forming acetylenosulphuric acid, which is not decomposed even by boiling water. The author has next prepared acetylenosulphate of potassa; and, on decomposing this salt, phenol was obtained in large quantity. Acetylenosulphuric acid should not be confused with acetylsulphuric acid, which is a totally different body, and readily decomposed, even by cold water.

Utility of Common Salt as Applied to Agriculture.—M. Peligot.—This lengthy paper is chiefly written with the view of criticising a paper published some time ago by M. Velter, "On the Utility of Common Salt to Agriculture, in consequence of its Ulterior Transformation into Carbonate, and, lastly, Nitrate of Soda." The chief result of M. Peligot's researches is, that when common salt naturally occurs in an arable soil, some plants assimilate this salt, but the greater number leave it unassimilated.

Milk met with in Algeria.—M. Commaille.—This paper contains the results of a series of analyses of milk from cows, goats, and sheep, taken at different periods after the birth of the young of these animals, while care is taken to ascertain the various races these different beasts belong to. Goat's milk, general average—Butter, 45·25; caseine, 35·34; lactine, 49·32; lactalbumine, 8·27; lacto-proteine, 1·90; ash, 7·77. Sheep's milk—Butter, 53·75; caseine, 41·85; lactine, 44·94; lactalbumine, 11·30; lacto-proteine, 3·16; organic acids, 4·63; ash, 9·22. The chief result the author points out is, that the milk in Algeria is better, that is to say, richer, especially in nitrogenised compounds, than the milk met with in Normandy and the Elsass.

On a Milk Mushroom (Champignon).—M. Hesling.—The author points out that, even long before milk becomes sour, there are generated in it very small organised spores of an *ascophora* species.

Annalen der Physik und Chemie, von Poggendorff, No. 8, 1869.

This number contains the following original papers and memoirs:—

Researches on the Impact of a Jet of Water.—Dr. Buff.—This is a very lengthy physico-mechanical essay, not bearing in any way upon chemical science. The makers of fire engines will find much interesting matter in this paper.

Limits of Magnetisation of Iron and Steel.—Dr. von Waltenhofen.—A monograph on this subject, the contents of which are entirely of a mathematico-physical nature.

Some Double (Tisin) Crystals of Sulphuret of Iron (Iron Pyrites).—Dr. Hessel.—This is a purely crystallographical essay on this subject, illustrated by a series of engravings.

Regular Cavities which Naturally Occur, or may be Artificially Produced on the Planes of the Crystals of Quartz.—Dr. J. Hirschwald.—Also a purely crystallographical essay, illustrated by several engravings.

Researches made for the Purpose of Determining the Electromotoric Force between Water and some Metals, by means of the Galvanic Compensation.—Dr. E. Gerland.—A mathematico-physical essay.

Meaning of Insulators in the Theory of Electricity.—M. Schwedoff.—This is the continuation of a lengthy monograph on this subject commenced two volumes previously; it is entirely a mathematico-physical essay.

Transversal Magnetismus of Iron and Steel.—Dr. E. Villari.—A very lengthy monograph, very concisely written, and purely mathematico-physical in its contents.

Researches on the Behaviour of Vapours towards the Law of Marriotte.—Dr. Herwig.—The second part of an extensive monograph on this subject, too lengthy and too abstrusely written to be fit for abstraction.

Meteorite of Krähenberg, near Zweibrücken.—M. E. Weiss.—This paper does not contain anything new on this subject, of which we gave an abstract of a paper taken from a previous number of this periodical (CHEMICAL NEWS, vol. xx., p. 83).

Observations of Solar Protuberances.—M. Zöllner.—We regret that we cannot extract this paper, as it is copiously illustrated with ten very beautifully executed coloured engravings, which are absolutely required for the proper understanding of the subject.

Evolution of Heat Caused by the Emission of Sound from Solid Bodies.—M. E. Warburg.—A purely physical essay.

American Journal of Pharmacy, September, 1869.

We learn from this number of the death of Prof. H. E. Dussauce, which took place at New Lebanon, Columbia County, N.Y., on the 20th of June last. The deceased, who was born on the 25th of December, 1829, at Paris, was a pupil of Chevreul, and was for a time one of the Professors of Industrial Chemistry in the Ecole Polytechnique. The deceased occupied the position of chemist in Tilden and Co.'s Laboratory, and was one of the editors of the *Journal of Applied Chemistry*, and the editor of several other works. The deceased was well known in Europe as an eminent technologist and an excellent analyst.

This number contains the following original papers and communications on subjects of scientific interest for chemists. We omit some papers relating to the practice of pharmacy, of which it should be said, however, that they highly deserve the attention of those concerned:—

Critical Note on Permanganate of Potassa as a Test for Distinguishing Chlorine, Bromine, and Iodine.—Mr. G. Macdonald.—The author has investigated this subject carefully, and made a series of experiments, the main results of which are, that this method of distinguishing, by means of the reaction produced by permanganate of potassa, between the three haloids above named, is only applicable to very dilute solutions, and, even then, care must be taken that the permanganate of potassa is also in very dilute solution, and added drop by drop, as any excess beyond what the iodide or bromide would decompose would be apt to give the liquid its own characteristic tint. Moreover, the method is applicable to simple solutions of haloid salts, and its use implies some previous knowledge by the operator, both of the composition and the strength of the solution under examination. In a compound solution of a chloride and iodide, this test, *per se*, would be of but little use, as only the presence of the iodide would be indicated, and recourse to other methods would be necessary for the detection of the chloride. In a solution containing no haloid whatever, as, for example, a solution of a nitrate or a sulphate, this test would indicate the presence of a chloride—that is, no change would be produced on the addition of the permanganate. In a solution containing organic matter, the test would, in many instances, be rendered worthless, since the permanganate is readily decomposed by such substances, with changes very similar to those produced by the action of iodides or bromides.

Sulphur in Louisana.—The Louisana Petroleum Company, while boring for oil near Lake Charles, reached, at a depth of 442 ft., strata of crystallised sulphur, some 2 ft. thick, and of very pure quality. On boring farther downwards, the augur passed, for a distance of 90 ft., through limestone rock, which yielded about 50 per cent of sulphur, with occasional strata of 6 to 8 feet in thickness of pure sulphur. The boring has now reached to a depth of 600 ft. The Company intend to begin mining operations for the extraction of sulphur, but the cost of such work cannot fail to be very large; yet it appears that there is so great a demand for sulphur in the States that mining it at this depth will pay.

Zeitschrift für Analytische Chemie, von Dr. C. R. Fresenius, second number for 1869.

This number contains the following original memoirs and papers:—

Preservation (Storing) of Solutions of Protochloride of Tin, Sulphuretted Hydrogen, and the like.—Dr. F. Mohr.—The keeping of large quantities of titrated solutions is what is meant by the author, who advises that such solutions, after having been made in large quantity, should be poured in bottles provided with a tubulure at the bottom, through which a perforated cork, into which a downward-bent glass tube is fitted, and that this tube should be connected with another longer tube, by means of india-rubber fittings, and so arranged as to admit of running fluid into a burette; the neck of the bottle is fitted with a perforated cork, wherein a narrow glass tube is inserted. In order to prevent the action of the air upon the fluid contained in the bottle, a layer of petroleum, 1 centimetre high, is poured on the fluid. Saturated aqueous solution of sulphuretted hydrogen may be preserved in the same manner; but the bottle containing it should be kept in a cool place, and not exposed to direct sunlight.

Analysis of Ferromanganese.—M. Darmstadt.—Ferromanganese is a peculiar variety of iron which contains a large quantity of manganese. The general plan of analysis followed in this instance by the author is the same as that published in Fresenius's last edition of "Qualitative Analysis"; the estimation of the carbon was made by Berzelius's method, dissolving the iron in neutral chloride of copper. The result of the analysis quoted, percentically, is:—Iron, 73·474; manganese, 21·064; cobalt, 0·007; zinc, 0·062; copper, 0·072; lead, 0·011; aluminium, a trace; titanium, 0·011; calcium, 0·175; magnesium, 0·035; arsenicum, 0·001; antimony and tin, 0·030; phosphorus, 0·109; sulphur, a trace; silicium, 0·059; carbon, 4·805.

Separation of Oxide of Uranium from Phosphoric Acid.—M. Reichardt.—The author refers to the separation of phosphoric acid from oxide of uranium where the latter is used in large quantity for the estimation of phosphoric acid. Dissolve the phosphate of uranium in hydrochloric or nitric acids, apply heat, add excess of chloride of iron, and, next, excess of solution of carbonate of soda; wherein, aided especially by the large quantity of carbonic acid which is thus set free, the oxide of uranium is readily dissolved, while the phosphoric acid is combined with the oxide of iron. The solution of oxide of uranium in carbonate of soda is acidified with hydrochloric acid, boiled to expel carbonic acid, and the oxide of uranium next precipitated with ammonia.

Estimation of Organic Matter and Nitric Acid in Well Waters.—M. Reichardt.—This paper is chiefly a review, criticising the value and reliability of a number of methods for the quantitative estimation of organic matter and nitric acid in potable water. From this paper we incidentally learn that the water of the well of the house, No. 42, Gerichtstrasse, Berlin, contains, in 1 litre, 0·675 grm. NO_5. The average of twenty-seven different samples of well-water of Liepzig is 0·346 grm. to the litre. The water of the waterworks of Liepzig contains 11·5 parts of NO_5 in 1,000,000 parts of water.

Modification of the Piknometer.—Dr. Gintl.—Since, without the woodcuts annexed to this paper, its contents could not be clearly understood, we only quote the title.

Estimation of Phosphoric Acid in the shape of Pyrophosphate of Magnesia.—Dr. Kubell.—This paper is a concisely written treatise, divided into two sections—the first of which treats of the solubility of the ammoniacal phosphate of magnesia in water containing ammonia; the other section treats of the precipitate caused, in an ammoniacal solution containing phosphoric acid, by excess of solution of magnesia. This treatise does not admit of suitable and useful condensation.

Changes Albuminates Suffer when they are Submitted to the Action of Water.—Dr. W. Schmidt.—Albumen, prepared from serum of blood, casein, fibrin, and other similar materials, were submitted, in sealed tubes, to the joint action of a high temperature, ranging from 135° to 150°, and water, in order to test the correctness of M. Meissner's statement that these materials yield, when so treated, peptones. This, however, is not the result of the author's researches, which have not brought to light any other results than those generally known on this subject.

Improvement of the Volumetrical Estimation of Copper and Zinc contained in Ores by means of a Standard Solution of Ferrocyanide of Potassium.—M. Galetti.—This paper is reserved for full translation.

Description of an Improved Apparatus for the Evolution of Sulphuretted Hydrogen.—Dr. Seelhorst.—Without the engravings annexed to this paper, it cannot be well understood.

Peculiar Appearance Shown by the Flame of Burning Hydrogen.—Dr. Seelhorst.—The author has repeated Barett's well-known experiments of holding in the flame of burning hydrogen gas very well cleaned glass rods, metals recently cleaned by filing them just previous to the holding in the flame, and has observed the same blue colouration as M. Barett did. But the author is not at all inclined to ascribe this colouration to the effect of burning sulphur, which should be so generally spread about in the shape of some sulphate, as to produce this colouration. The author, though abstaining from stating any precise cause at all, inclines to the belief that the cooling effect of the cold body held in the flame has something to do with this phenomenon. Perfectly pure hydrogen, burning from a platinum burner, as well as from iron or glass burners, exhibited the phenomenon, when cold bodies, just after having been cleaned by scraping or filing, were held in that flame. These experiments were conducted in a laboratory, repeated in a lecture-hall, and in the taproom of a *café* with the same result.

Estimation of Lime and its Separation from Magnesia when Dolomites are to be Analysed.—Dr. A. Cossa.—The author's object has been to determine what the accuracy is of estimating lime as quicklime or caustic lime, instead of weighing it as carbonate of lime. The experiments were made—(1) With pure oxalate of lime previously dried at 100°; (2) with carbonate of lime precipitated from a solution of pure chloride of calcium by means of pure

carbonate of soda; (3) with pure, native carbonate of lime, Iceland spar. The result of an average of three experiments with No. 1 is 0·07 per cent too low; with No. 2, 0·35 per cent too low; with No. 3, 0·27 per cent too high. As regards the analysis of dolomite, the author states that, when care is not taken to re-dissolve the precipitate of oxalate of lime first obtained and re-precipitate this a second time, it is always so contaminated with oxalate of magnesia or ammonio-oxalate of magnesia that the quantity of lime found as carbonate may be 0·62 per cent in excess of what it ought to be, while the loss for carbonate of magnesia may even be as high as 0·78 per cent.

Analysis of Soft Lead.—Dr. Fresenius.—This paper or treatise is an exhaustive monograph on the analysis of refined lead and the estimation therein by volumetrical methods of iron, copper, zinc, antimony, and other metals. This treatise, as might be expected from the eminent author, is as complete as can be desired, but it is too lengthy and too concisely written for useful abstraction.

Comparative Researches on the Estimation of Phosphoric Acid.—M. Kissel.—The author treats on the gravimetrical and volumetrical methods in use for the estimation of this acid. (*a*) Direct estimation as pyrophosphate of magnesia; average result of three carefully conducted experiments, 99·53 per cent; result by the same method, but with the correction required for the solubility of the ammonio-phosphate of magnesia in ammoniacal water, average of three experiments, 100·22 per cent. (*b*) Indirect estimation as pyrophosphate, following a previous precipitation as molybdo-phosphate of ammonia; average result, without correction for solubility of ammonio-phosphate of magnesia, 99·09 per cent, with that correction, 99·79 per cent; estimation (gravimetrical) as phosphate of oxide of uranium; average result, 100·33 per cent; estimation as basic phosphate of iron; average result, 99·68. Volumetrical methods: Average result of four experiments with acetate of oxide of uranium, 100·12 per cent. The author has purposely made a series of experiments in order to ascertain the influence of repeated solution and re-precipitation of the ammonio-phosphate of magnesia, obtained in quantitative research, also the influence of excess of ammoniacal salts and the action of dilute ammonia upon pure ammonio-phosphate of magnesia, the results obtained do not materially differ from what is generally known on this subject and published thereon in works on analytical chemistry.

Application of the Principle of Areometry to Quantitative Chemical Analysis.—Dr. Gintl.—The plan devised by the author is extremely ingenious, and deserves the attention of analysts; but we cannot condense his paper or make the principle even understood without the reproduction of some engravings absolutely necessary for the explanation of the subject.

Detection of Bitter Substances other than Hops in Beer.—M. L. Enders.—In order to separate lupuline from quassiine, absynthiine and menyanthine, the author proceeds as follows:—Alcohol is applied to separate gum, a mixture of strong alcohol and ether to separate sugar from beer; the solution of bitter substances is next treated with acetate of lead; a precipitate ensues which contains lupulin and hop-resin; treat precipitate with H_2S, separate PbS, wash with alcohol, evaporate the filtrates to dryness, exhaust residue with chloroform, and repeat this operation, adding a large quantity of warm water; evaporate chloroform when the hop-resin is left as an insoluble matter in the water, which, after separation of this resin, is also evaporated to dryness; the residue has a bitter taste; exhibits when dissolved in water an acid reaction to test paper; is soluble in alcohol, ether, and chloroform; the weak alcoholic solution is precipitable by acetate of lead, but not by tannic acid; does not give, when treated with ammoniacal silver-solution, a deposit of metallic silver. These characters indicate lupuline. The filtrate from the solution above alluded to is freed by means of H_2S from excess of lead, the sulphide of that metal removed by filtration, the filter washed with hot water, and the filtrate heated in order to expel sulphuretted hydrogen gas; and next, a solution of tannic acid is added; in case a precipitate ensues, it is collected on a filter, some pure carbonate of lead is added to the precipitate while yet wet, and the mass is dried, next boiled with alcohol, the filtrate therefrom evaporated to dryness and exhausted with pure ether. This ethereal solution is evaporated to dryness, the residue is either soluble in alcohol, or in a large quantity of hot water, the aqueous solution is precipitable by means of tannic acid, not by acetate of lead; the precipitate is first mixed with concentrated sulphuric acid, and, on addition of some water, yields a bluish violet colour. The substance boiled with ammoniacal solution of silver yields a metallic mirror: these characteristics indicate absynthiine. The residue insoluble in ether is soluble in alcohol; this solution, after having been diluted with water, is precipitable by tannic acid, not by acetate of lead; the substance, on being heated with ammoniacal solution of silver yields a metallic mirror, indicating menyanthine; absence of metallic mirror indicates quassiine.

Comptes, September 4, 1869.

Origin of the Alkaline Chlorides found in the Water and Rocks of the Coal-Formation of Luijk, Liège (Belgium).—M. Malherbe.—After referring to the doubts existing about the question whether the plants which have given rise to the coal-fields have been submerged by fresh or salt water, or by a mixture of both, the author contends that, as far as the coal-basin above named is concerned, his opinion is that the plants which served to form the coal, were submerged in a mixture of fresh and salt water, since not only the water pumped up from the pits in the locality mentioned contains a large proportion of alkaline chlorides, but the rocks in that part of the country also contain a considerable quantity of these salts. The author's opinion is not shared by the well-known eminent Belgian geologist, M. Omalius d'Halloy, who states that coal has been formed in a similar manner as peat is at the present day, in stagnant fresh water; but the presence of the alkaline chlorides is accounted for, by later irruptions of the sea, and by the many commotions the coal formations have been subject to long after they were formed.

Revue Hebdomadaire de Chimie, September 2, 1869.

This number contains an excellent description of—

The Freezing Apparatus Invented by M. Toselli.—The author applies freezing mixtures made up without the addition of acids, and chiefly prefers the following salts:—Nitrate of ammonia, carbonate of soda, sal-ammoniac, and chloride of potassium, mixed in certain quantities together. The mixture best adapted for his apparatus is made up of equal parts of nitrate of ammonia, carbonate of soda, and water, wherewith a lowering of temperature of −33° can be obtained. Without the reproduction of the woodcuts annexed to this paper, it would be useless to try to describe the apparatus applied by the author, who conducts, at Paris, a business, on a large scale, for the artificial production of ice, and the sale and making of his apparatus and the salts used for the production of cold. According to all accounts, his invention is the best and most applicable of the kind hitherto made.

Les Mondes, September 9, 1869.

The Deepest Artesian Well in the World.—If the American reporter of this periodical is well informed there exists at Saint Louis, U.S., an artesian well, which, as far back as the year 1854, had been bored to a depth of 2199 feet, without reaching water bearing strata. In 1865, the previously suspended borings were resumed, and are yet pushed forward; but though a depth of 2852 feet has been reached, no water bearing strata has been found. The borings now proceed only about three inches depth every day, in compact solid granite, and the cost per month amounts to 1600 dollars.

NOTES AND QUERIES.

Estimating Ammonia.—In answer to the query of "A. Z." (CHEMICAL NEWS, vol. xx., p. 156) respecting a ready commercial method of estimating the percentage of ammonia in sulphate of ammonium, I beg to say that the readiest and most reliable method for this purpose is as follows:—Place a known weight of the salt in a flask fitted with cork and bent tube with bulb (the bend and the bulb are to prevent spirting and carrying over of any caustic liquor by the steam), and, having dissolved in a small quantity of water, distil, with a strong solution of caustic soda, potash, or milk of lime, into a beaker containing a known volume of a titrated solution of hydrochloric acid. The liquid in the flask is boiled till two-thirds are distilled over into the acid, which must be kept cool by immersing the beaker in a vessel of cold water, and keeping a stream of water circulating through the latter during the experiment. The tube is now carefully withdrawn from the acid, still keeping the lamp under the flask, or the contents of the beaker would immediately be sucked back. Just as the tube emerges from the liquid, it is well rinsed with the wash-bottle. The partially-neutralised solution in the beaker is washed out into a basin, tincture of cochineal added, and then the excess of hydrochloric acid is determined at once, in the cold, by means of a sodic carbonate solution of exactly equivalent strength to the hydrochloric acid. The volume of sodic carbonate solution subtracted from that of the hydrochloric acid equals the volume of acid solution required; and the HCl solution should, for the sake of rapidity of working, be so graduated that the number of volumes required should equal the percentage of NH_3 in the salt. If pyrites has been used in the manufacture of vitriol, the vitriol is contaminated with anhydrous persulphate of iron (as a white deposit, which disappears on dilution), and also with a large quantity of arsenic: if, then, iron and a comparatively large quantity of arsenic be found to exist in a sample of vitriol, I think "A. Z." may take it for granted that pyrites has been used in this case. This method is applicable for the estimation of ammonia in any of its salts, providing that these be free from any organic nitrogenous matter. The caustic solutions (potash, soda, or lime-milk) should be well boiled previous to use, and allowed to get quite cold again: this is to free them from all traces of ammonia. In a subsequent communication, I will give the methods for the calculation and construction of volumetric solutions, from which the percentages may be immediately ascertained as being identical with the number of volumes of such volumetric solutions required.—WATSON SMITH, F.C.S., West Gorton, near Manchester, Sept. 27, 1869.

TO CORRESPONDENTS.

Enquirer.—We do not know if Professor Jellett's paper has been published or not.

A Constant Subscriber.—We know of no book treating on the proximate analysis of bodies only, but it is treated of in Watts's "Dictionary" under the word "analysis."

A. B. C.—(1) A new work on Dyeing is in the press; (2) Reimann's work on Aniline, price 10s. 10d., post free from our office; (3) Apply to Professor Calvert, at the Royal Institution, Manchester; (4) Animal mordants will fasten aniline dyes on cotton.

THE CHEMICAL NEWS.

VOL. XX. No. 515.

ON MICROSCOPICAL MANIPULATION.*

By W. T. SUFFOLK, F.R.M.S.

(Continued from p. 159.)

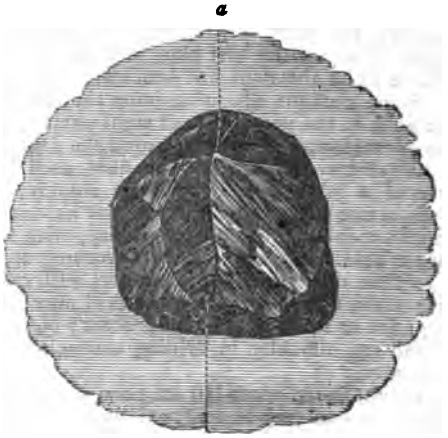
THE subject of the present chapter may be considered rather as mechanical than microscopical; in fact, it relates more to the workshop than to the study. It may, perhaps, seem strange to write about making apparatus and preparing materials in these days when nearly everything can be bought often better and more cheaply than it can be made at home, and when it is not as it was within the memory of many microscopists, who were obliged to cut their glass slides, or, at all events, to order a glazier to make them: but the more dexterous a person is with his fingers the better microscopist he is likely to make. Very often the success of an observation depends upon the observer being able to make some little contrivance to aid his researches, and it is for that purpose that the subject of the mechanics of the microscopical laboratory finds a place here.

The first material that engages the attention is glass. It comes under notice in several forms—the plates of glass upon which objects are mounted, the thin covering glass, and glass tubing. The glass generally used for mounting objects is a description of glass known as patent plate. Crown glass is sometimes used, but patent plate is perhaps the best. It is made from that commonly known by the name of cylinder glass, which is manufactured by the glass being blown, first of all, into a globe, then, by dexterous manipulation on the part of the workman, it is elongated, and a cylinder is formed. This cylinder is ripped up, and put in an annealing oven: it unbends at the slit, and rolls itself out flat. In this state it is known as sheet or flatted glass. The glass then undergoes the same treatment as plate glass. It is ground down and polished, and then it becomes the patent plate. It is a thin glass, with a beautiful surface, so accurately worked that the plates will adhere together if pressed, just as good specimens of ordinary plate.

The tool used for cutting glass is the well-known glazier's diamond. It seems to have nothing in common with ordinary cutting tools: an incision or scratch with a diamond or other instrument, such as a flint or chilled-steel point, will not make the clean fracture we are so familiar with when the cutting diamond is used by a skilled hand. The diamond would seem rather to act by inducing some molecular displacement than by any actual penetrative power that it possesses. This view would seem to be supported by the appearance presented by the glass adjacent to a diamond cut when examined by the microscope with the aid of polarised light, which shows that the glass has been subjected to some kind of strain. Rubies and sapphires, if worked to the form of the natural edges of the diamond crystal, will cut glass, but lose the power when the curved edge wears away. A very interesting paper on the fracture of glass and the action of the diamond, by Mr. F. H. Wenham, will be found in the *Microscopical Transactions* for 1868, p. 105. (See also *Holtzapffel*, "Turning, &c.," vol. i.)

There is some little art in using the cutting diamond: it is not any part of a diamond that will cut. It is very easy, indeed, to scratch with a diamond, but it is only in certain directions that it will make the so-called cut. The glazier's diamond (Fig. 13), when viewed under the binocular microscope, will be found to exhibit a well-defined and slightly curved edge, *a*, *b*. The diamond is carefully set so that this edge (which is a natural crystalline one) lies parallel with the oblong mounting, and, as the diamond requires to be held in an inclined position to secure a clean cut, the top of the setting is always bevelled to the proper angle. It is allowed a little play horizontally on a pivot, so that, upon placing the diamond in contact with a rule, it will always place

FIG. 13.



itself in the cutting direction, and, by keeping the end of the setting parallel with the glass, it will be in a position for cutting. It is then drawn along; and those who have seen a glazier cut glass will remember the curious noise which accompanies the operation—something between a ringing and a hissing: the sound is very different from a scratch. The glass breaks at the place upon being bent. With a little practice, the cutting of glass will be very easy indeed; but it is not worth while, as a general practice, to cut slides, as they can now be bought at a cheap rate: it is chiefly for exceptional purposes that facilities for cutting glass are of value. Sometimes a piece of glass of extra size or unusual shape is required, and then time is often saved by being able to do the work, instead of waiting until the services of a glazier can be obtained.

The other kind of glass employed in mounting objects is the thin glass for covers. The details of its manufacture are unknown to me. It is remarkable for its extreme brittleness. In cutting, the glazier's diamond is not employed, but a splinter known as the writing diamond. The operation is attended with some difficulty, as the glass is

* The substance of a course of lectures delivered to the members of the Quekett Microscopical Club, January—April, 1869.

very likely to crack and star under the diamond. This is best prevented by placing the thin glass to be cut on a piece of wet plate-glass, which affords support, and effectually prevents splitting and cracking. As in the case of the 3×1 slides, it is hardly worth while to cut up squares and circles of thin glass, as it can be easily procured of the opticians already cut into the most useful sizes, or, if required in large quantities, of the wholesale glass warehouses. Of course pieces of unusual sizes and shapes are sometimes required, and then the power of cutting becomes of value.

The writing diamond is also used for making marks and writing on glass. Some persons write the names of their objects on the glass instead of on a label: it has the advantage of durability, but is not so legible as an inscription on paper..

Sometimes it is required to drill a hole in a piece of glass. This is a matter of no very difficult accomplishment. A good hard drill, if it is kept moistened with turpentine, will, with a small amount of patience and labour, eventually work its way through a piece of glass. Care should be taken that the glass rests upon a cork bed, or something soft, but yet firm, to give it sufficient support, or it may break just before the point of the drill makes its way through. Perhaps the best plan is to begin on the other side when the drill has penetrated about halfway. Some persons are of opinion that dilute sulphuric acid, in the proportion of eight parts of water to one of acid, serves for moistening the drill better than turpentine. Of course the fluid used is the reverse of a lubricant: if oil were employed, the drill would not cut. The drills are best hardened by heating to redness and cooling suddenly with strong sulphuric acid. The edge requires working up from time to time upon an Arkansas stone, with oil. In drilling a thick piece of glass, the drill may require setting once or twice during the process; but I have never had any difficulty in drilling through a thick piece of plate.

The rough, sharp edges left on glass after cutting with the diamond may be removed by grinding with fine emery and water upon a smooth paving-stone or thick plate of zinc: the glass-cutters usually employ emery upon a lap or horizontal wheel.

For many cutting processes, tools made of corundum and shellac are very useful; this composition, in the form of wheels, files, hones, &c., of several degrees of fineness, can be obtained of Mr. D. Lyon, 43, S. John's Square, Clerkenwell, E.C. These tools, especially the wheels, are employed by dentists, in cutting and shaping the semi-vitrified porcelain used in the manufacture of artificial teeth. The use of the corundum composition in this country is comparatively recent, although it has been employed for centuries by the native jewellers of India.

Corundum is a crystalline mineral, identical, or nearly so, in composition with the sapphire, ruby, topaz, and amethyst, equally hard, but wanting in transparency and lustre. Emery is nearly similar, but occurs in a granular form, and does not cut so well, although there are many purposes for which it is more serviceable than the harder corundum.

These tools must be plentifully supplied with water when in use, as, unless kept cool, they soon lose their shape, which would be the case if used dry, as they would rapidly heat and melt with the friction of rasping and grinding a hard substance.

Glass plates may be smoothed, and even rounded at the edges, with the greatest ease, with a corundum file, and almost as quickly as brass could be filed. A tapering tool is useful for enlarging a hole drilled in glass; and the hones serve for grinding sections of substances too hard for the ordinary stones. As the material becomes better known, many other uses will, no doubt, be found for it.

Glass is frequently used by the microscopist in another form, that of tube. It is chiefly employed in making the dipping tubes, with which objects such as free swimming animals and deposits in water are taken up, and for the pointed tubes, or pipettes, with which small portions of fluids are removed and deposited where they may be needed. The manufacture of these bent tubes, or pipettes, is not a matter of difficulty. The processes of drawing glass tube to points, and bending, are very frequent in the laboratory. The best source of heat is obtained from the Bunsen burner, which gives a very large flame without smoke and of great heating power by the consumption of a mixture of air and coal gas. It can be obtained of the chemical instrument makers for a very small sum; a spirit lamp, however, will answer the purpose tolerably well if the wick is a large one. A piece of glass tube, in which it is intended to make a bend, should be heated to a slight redness, and then carefully and slowly bent to the required angle. If an attempt is made to bend a tube suddenly, it will produce a choke, or contraction, in the bend. It is also necessary to heat a considerable length of tube. Pieces of glass tube are very easily detached, by making a notch on them with the edge of a file, and they are then sure to break straight across; any length of glass tube can be cut off in this way. The process most frequently required to be performed by the microscopist is the drawing tubes out into pointed ends for pipettes. To effect this, heat the tube in the flame; when the tube has become sufficiently soft, it can be drawn out to any length and fineness you please. The rough edge at the cut ends of tubing may be taken off by heating the ends in the flame, which will melt the edges and leave them rounded. This rounding of the edges is, perhaps, effected more rapidly by using a blowpipe, which facilitates the fusion of the glass. Sometimes a pipette curved as well as pointed is required; there are many purposes for which it is extremely useful. This is easily made by a little variation of the other process; while it is being drawn out, give it a skilful bend at the proper moment. Always keep tubes of glass revolving while they are being heated, and do not heat them more than is absolutely necessary, as, when the tube is made very hot, it is extremely pliable, and likely to lose its shape. With a little ingenuity a number of useful things may be made out of glass tube. A variety of these pipettes will be found useful, and they are rather expensive to buy.

Glass, whether in the form of slides or thin glass, always requires cleaning. The best cleaning fluid is methylated spirit, which, as it is not subject to duty, and can be obtained cheaply, may be made free use of for this and nearly all the operations of the microscopist in which strong alcohol is required. Care must, however, be taken to obtain pure methylated spirit, and not what is commonly known as "methylated finish," which contains a small portion of shellac in solution, and is quite useless for all microscopical and laboratory purposes, and which is not unfrequently sold when methylated spirit is enquired for.

I am indebted to the Rev. J. B. Reade for the history of this adulteration. Formerly, methylated alcohol was allowed to be sold without a licence; but certain persons, finding that it was cheap, and not being particular about the flavour of methylic ether, used it for making grog. This fact coming to the knowledge of the excise authorities, its sale by unlicensed dealers was prohibited, unless containing shellac in solution, a mixture which would not spoil it for its chief use, that of varnish making, while, upon mixture with water, the gum would be precipitated, making a very disagreeable turbid compound. There is no difficulty in obtaining pure methylated alcohol in large towns, where one or more licensed dealers are generally to be found. It can be obtained perfectly pure, either in large or small quantities, of Messrs. Jackson and Townson, Bishopsgate Street, and of most other dealers in chemicals. It should not leave any residue upon evaporation, or become turbid when mixed with water; any spirit having these defects should not be used for microscopical purposes.

Great care should be taken that the cloths used for cleaning glass be perfectly free from soap or dirt, otherwise they will leave the surfaces of the slide covered with striæ. Old linen, or cotton cloths, are to be preferred to new ones; they should, before use, be boiled in water and common washing soda, to remove all soap left from former washings. They are then to be washed several times in clean water, until all trace of the soda is removed, and then dried, but not ironed, as the rough fluffy condition they will be left in is extremely favorable for cleaning glass. After the spirit is cleaned off with the cloth, any fibres that may be left from the cloth should be removed with a soft wash-leather.

Thin cover glass is treated in a similar manner, but, on account of its excessive brittleness, requires great care in cleaning. After a little practice, it is quite easy to rub it with the cloth and leather between the thumb and finger; but, should any difficulty be experienced, which may be the case with the thinnest kinds, it will be found that it can be rubbed with considerable force, without injury, between two discs of wood covered with wash-leather. The great thing in rubbing a brittle substance is to support it well behind; this is the whole secret of cleaning thin glass between the finger and thumb.

For joining together pieces of glass, and for attaching metal to glass, the cement known as marine glue is usually employed. It consists of india-rubber, shellac, and coal naphtha, combined in various proportions, according to the purpose for which it is intended to be used. It is, I believe, difficult to make in small quantities; but there is no trouble in obtaining it, as it is sold by most microscope makers. As this cement will only adhere to hot surfaces, it is necessary to have some means of applying a steady heat to the pieces of glass, &c., to be joined; and as this cannot be done by means of the unprotected flame of a lamp, a hot-plate is generally employed. This can be obtained, ready made, of the opticians; but a piece of thick brass plate, about 6 or 7 inches long and 2 inches wide, placed upon one of the rings of a retort stand, will answer admirably; it can be heated by means of a spirit lamp or gas flame placed underneath. Supposing, for example, it is required to attach a ring of glass or metal to a glass slide, to form a cell for an object to be mounted in. The glass slide is placed upon the hot-plate, first of all, at the part most distant from the lamp, to avoid breaking it by too sudden heating, and then moved gradually to the hotter part; the ring is also heated on the plate, a piece of marine glue is held on the point of a needle in a handle, or other convenient holder, and rubbed on the heated glass over the surface to which the ring is to be attached. When a sufficient portion of glue is melted on the glass, care being taken to heat the glue sufficiently for free working, while overheating amounting to boiling is to be avoided, the heated ring is then lifted on with a pair of forceps, which, for this and all purposes where they are likely to be made hot, should be of brass, or else an old pair of steel forceps, which are to be kept for such uses. The ring is then to be turned round backwards and forwards on the glass, to spead the cement equally, and then removed from the hot-plate and pressed on a piece of wood, to expel superfluous glue, and allowed a little time to set; when set, but still warm, the greater part of the cement can be scraped off with a blunt knife, a process much more difficult if it is allowed to become quite cold. A number of cells can be attached and roughly cleaned at one time, the plate next required being heated while the one cemented is being cleaned off. When quite cold, the slides can be thoroughly cleaned with a piece of rag and a free use of methylated spirit; they should then be rubbed bright with a clean cloth. Some persons use liquor potassæ for cleaning off superfluous marine glue; it does this very effectually, but not so rapidly as strong alcohol, and the operation is a rather unpleasant one, as the alkaline solution first softens, and then removes the skin from the fingers.

The adhesion of marine glue, and other cements, to glass surfaces, is much improved by grinding, which gives the cement a better hold than it would have on a polished surface, although marine glue will adhere well to polished glass, provided the surface is free from grease, which may be insured by a cleaning with methylated spirit. The adhesion of two pieces of glass cemented with marine glue is so perfect that they generally break in any place rather than at the joint.

(To be continued.)

ON THE

SOLVENT TREATMENT OF URIC ACID CALCULUS

AND THE

QUANTITATIVE DETERMINATION OF URIC ACID IN URINE.*

By the Rev. W. V. HARCOURT.

WHEN the British Association met at Manchester in 1861, Dr. Roberts, Physician to the Royal Infirmary of that city, communicated a paper respecting "The Power of Strong and Weak Solutions of the Alkaline Carbonates on Uric Acid Calculi,"† in which he showed the fallacy of the experiments supposed to have proved their inefficacy in a report formerly made to the French Academy by MM. Gay Lussac and Pelouze.

Dr. Roberts found that solutions of the carbonated alkalies containing more than 120 grains of the salt in a pint of water arrested their own action by forming an

* Read before the British Association, Exeter meeting, Section B.
† "Report of the British Association, Manchester, 1861," p. 90.

insoluble crust of biurate on the calculus, and that the maximum of solvent power lay in solutions which contain 50 or 60 grains in the pint. At this strength, no incrustation was formed when the carbonate of potash was employed; and 21·4 grains per cent of the weight of the calculus were removed by a flow over it of 6 pints in twenty-four hours. The carbonate of soda followed the same general course, with inferior efficacy.

In 1865, Dr. Roberts communicated to the Royal Medical and Chirurgical Society of London* a paper in which he showed, by a series of well-devised experiments, how this discovery might be applied, with a reasonable prospect of advantage, to medical practice; and laid, for the first time, a scientific basis for attempts hitherto empirical and contradictory at dissolving the stone. The most remarkable of these experiments was that in which he passed the urine of a patient who was taking citrate of potash at the rate of 40 grains in 5 ounces of water every two hours over a fragment of uric calculus, and, by this process, reduced it in twelve hours from 180·5 to 174 grains, or at the rate, in twenty-four hours, of 13 grains.

In July, 1868, I was made aware, by an eminent surgeon, Mr. Spencer Wells, of the presence of a stone in the bladder, one diameter of which appeared to measure 1½ inches; and I was advised by Mr. Wells (and by Sir H. Thompson, who confirmed his opinion as to the size of the stone), to aim at preventing its enlargement by such doses of citrate of potash as might keep the urine in a state approaching neutrality. In conversation with my excellent friend, the late Mr. Hodgson, who, when surgeon to the Birmingham Hospital, had had great experience in this complaint, I learned that he had met with so much success in the application of an empirical medicine of much celebrity, manufactured in that neighbourhood, and consisting of carbonates of potash, that, in any case of uric acid calculus, he would advise the experiment of its administration.

Mr. Wells afterwards drew my attention to the experiments of Dr. Roberts, which appeared so satisfactory that I determined to make trial of his method of treatment, and to ascertain, if possible, by chemical analysis, the excess of uric acid above the normal quantity contained in the urine which it might be considered as removing from the calculus.

I felt the great importance of the inquiry, and had the advantages of more than ordinary leisure, a long familiarity with chemistry, a well-furnished laboratory, and an assistant in executing the experiments on whose accuracy I could fully rely.†

I will now proceed to lay before the Section a short abstract of the chief results which I have obtained from an unintermitted course of careful experiments on all the urine voided during the past twelve months, some of which will be found of value to future experimenters, though, from causes which I shall describe, they have not realised all my expectations. If, as I had supposed, there had been any known chemical method of determining, with a near approach to accuracy, the amount of uric acid in urine, then the quantities of that acid which Dr. Roberts had found to be removed from calculi out of the body were abundantly sufficient to be ascertained by analysis, on the supposition that the same process went on in the bladder under the treatment recommended by him. I had scarcely, however, commenced my course of experiments before I became convinced of the fallibility of the methods in use for separating uric acid; and the experiments which I have to describe will place that fallibility in a strong point of view.

The method first employed was the ordinary one of adding 5 per cent of hydrochloric acid, allowing the mixture to stand forty-eight hours, and then, after decantation, collecting the uric acid on a small filter, washing it with distilled water, and drying it at 212° F. till it ceased to lose weight. The first seven determinations, from the 20th of August, 1868, to the 26th, inclusive, were made each day on the urine of the preceding twenty-four hours, in a neutral or slightly alkaline state, brought to that state by doses of from 120 to 165 grains of citrate of potash. The quantities of uric acid obtained varied from 11·08 to 8·43 grains. In the subsequent daily determinations, down to the 5th of September, acid reactions were interpolated, due to the use of smaller alkaline doses, which lowered, proportionably, the amount of uric acid obtained; and, when no alkali had been taken for two days, and the urine was, in consequence, strongly acid, the quantity of uric acid found was only 2·35 grains.

From this time commenced a course of large quantities of citrate of potash, amounting, during fourteen days, to 315 grains in twenty-four hours, taken in a state of effervescence, in doses of 45 grains, dissolved in 3 fluid ounces of water. For ten of these days, the hydrochloric acid was used to precipitate the uric acid; and the determination of this gave from 11·95 to 6·00 grains. In every case but the last, the whole urine of the twenty-four hours had been used; but, in the last, half was treated with hydrochloric acid, and the other half with the same proportion of nitric acid: that treated with the former acid gave 6·42 grains, while that with the nitric acid gave only 1·97 grains. On the following day, half the urine was treated by Lehmann's process, and gave 6·40 grains; half with nitric acid and acetic acid, in equal proportions, which gave 4·09 grains uric acid. The preference, however, assigned by Dr. Thudichum, in his able and well-known treatise on the "Pathology of the Urine," to nitric over hydrochloric acid as having given him better results led me to continue its use.

The quantity of citrate of potash taken was then raised to 350 grains for four consecutive days. On the first of these days, the uric acid found was 1·54 grains; on the second, 1·23 grains. These results were so extraordinary that, for the purpose of corroborating them, or discovering an error in the analysis, I sent 40 fluid ounces out of 61 fluid ounces voided on the latter day to Dr. Thudicum, who was so good as to furnish me with his analysis of it, containing the weights of sulphuric acid, phosphoric acid, chlorine, potash, urea, and uric acid which he had obtained. The uric acid amounted to no more than 0·775 grains.

This result led to one of two conclusions. Either independently of any question of the solution of the calculus the presence of uric acid in the bladder had been almost entirely prevented by the alkaline treatment, or the process for obtaining it was altogether unreliable. Taking the latter alternative as far the more probable, I endeavoured henceforward to improve the analysis. The mucus secreted from the bladder by the alkaline action being now a good deal in excess, I was advised that it would be prudent to diminish the quantity of alkali taken; and it was accordingly reduced, for five days, to 300 grains of the citrate, and, for eight days, to quantities varying from 270 to 240 grains. The alkalinity was now determined for every voiding with hydrochloric acid. 2·5 per cent of that acid was added to each; and, as it had been observed that uric acid was lost by decantation, however careful, the portions of urine operated upon were entirely filtered, and the water with which the precipitates were washed was acidified with acetic acid. Under this treatment, on the fifth day of taking 300 grains of citrate, the alkalinity, measured by a standard solution of hydrochloric acid, and estimated in grains of carbonate of potash, was 25·5 grains per pint. The uric acid obtained weighed 4·74 grains; and the series below 300 grains of citrate gave quantities of uric acid varying from 2·91 grains, the alkalinity being 23·05 grains per pint, to 8·42 grains, the alkalinity being 17·2 grains per pint.

One-half of that which, with 2·5 per cent hydrochloric

* *Medico-Chirurgical Transactions*, vol. xlviii., p. 89.

† My assistant, Mr. W^m P. Horn, learned, in Sir Benjamin Brodie's School of Chemistry, in Oxford, those habits of precision in manipulating and accuracy in observing which are essential to chemical experiments.

acid, had yielded 8·42 grains was treated with 5 per cent nitric acid, and kept at the temperature of 90° F.; and, to render the experiment analogous to Dr. Thudichum's analysis, the alkalinity and dilution were brought to a similar standard by additions of carbonate of potash and water. The uric acid thus obtained weighed 2·07 grains, showing a loss, by this method, of 6·35 grains.

The following table contains an account of the uric acid obtained on the thirty-five days from October 9th to November 12th, inclusive, as well as of the potash taken, and the quantity and alkalinity of the urine.

Citrate of potash.	Alkali, per pint.	Uric acid.	Urine voided, in ounces.
220	16·3	6·9	51·4
20	16·8	5·6	46·6
10	22·1	8·1	40·6
255	4·2	12·2	49·7
240	19·1	7·9	47·1
240	21·3	10·6	50·7
240	30·9	9·3	55·1
225	20·0	8·4	51·9
260	36·2	6·4	46·4
270	19·5	5·5	59·0
230	18·4	6·5	56·5
240	16·8	9·1	60·7
270	22·6	7·1	53·5
270	29·0	6·6	63·5
255	27·5	8·4	59·7
285	35·4	3·23	62·5
255	40·3	7·1	52·0
240	29·4	9·6	52·0
240	19·8	8·8	52·9
225	23·3	8·7	60·3
140	10·0	11·9	64·7
140	5·0	5·1	57·2
120	1·4	4·9	44·0
120	4·2	6·4	45·0
25	5·2	7·8	51·5
185	7·6	8·4	52·5
225	26·3	7·3	51·5
210	17·4	9·7	61·9
210	22·0	7·3	64·5
210	16·4	8·3	76·4
210	19·2	8·5	42·5
210	19·5	9·4	51·4
210	19·8	9·9	63·5
195	21·3	7·6	53·5
180	21·2	11·6	55·5

In this table, the highest quantity of uric acid, 12·2 grains, is connected with an alkalinity of 4·2, while the lowest quantity, 3·2, was obtained when the alkalinity was as high as 35·4. Twenty days, in which the alkalinity of twenty-four hours varied from 19·2 to 40·3, gave an average of 7·94 grains; whilst fifteen days, when the alkalinity was from 19·1 down to 1·4, gave an average of 8·08 grains. These data would lead to the supposition that the alkali had exercised no action on the calculus; but, on the other hand, the great and sudden rise of the uric acid, when the alkalinity descended from 22·1 to 4·2, might raise a suspicion that the alkaline treatment may reduce the secretion of uric acid, and, in that case, the absence of solvent action cannot be inferred.

A good deal of blood passed with the urine from the 13th to the 16th of November, accompanied with some diarrhœa and sickness. On the 17th, the determination of the uric acid was resumed; the alkalinity on that day being 5·3; the uric acid was 11·55 grains. On the following day, the acidity being 10·8, the uric acid was 10·38 grains.

I now instituted some new experiments, on the effect which different degrees of dilution in urine produce on the separation of uric acid. On November 19th, 40 grains of citrate of potash having been taken, the urine voided in twenty-four hours amounted to 31 fluid ounces; it was neutral; the sp. gr. was 1·032. It was divided into three equal portions, one-third in the natural condition treated in the usual manner with 2·5 per cent. Hydrochloric acid gave uric acid at the rate, for twenty-four hours, of 11·78 grains; one-third, diluted with its own bulk of water, and of sp. gr. 1·022, treated in like manner, gave uric acid 10·99 grains; one-third, evaporated down to half its bulk, and then heated with the same quantity of hydrochloric acid, gave, uric acid, 13·81 grains. November 22nd. 180 grains of citrate having been taken, the alkalinity being 1·96, and the sp. gr. 1·030, the urine for the twenty-four hours, amounting to 41·5 fluid ounces, was divided into two portions, one of which, in the natural condition, gave 12·32 grains, the other, concentrated to one third, sp. gr. 1·070, gave 14·78 grains of uric acid. On the 23rd, the same quantity of citrate being taken, the alkalinity, 18·05, sp. gr. 1·028, the quantity of urine, 42 fluid ounces, one-half in the natural condition, gave 12·72; the other half, concentrated to one-fourth, sp. gr. 1·072, gave 14·94 grains of uric acid. On the 24th, the same quantity of citrate being taken, the alkalinity, 20·4, sp. gr. 1·030, the quantity of urine 35 fluid ounces; one-half, in the natural condition, gave 10·318; the other half, concentrated to one-fourth, sp. gr. 1·074, gave 12·135 grains of uric acid. On the 25th, the same quantity of citrate being taken, the alkalinity, 21·2, sp. gr. 1·031, the quantity of urine 43 fluid ounces; one-half, in the natural condition, gave 9·94 grains; the other half, concentrated to one-fourth, sp. gr. 1·075, gave 11·02 grains of uric acid. Again, on the 30th, 155 grains of citrate having been taken, the alkalinity, 37·6, the quantity of urine, 40 fluid ounces; one-half, in the natural condition, gave 8·53; the other half, concentrated to one-third its bulk, gave 12·66 grains of uric acid.

These give very nearly the two extremes of difference in forty comparative experiments, in the last fifteen of which the urine was reduced to a standard volume of 6 or 3 fluid ounces, according as half or quarter of the urine was employed; the average difference in these fifteen was 3·03, and in the former twenty-five, reduced to the proportions above described, 3·09 grains. What was the cause of the variation in the differences does not appear; it occurred equally, whether the urine was acid or considerably alkaline.

It follows, I think, from these experiments, that, to any average quantity of uric acid obtained from an unconcentrated urine, 3 grains may be added; and the last experiment described in this paper makes it probable that the employment of a better method of analysis may increase this augmentation.

I was not satisfied, however, that sufficient accuracy of analysis had yet been obtained, and I have since employed the following process, which promises more perfect results:—A fourth of the urine of twenty-four hours is evaporated to 3 fluid ounces; it is treated with a mixture of hydrochloric acid and alcohol in equal parts, each being 2·5 per cent of the quantity of urine employed; it is allowed to stand for forty-eight hours, drained on a small filter, washed with alcohol (methylated spirit), and then with equal parts of acetic acid and water. The colouring matter and phosphates, &c., are thus removed, and the uric acid is of a light colour and perfectly, though confusedly, crystalline.

The advantage which this method possesses over those heretofore in use is shown in the experiment which follows:—In urine having an acidity of 5 grains per pint, the nitric acid method of Dr. Thudichum gave 1·16 grains of impure uric acid; the ordinary hydrochloric acid method gave 5·53 grains; the method above described gave 9·90 grs. of uric acid. I have found this method equally effective in the treatment of acid urine neutralised by potash, and am inclined to believe that it might be not less applicable to that which contains a greater amount of chloride of potassium.

On the whole, these experiments, though they have failed to realise my expectation of testing, by analysis, the effect of Dr. Roberts's solvent treatment on vesical

calculus, may serve to point out to others the road to success in such an attempt; and if they do so, the labour of a twelvemonth will not have been spent in vain.

There is one prominent chemical fact attending these experiments which remains to be noticed—viz., the greater amount of uric acid obtained before the alkaline treatment commenced, than in the last experiment by the same process, in the proportion of 9·56 to 5·53 grains. A similar diminution has taken place in the mineral acids; whilst from 120 to 150 grains of citrate of potash were required for neutrality in August, 1868, in March and April, 1869, from 30 to 60 grains sufficed for the same purpose. Dr. Thudichum's analysis, in September, 1868, gave—of sulphuric acid, 51·1 grains, of phosphoric, 45·7 grains. The analysis made in my laboratory, in March, 1869, gave—sulphuric acid, 25·9, of phosphoric, 34·2 grains, a difference scarcely to be accounted for without reference to the alkaline treatment undergone in the first three months of the interval.

Though I have been unable to produce any *chemical* evidence in favour of the solvent treatment, a fact observed during the whole course of that treatment, and not afterwards, persuades me that a solvent action was really going on. This fact consisted in a small amount of constant deposit, in which fragmentary particles of uric acid were discerned by the microscope, enveloped in mucus, and bearing, in the opinion of Mr. Wells, as well as my assistant, a close resemblance to the detritus left by the incomplete action of carbonate of potash on fragments of uric acid calculi. I suppose these to have been washed out of the bladder in consequence of a partial solution. That no such solution should have been brought into evidence by the many determinations of uric acid, however imperfect, which I have here described, if it cannot be fully accounted for by that imperfection, may possibly be due to a physiological effect of the alkaline treatment in preventing the formation of uric acid, which may have counterbalanced the excess expected from solution of the calculus. This point, a course of experiments which need not be very long, conducted by a process of analysis reliable within a tenth part of the weight of uric acid obtained, ought hereafter to determine.

My experience of the effect of doses of 300 grains of citrate of potash taken in twenty-four hours has convinced me that no disadvantage to health need be dreaded from such a course. I have not suffered so much from dyspepsia during the last twelvemonth as in many former years. Bleeding from the bladder has, indeed, supervened twice, but without any pain or irritation, and I have had no other symptom of the complaint; and this is the experience of a man of eighty years of age, who has been for some years an invalid.

PS. I have omitted to state that the calculus was judged to be uric from the previous passage of crystals of uric acid. Since the alkaline treatment, the urine has been perfectly clear, free from all deposits. It was never ammoniacal when voided, and contained no albumen.

ON SOME

REACTIONS OF CHLOROSULPHURIC ACID.*

By JAMES DEWAR, F.R.S.E., and GEORGE CRANSTON, Edinburgh.

During the course of several experiments on the action of chlorosulphuric acid on phenol, we have noticed one or two decompositions with simple carbon compounds that may be of some interest. Since Kekulé's researches on the phenol sulpho-acids, chemists are agreed that, in these acids, the radical HSO_3 functions as a monadic group. It was but natural to expect that, if we substituted chlorosulphuric acid for sulphuric acid in forming these compounds, we should arrive at similar bodies, with this difference, that, in the one case, we should eliminate the hydrogen of the group acted on as water, and, in the other, as hydrochloric acid. Now, a critical examination of recent researches in the aromatic derivatives shows that certain groups or elements used as substituting agents tend to approach or separate, thereby producing isomeric compounds: for instance, Korner's celebrated synthesis of resorcine starts from dinitrobenzine, where the relative position of the two NO_2's is maintained throughout the number of complex compounds through which this chemist passed in order to replace the NO_2's by hydroxyls. But, if we examine the intermediate compounds produced, it is evident that, if we could change the conditions or modify the relations of the substituting groups, we might arrive at the same products by direct substitution. Thus the dionitrobenzine produced in the second stage of the fore-mentioned synthesis might be made directly if we could form nitro compounds by some reagent other than nitric acid. The experience we possess at the present time is too meagre to admit of any attempted prediction of what would be the effect of substituting the same radical from different sources.

It was our intention to have investigated one reaction from this point of view, and we chose, for this purpose, an examination of the sulpho acid, or acids that would be produced by the action of chlorosulphuric acid on phenol, as compared with the sulpho acids produced when sulphuric acid is used. We were engaged in this direction when Engelhardt published his interesting paper bearing on this point. We have, however, noticed one or two reactions of this substance that may be acceptable at the present time.

The chlorosulphuric acid used in this investigation was prepared by the direct action of sulphuric acid on hydrochloric acid. We found the reaction to go with great ease and rapidity, the temperature of the sulphuric acid, containing a large percentage of sulphuric anhydride, rising to 120° C. The substance had all the properties ascribed to it by Williamson. In our first experiments, we attempted to prepare the acid by acting on sulphuric acid with pentachloride of phosphorus, as described by Williamson. We found it impossible to free the chlorosulphuric acid completely from oxychloride of phosphorus.

We attempted the formation of Kolbe's trichlormethylsulphurous acid by the action of chlorosulphuric acid on chloroform, expecting $CHCl_3+Cl(HSO_3)=CCl_3(HSO_3)$. We found that, when equivalent quantities of chlorosulphuric acid and chloroform were heated in a sealed tube to 120° C., instead of obtaining Kolbe's acid, we got the decomposition products of this acid—sulphurous acid, hydrochloric acid, and chlorocarbonic acid, thus—$CCl_3(HSO_3)=CCl_2O+HCl+SO_2$. The pressure in the tubes being so enormous, we found them extremely liable to burst. No doubt tetrachloride of carbon would give a similar decomposition, with the difference that SO_2Cl_2 would be produced simultaneously. This reaction is interesting, as Schutzenberger has just shown the formation of phosgene gas by the action of sulphuric anhydride on tetrachloride of carbon.

We have examined, also, the action of chlorosulphuric acid on bisulphide of carbon. When equivalent quantities of chlorosulphuric acid and bisulphide of carbon were heated in a sealed tube to 100° C. for some hours, we found the non-miscible liquids changed into a clear, mobile liquid, from which had deposited large yellow crystals of sulphur. The tubes, when carefully opened, continued to evolve gas until the whole of the mobile liquid disappeared: the liquid was condensed sulphurous acid. The gas was collected over water, when a large quantity was rapidly absorbed. The gas not absorbed after it had stood for some time over water we have carefully examined, and found to have all the properties of oxysulphide of carbon. This reaction is interesting as showing the formation of oxysulphide of carbon by direct

* Read before the British Association, Exeter meeting, Section B.

substitution of sulphur in bisulphide of carbon by oxygen. The reaction is evidently—

$$CSS + Cl(HSO_3) = CSO + HCl + SO_2.$$

Probably the reaction would succeed better by the action of sulphuric anhydride on bisulphide of carbon. In this case, the pressure in the tubes would be greatly diminished by evading the presence of the hydrochloric acid gas. Lautenberg has recently shown the formation of oxysulphide of carbon in many reactions; and this is another instance in which it is produced.

THE PREPARATION OF SESQUICHLORIDE OF CARBON.

By H. BASSETT, Esq.

THE vapour of tetrachloride of carbon is passed moderately slowly through a glass tube about 30 inches long, kept at a moderate red heat. The end of the tube fits into a quilled receiver, provided with a tube to carry off the excess of chlorine. The liquid condensed is dark yellow, from the chlorine held in solution, and consists of sesquichloride of carbon, C_2Cl_6, and the liquid chloride, C_2Cl_4, with unaltered tetrachloride. It also contains a very small quantity of the chloride C_6Cl_6.

On exposing this liquid to a good light, the excess of chlorine is absorbed by the C_2Cl_4. It is then distilled with a thermometer. When the temperature has risen to 150°—160°, the residue in the retort consists almost entirely of C_2Cl_6, retaining the trace of C_6Cl_6 and a little impurity, which gives it rather a dark colour. It is poured out into a dish, when it soon becomes solid, and may be purified by crystallisation, or by distillation with the vapour of water. The distillate under 160° is then saturated with chlorine in a good light, when the whole of the C_2Cl_4 is converted into perfectly white C_2Cl_6, which is easily separated from the unaltered CCl_4 by distillation.

In this manner there would be no difficulty in preparing the sesquichloride in any quantity.

ON A VERY CONVENIENT METHOD OF ASCERTAINING THE CONSTITUTION OF FLAMES.

By M. L. DUFOUR.

M. DUFOUR recommends the following process for demonstrating, for instance, that the flame of a candle is formed of a hollow cone, luminous on the outside only, and dark in the interior. For this purpose it is necessary to cut the flame; the most preferable method of doing this is by means of a sheet of water or air. The arrangement is as follows:—A caoutchouc tube has, at one of its extremities, a gas jet, such as is used for common gas flames; this jet has an almost semicircular slit of 0·4 m.m. in depth. The other end of the tube communicates with a reservoir of water placed at a convenient height. Upon a suitable pressure, the water flows out by the slit in the jet, producing a clear sheet capable of preserving, for a sufficient length of time, an invariable form and size. The slit is placed in such a manner that the sheet presents a horizontal surface; and this will easily cut the flame of a candle, showing a perfect section. The hot gases and carbonaceous particles are carried off by the water. On placing the eye above the hollow cone, the luminous wall, &c., can be distinctly seen. Sections may easily be made near the wick or near the point; nothing hinders observation, which may be prolonged at pleasure, and a lens may be used if desired. A flame of gas may be cut and examined in the same manner, but the current of gas must not be strong enough to traverse the sheet of water. If a current of air be caused to come out of the slit by bellows, an invisible sheet of air is formed which is, also, very convenient for making a section of flame. Close observation is quite possible; for the aërial current prevents the heated gases from reaching the eyes, and a lens may be used, as in the former case. The flame forms a cone, whose luminous walls are extremely thin, and their interior can be plainly seen. A platinum wire may be introduced across the section; and, on being plunged as far as the wick, it will remain unreddened in the dark interior of the cone.

A jet of gas issuing from a circular opening, of from 1 to 2 m.m. in diameter, may also be cut very conveniently by the sheet of air. It will be seen to consist of a cone whose walls are brilliant and extremely thin. Upon bringing the sheet of air close to the aperture whence the gas escapes, the flame will be divided at its base and will reappear a little higher. By this means, the entire length of the luminous cone, its thin walls, and their interior may be examined.

If a jet of gas produced by a fan-tail burner be cut, the luminous fan will be found to consist of two brilliant blades, between which there is a narrow obscure space. The blades are at a greater distance apart, and the dark space is wider towards the end of the fantails; and, by assuming a suitable position, it is easy to see through the section of flame into the dark space which separates the brilliant walls, and at the end of this will be seen the slit by which the gas escapes.

Instead of throwing the sheet of air perpendicularly to the flame, M. Dufour thinks it better to throw it partly on one side, on such a plane as to make a slight angle with the axis of the conical flame, or with the plane of the fan-shaped flame. A lateral suction is then produced by the influence of the current, which draws the flame, and inclines it against the sheet of air, by which it is cut. By placing the sheet of air on a more or less inclined plane, and approaching or removing it from the base of the flame, the section is easily made at points more or less distant from that base.

The method described above may, of course, be applied to any kind of flame. M. Dufour suggests that it might be of service in the chemical analysis of flames. When a flame is cut by a sheet of water, the water draws off the gases of which it is composed. If the section be made with a sheet of air, it will be easy, by placing suction pipes throughout the length, and ending at fixed points in the interior of the cone, to collect the gases whose composition is desired to be ascertained.—*Les Mondes.*

THE ECONOMICAL PURIFICATION OF ZINC CONTAINING IRON.

By W. H. CHANDLER.

IN the galvanising of iron, the article to be galvanised, after being thoroughly cleansed, is dipped into a kettle of molten zinc, which forms an alloy with the iron at the surface of contact, and by repeating the dipping the thickness of the superimposed zinc may be increased at pleasure. In the prosecution of this manufacture, the zinc is held in large iron troughs or kettles, which are rapidly corroded in those portions nearest the fire. An alloy of zinc and iron is formed, to which also the articles, being galvanised, in some degree contribute. This alloy being heavier than the purer zinc, sinks to the bottom, and, from time to time, is removed by perforated ladles.

The composition of the alloy is of course somewhat variable, depending upon the temperature and fluidity of the zinc and the careful straining from the fluid metal.

The two analyses here given were made by the writer a number of years since:—

Zinc	94·27	94·15
Iron	5·46	5·00
Lead	0·27	0·56
Tin	trace	0·29
	100·00	100·00

These samples were taken from a re-melting of a large quantity of the alloy, which is the only practicable method of obtaining a fair, average specimen.

The quantity of this dross or refuse is quite considerable, amounting probably, in the United States, to several hundred tons per annum. Formerly it was sold for use in coarse brass castings, and to some extent it was re-distilled. At one establishment in Boston circular clay retorts, similar to those in use in the gas manufacture, were employed, the molten alloy being introduced through an inverted syphon in the iron mouthpiece and the condensing tube, connected with the reverse end of the retort, dipping in a pot of molten zinc; thus all access of air to the interior of the retort was prevented, and little or no oxidation of the zinc occurred.

Several years since, a small lot of this refuse zinc was received at a metallurgical establishment in Massachusetts, in which the writer was employed as chemist, and, in experimenting upon it, one of the foremen of the establishment originated a method by which the zinc could be obtained quite free from iron. Finally, after re-building his furnaces and in various ways altering and modifying his manipulations, the samples of purified zinc being analysed after each alteration of the process, a good commercial article was obtained containing only one-tenth of one per cent of iron.

The process consists in melting the refuse in an iron kettle, raising the heat nearly to the point of volatilisation of the zinc, and then, by a proper regulation of the heat, cooling the mass slowly from the bottom, by means of a special arrangement of flues. An alloy of zinc and iron, containing a much larger percentage of iron than the original refuse, gradually forms, falls to the bottom of the kettle, and is removed by a perforated ladle, while the fluid metal is much purer. The quantity of alloy to be ladled out depends upon the impurity of the original refuse. The purified zinc and the concentrated impurity are melted in separate kettles, and each treated as in the first operation.

One more fusion and refrigeration of the purified zinc and the still more impure zinc, render the former a good commercial spelter and the latter too impure for further economic treatment.

This process is the reverse in its reactions from Pattison's process for desilverising silver-lead ores. In the latter case the purer lead crystallises from the more fluid lead and silver, whereas in the former, the more impure alloy separates from the purified zinc.

The residue from this process, which is sold for distillation, consists of hexagonal prismatic crystals of a fixed alloy of iron and zinc, loosely agglomerated together so as to crumble in the hand.

When the operation of refining is badly conducted, more or less zinc acts as a solder for the crystals. They are beautifully iridescent, exhibiting all the colours of the rainbow, owing to a surface oxidation. A number of specimens of various colours were selected for analysis and showed a composition of—

Zinc	90·50
Iron	9·50
	100·00

Upon fusing these crystals, which requires a high temperature, and cooling as before, a small percentage of purified zinc is obtained, and an alloy containing as much as 12½ per cent of iron. This is compact, somewhat brittle, and exhibits no evidences of crystallisation.

This last-mentioned fusion is not made in practice, as the great heat required for its accomplishment rapidly burns out the iron kettles.

By a similar process lead has been removed from zinc with great accuracy, the amount obtained closely approaching the quantity therein. From a lot of Silesian spelter was separated lead perfectly malleable, and containing scarcely a trace of zinc. The purification of the lead, obtained from the process of desilverisation of silver-lead by means of zinc, could undoubtedly be accomplished by a modification of this process.

NOTICES OF BOOKS.

On Fresh Meat Preservation. By John Gamgee. London: Robert Hardwicke. 1869.

We have, in a pamphlet bearing the above title, an address delivered by Mr. Gamgee before the Board of Agriculture of Amherst (Massachusetts), on a mode of preserving meats for an indefinite time. After many trials, the process which was found to act best was the exhaustion of air from the vessel containing the meat to be preserved, and the introduction of various vapours. Among other substances, the following were tried:—Ozone, chloroform, ether, tetrachloride of carbon, bichloride of methylene, carbolic acid, chlorine, hydrochloric acid, and binoxide of nitrogen; but these were ultimately abandoned for sulphurous acid, introduced into the preserving vessel condensed in the pores of charcoal. "I believe," writes Mr. Gamgee, "that charcoal, saturated with sixty-five times its volume of sulphurous acid, will remain, to the end of days, the cheapest, most manageable, and most universally employed antiseptic that the meat preserver can use. It is, perhaps, bold to predict, that which I do with the greatest confidence, that charcoal and sulphurous acid will, in a few years' time, to a great extent, supersede the use of salt." For various reasons, however, sulphurous acid could not be used alone; and the experiments of Hoppe Seyler suggested the simultaneous employment of carbonic oxide, as it was found to preserve the colour of the meat and to expel the oxygen from the tissues; it also acted as a neutral gas to surround the meat in air-tight vessels in place of atmospheric air. The meat to be preserved was placed in a vessel capable of being exhausted by an air-pump; lumps of charcoal saturated with sulphurous acid were then added, and the vessel was exhausted as completely as possible; carbonic oxide was then introduced until the normal atmospheric pressure prevailed within the preserving vessel. Meat thus preserved was found to keep perfectly, not alone in closed cans, but in open vessels, and it could not be distinguished, as regards taste, from recently killed meat. Of course the chief obstacle to the adoption of the process is the expensive nature of the apparatus, and attempts have been made to displace the oxygen from the neighbourhood of the meat, by driving carbonic acid through the preserving vessel by means of a fan; it is obvious, however, that the tissues would still remain charged with oxygen. Whatever may be the value of this process on the large scale, there can be no doubt that few inventions could, at the present time, be of greater value to the human race at large than one which would secure the utilisation, as food, of the thousands of tons of meat which are now wasted in Australia and Texas, and the Argentine Republic. To allow myriads of oxen to attain maturity, and to destroy them for the sake of their skins alone, seems an act comparable to that of the Roman Emperor who caused several hundred flamingoes to be destroyed that he might be provided with a dish of their tongues.

Cleveland and its Metropolis. September 21st, 1869. Middlesborough-on-Tees: Printed at the *Gazette* Steam Printing Works. 1869.

We have received this neat little pamphlet accompanied by a very good map of the district. Its pages contain a very large amount of diversified information, written and compiled with care, and published especially for the information of those members of the Steel and Iron Institute, who, on the occasion of their first provincial meeting at Middlesborough, repair thither and are strangers to the district. We have an historical and archæological review of Cleveland, next a brief but very comprehensive account of the geology of this part of the county of York, followed by a brief history and description of the municipal and parliamentary borough of Middlesborough. The last two pages are devoted to the quotation of analyses of ironstone of this district, coke, best Durham, Weardale limestone, Forcett limestone, pig-iron, No 1, Acklam ironworks, and an analysis of grey-coloured slag. The authors of these analyses are Messrs. Crossley and Pattinson. At the end of the work a short description is given of the Acklam Ironworks, owned by Messrs. Stevenson, Jaques, and Co. The map which has been sent along with this pamphlet has been published by Messrs. Gillan, Schmitz, and Co., iron merchant and shipowners, Middlesborough and Glasgow, is excellently executed, and deserves creditable notice, especially since this kind of very useful publications, showing as it does the blast furnaces, rolling mills, &c., is too much neglected in this country. Maps indicating the different local industries of a county are very useful, and the getting up and publishing of them deserve every encouragement.

MISCELLANEOUS.

Method of Producing upon Iron a Durable Black Shining Varnish.—M. Weiszkopf.—Take oil of turpentine, add to it, drop by drop and while stirring, strong sulphuric acid, until a syrupy precipitate is quite formed, and no more of it is produced on further addition of a drop of acid. The liquid is now repeatedly washed with water, every time refreshed after a good stirring, until the water does not exhibit any more acid reaction on being tested with blue litmus paper. The precipitate is next brought upon a cloth filter, and, after all the water has run off, the syrupy mass is fit for use. This thickish magma is painted over the iron with a brush; if it happens to be too stiff, it is previously diluted with some oil of turpentine. Immediately after the iron has been so painted, the paint is burnt in by a gentle heat, and, after cooling, the black surface is rubbed over with a piece of woollen stuff dipped in, and moistened with, linseed oil. According to the author, this varnish is not a simple covering of the surface, but it is chemically combined with the metal, and does not, therefore, wear off or peel off, as other paints and varnishes do, from iron.

Oxidation of Ammonia.—Chemists are acquainted with the experiment for showing the oxidation of ammonia, in which a red-hot spiral of platinum wire is introduced into a bottle containing a thin layer of strong ammonia on the bottom; white fumes appear of nitrite and nitrate of ammonia. This experiment may be made far more conspicuous in the following manner:—Take a piece of combustion tube, about 40 or 50 centims. in length; place in the middle thereof a layer of 4 or 5 centims. of platinised asbestos. At one of the open ends of the tube a rolled-up piece of blue, and at the other end a similar piece of red, litmus-paper is placed; the last-named open end of the tube is connected, by means of properly arranged tubing, with a flask containing liquid ammonia; the other open end of the tube, where the blue-coloured litmus-paper is placed, is similarly connected with a flask filled with air. The platinised asbestos is next heated to redness, and kept in that state by suitable means. By the employment of a properly arranged tube, a current of air is slowly blown through the flask containing ammonia; when this is continued for a few moments the red litmus-paper will be observed to become blue, and the blue litmus-paper, at the other open end of the tube, will be seen to become red, whilst, at the same time, there will be deposited at the colder portions inside the tube, behind the red-hot platinised asbestos, a broad white ring of nitrite and nitrate of ammonia, while red vapours begin to fill the empty flask. When the gas, after having passed over the platinised asbestos, is made to come into contact with a strong solution of protosulphate of iron, to which some few drops of sulphuric acid have been added, this solution soon becomes deep blackish brown. A solution of iodide of potassium, to which a clear starch paste has been added, is, on being brought into contact with this gas, instantaneously coloured blue; while a strong solution of indigo in concentrated sulphuric acid, after having been gently heated, is very rapidly decolourised on coming into contact with this gas.—*Berichte der Deutschen Chemischen Gesellschaft zu Berlin.*

CHEMICAL NOTICES FROM FOREIGN SOURCES.

In accordance with the generally expressed wishes of our friends and readers, we have effected arrangements to enable us to give, under the above heading, notices of EVERY CHEMICAL PAPER IN THE WORLD, *as soon as possible after publication. Whenever possible, these notices will appear in the form of carefully prepared, although necessarily brief, abstracts; as respects papers either too long or too abstruse to render condensation possible, their titles will be chronicled; and in all cases accurate reference will be made to the original publication. The two half-yearly volumes of the* CHEMICAL NEWS, *with their copious indices, will therefore be equivalent to an English edition of the "Jahresberichte," with the additional advantage of keeping the readers week by week on a level with the latest advances of science.*

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus des Séances de l'Académie des Sciences, September 27, 1869.

This number, an unusually thin one, opens with a brief, but very touching speech of M. Dumas, announcing the demise of the late Master of the British Mint, who was a corresponding member of this institution. The eminent speaker dwelt for a few moments on the great scientific merits of the deceased, pointing out his discoveries and researches, and expressing regret at the loss of such an eminently distinguished *savant*.

The following are the original papers and memoirs relating to chemistry contained in this number:—

Action of Permanganate of Potassa upon Asparagine.—M. Campani.—Asparagine is converted, by the action of water alone, into aspartate of ammonia. According to this author, asparagine is converted, by the oxidising action of permanganate of potassa, into ammonia, oxalic acid, carbonic acid, and a trace of hydrocyanic acid.

The Vacuum as a means of Preventing Explosions in Coal-Pits.—M. Raffard proposes that, on Saturday evenings, all the shafts of a coal-pit, one only excepted, shall be hermetically closed, and that that shaft shall be put into communication with an air pump, which, on withdrawing the air, will cause the marsh gas, fire-damp, freely to issue from the pores of the coals, and thereby cause a thorough cleansing of the air of the pit. It is very difficult to imagine that such a proceeding will have any really useful effect.

New Hygrometer.—M. Crestin.—The author proposes to place, on the plate of an areometer, a quantity of perfectly dry common salt; the areometer is then placed in pure water, which is covered by a layer of oil. While the salt absorbs moisture, the areometer gradually sinking into the water indicates the degree thereof.

Chinese Industry.—M. Champion.—The author has published a work on the ancient and modern industries of the Chinese Empire. This work is highly spoken of by M. Dumas, who points out that the Chinese excel Europeans in many matters.

Berichte der Deutschen Chemischen Gesellschaft zu Berlin, No. 13, 1869.

From the proceedings of the meeting of this Society, held under the presidency of Dr. A. W. Hofmann, on the 12th of July last, and recorded in this number, we find, among the foreign gentlemen elected members of this Society, the names of Prof. Abel, of Woolwich; Dr. E. H. Kinson, Sandhurst, Farnborough; and Dr. W. Odling. The following papers and communications were read:—

Constitution of Tourmalin.—M. C. Rammelsberg.—In the introduction to this essay, the author points out the difficulties which beset this subject, which has frequently been worked at by various mineralogical chemists; but, notwithstanding the author himself made a large number of analyses of this mineral, several points of interest were not clearly elucidated, among these—(1) The behaviour of tourmalin on ignition; (2) the degree of oxidation of iron, forasmuch as this metal occurs in this mineral, which is not the case with all varieties thereof; (3) the precise quantity of boron contained in tourmalin. Tourmalin is a very complex mineral; it contains the following elements:—H, K, Na, Li, Fl, Mg, Ca, Mn, Fe, O, Si, B, and Al. Tourmalines are found not containing Li, Fe, Mn, or Ca. The colourless, or pale red-coloured tourmalin, from Elba, contains 0·2 per cent of MgO; a brown variety, from Windischkappel, contains 11·8 per cent MgO; the black tourmalin, from Andreasberg, contains 17·4 per cent FeO. Magnesia tourmalines are yellow or brown-coloured; the magnesia-iron tourmalines are dark brown or black-coloured; iron tourmalines are quite black-coloured; and the tourmalines which do not contain any iron at all but manganese, are rose or pink-coloured, or sometimes even colourless. As regards the fundamental composition of this mineral, it is a tri-silicate—

$$\underset{\text{I}}{R_6}\underset{\text{II}}{SiO_5}—\underset{\text{VI}}{R_2}SiO_5—RSiO_5.$$

The author proceeds at length, enumerating the various species of this mineral, according to the prevalence therein of certain elements; but, strictly speaking, this portion of his paper rather belongs to

mineralogy, and our space, moreover, forbids us to quote the large number of formulæ required to elucidate this subject.

On Chloral.—MM. Martius and Mendelssohn-Bartholdy.—The authors state that they have been induced to try whether it would not be possible to prepare chloral in large quantities, so that if this substance should become used in pharmacy, it could be obtained in a pure state. The hydrate of chloral would, according to the authors, answer this purpose by far the best. This hydrate ought to be a white crystalline mass, endowed with considerable hardness; it should dissolve readily in water, and be devoid of any smell of chloride of carbon or hydrochloric acid, while it should exhibit its peculiarly strong smell. The authors exhibited at this meeting several pounds' weight of chloral, and stated that they hope shortly to be able to exhibit to the members of this Society the synthesis of chloroform by an easily executed method, as also trichloracetic acid, made according to M. Liebreich's method.

On Euxanthon.—M. A. Baeyer.—According to the researches of the late Prof. Gerhardt, the euxanthon, obtained by M. Erdmann from the euxanthinic acid contained in Purrhee, should be composed according to the formula $C_{10}H_8O_8$. The author found that, when vapours of euxanthon are passed over powder of zinc heated in a combustion tube, there is formed a semi-solid hydrocarbon, resembling diphenol; and he concludes, hence, that euxanthon is not a derivative from naphthaline, but has to be referred to a benzol containing four atoms of carbon in a peculiar form. The author, on treating euxanthon with bichromate of potassa and sulphuric acid, did not succeed in obtaining products of oxidation of euxanthon, since the reaction became too violent; but, on fusing euxanthon with caustic potassa, a new substance was obtained, which the author calls euxanthonic acid, $C_{13}H_{10}O_8$. It is a weak acid, which yields, with basic acetate of lead, a reddish yellow-coloured precipitate; with chloride of iron, it yields a red colouration; euxanthon, on the contrary, yields, with that reagent, a green colouration. Euxanthonic acid is far more readily soluble in water than euxanthon.

Synthesis of Picolin.—M. Baeyer.—When acrolein-ammonia is submitted to distillation, an aqueous ammoniacal fluid and a basic oil are obtained. M. Claus discovered that the double salt of platinum of that base possesses the same composition as the picolin platinum salt, $NC_6H_7Cl.PtCl_2$; but the properties of that salt do not at all remind one of picolin. The author of this paper found that the aqueous ammoniacal fluid, which has not been investigated by M. Claus, contains a large quantity of picolin, and this picolin exhibits the very identical properties possessed by the picolin obtained from coal-tar and bone distiller's tar. The author explains the origin of picolin in the following manner:—Fatty substances yield acrolein, and, under the joint influences of ammonia and a high temperature, picolin is formed, according to the following formula:—

$$2C_3H_4O + NH_3 = NC_6H_7 + 2H_2O.$$

Derivatives from Naphthaline.—MM. Darmstädter and Wichelhaus.—The authors continue in this paper the communication of the results of their experiments on this subject, and describe, at great length, how they succeeded, by a very complex process, in obtaining bicyanaphthaline—

$$C_{10}H_6\begin{cases}CN\\CN\end{cases}$$

This substance exhibits needle-shaped pale yellow crystals, difficultly soluble in alcohol and ether, insoluble in water, and fusing at 204°. From this substance, the authors have prepared a compound which they call bicarbonaphthalinic acid—

$$C_{10}H_6\begin{cases}CO.OH\\CO.OH\end{cases}$$

This substance is a solid crystalline material, very difficultly soluble in boiling water, soluble in alcohol, not fusible nor decomposed at 240°. The authors refer, in this paper, to three varieties of bicyanaphthaline, in addition to the substance of that name already alluded to, and each obtained from a different naphthaline compound.

Action of Fusing Hydrate of Potassa upon Stearolic Acid.—M. S. Marasse.—The author, after referring to the labours of Messrs. Frankland, Duppa, Overbeck, and others, on this subject, states that stearolic acid is not a substituted acrylen, but that the molecule of this acid contains twice the group C=C. Acting upon this idea, the author has succeeded in so managing the action of the fusion with hydrate of potassa as to obtain from stearolic acid a homologue of acrylic acid. The new acid thus obtained is a colourless fatty matter fusing at 21°; its formula is $C_{16}H_{30}O_4$.

Constitution of Benzol.—M. A. Kekulé.—Unless we reproduce the woodcuts annexed to this paper, and essential to its proper elucidation, we cannot usefully give an abstract of it.

Crotonaldehyde.—M. A. Kekulé.—This paper contains the results of a series of experiments, made with the view to prove, experimentally, the mode of the combination of the atoms of carbon in benzol. The paper is too lengthy, and so crowded with formulæ, that it is impossible to give a proper abstract of it.

Lecture Experiments.—M. Kessler.—No. 1. Ignition of a mixture of H and Cl by means of the flame of CS_2 burning in NO, is rather awkward to manage. The author uses the magnesium light for that purpose. After having fastened a bottle filled with H and Cl to a retort stand, a piece of magnesium ribbon is taken hold of with a pair of forceps, ignited in the flame of a spirit-lamp, and moved, close to the bottle, up and downwards. A slight shock indicates the end of the reaction. The bottle is next opened under water.—No. 2. When burning magnesium wire is placed in a vessel containing CO_2, the latter is decomposed, and carbon deposited. Some HNO_3 should be poured into the vessel at the end of the reaction, in order to dissolve some magnesia resulting from the combustion, and to make the deposit of C distinct.—No. 3. Water having been poured in a rather wide-mouthed flask, it is made to boil as briskly as possible. When, after this boiling has been continued for some time, previously-ignited magnesium wire is held deep down in the mouth of the flask, it continues to burn. The same metal burns with great brilliancy in N_2O and NO, also in H_2S and SO_2, but is extinguished by CO. The floating of soap bubbles upon CO_2 is exhibited with the least expenditure of that gas when it is made to pass through the narrow neck of a large glass funnel.

On Diazocyanbenzol.—M. P. Griess.—This paper contains a first instalment of the results obtained when experimenting on the products of decomposition of diazocyanbenzol. Among these, the author found diazocyanbenzolimid—

$$\left.\begin{matrix}[C_6H_3(CN)N_2]''\\H\end{matrix}\right\}N + 3NHBr.$$

This substance is a solid body, almost insoluble in water; readily soluble in warm alcohol; crystallising, from the solution in that fluid, in large needle-shaped bright yellow-coloured crystals; fusing at 57°, and exploding when more strongly heated. Iodinecyanbenzol, also a solid substance, insoluble in water, readily soluble in alcohol and ether, and fusing at 41°.

Some Derivatives from Anethol.—M. Ladenburg.—After referring to his former researches on this subject, the author states that he has succeeded in obtaining anol, a solid substance fusing at 92·5°; soluble in alcohol, ether, and chloroform; and boiling at 256°. Formula, $C_9H_{10}O$. Chloranethol is a somewhat yellowish-coloured fluid which solidifies at a low temperature, and becomes fluid at −6°; boils at 257°; sp. gr., 1·1154. When this body is treated with caustic potassa, and heat applied, there is formed a substance, $C_{10}H_{10}O$; it is a liquid insoluble in water, and boiling at about 242°.

Chrysophanic Acid.—M. Rochleder.—When this acid is distilled along with powdered zinc, anthracen is formed. After this statement, the author proceeds to discuss the formula which chrysophanic acid ought to have, and, having found that chrysophanic acid, dried at 100° (all analyses made of this substance have been made with quantities thereof which were dried at that temperature), retains water, which can only be expelled at 115°, aided by a current of dry carbonic acid gas. The author ascribes to this circumstance the discrepance of the results of the elementary analyses made of this substance, and suggests that the formula of the acid dried at 100° should be written $4(C_{14}H_{10}O_4)+OH_2$. The author also found that chrysophanic acid made from rhubarb root is always contaminated with emodin; but this substance being soluble in a hot solution of carbonate of soda, wherein chrysophanic acid is insoluble, the two may be separated from each other in that manner. Emodin may be precipitated by acids from its alkaline solution, and, after having been carefully washed with water, may be dissolved in alcohol 80 per cent, and obtained in crystals on evaporation of that solution. Emodin exhibits an orange-yellow colour. The chrysophanic acid which has been separated, as described, from emodin, should first be well washed with water, and next repeatedly treated with boiling alcohol of 90 per cent, and thus obtained in pure state. So purified, the formula for dry chrysophanic acid is $C_{14}H_{10}O_4$.

On Naphthaline Red.—Dr. A. W. Hofmann.—At the Paris Exhibition of 1867, there was only one naphthalin colour exhibited, to wit, the naphthaline yellow (dinitro-naphthol) discovered by Dr. Martius. The author says that he has received, from his friend M. Scheurer-Kestner, a quantity of a very remarkable substance, now known as naphthaline red on the continent, and in England designated Magdala red. This substance, as sent to Dr. Hofmann, exhibits a blackish brown, somewhat crystalline, powder, soluble in alcohol, yielding a deeply red-coloured solution, on evaporation of which greenish crystals endowed with metallic lustre are obtained; these crystals proved to be the chloride of a base which, on analysis, was found to be composed of $C_{20}H_{21}N_3$. The eminent author proposes to investigate this subject more fully, for which reason the brief account here given may suffice for the present, the more so as the manufacture of this naphthaline red (first made at Bâsle, on the large scale) is as yet rather uncertain.

On Xylidine Red.—Dr. A. W. Hofmann.—When pure xylidine is treated with oxidising agents, no red-coloured pigment is obtained; neither is this the case when, after having been mixed with toluidine, xylidine is treated as is done for the preparation of rosaniline; but when xylidine is mixed with aniline, and then treated with the agents used to make rosaniline, a most beautiful carmine red pigment is obtained which dyes wool and silk a very fine colour. The probable composition of this pigment is $C_{22}H_{22}N_2,H_2O$.

Contribution to our Knowledge of Chrysaniline.—A. W. Hofmann.—When a solution of pure chrysaniline in pure wood-spirit (methyl-alcohol) is mixed with iodide of methyl, and heated in a sealed tube, for about six hours, to 100°, a solid crystalline substance is obtained, which, after having been purified, may be dissolved in boiling water, from which solution beautifully orange-carmine red crystals are deposited, which constitute the diiodhydrate of trimethyl-chrysaniline, $C_{20}H_{14}(CH_3)_3N_3,2HI$; the solution of this salt dyes wool and silk a deep orange-yellow, verging upon scarlet-red. From this substance, on being treated, when in solution, with ammonia, the monoiodhydrate of trimethyl-chrysaniline is obtained—

$$C_{20}H_{14}(CH_3)_3N_3,HI.$$

Trimethyl-chrysaniline yields, with acids, very well-defined salts, which are rather readily soluble in water, excepting the nitrate and picrate. Chrysaniline behaves with iodide of ethyl as it does with iodide of methyl.

Porphyritic Rocks of Austria.—M. G. Tschermak.—The Vienna correspondent of this Society, M. Ludwig, writes to the effect

that the author named at the heading of this paragraph has made a series of researches on augite and amphibole. The former mineral, if crystallised, is a combination of $MgCaSi_2O_6$ and the therewith isomorphous $FeCaSi_2O_6$. Augite, which is imbedded in rocks, contains alumina, and, moreover, a silicate made up according to the formula, $MgAl_2SiO_4$. The composition of amphibole is rather more complex, because it also contains a soda silicate.

On Benzylic Acid.—M. A. Jena.—When benzile is heated with an alcoholic solution of caustic potassa, benzylic acid is formed, and also benzoic acid. Benzylic acid is formed more readily when benzile is heated with water in sealed tubes. Pure benzylic acid fuses at 150°; moistened with concentrated sulphuric, it becomes red-coloured; heated for some length of time to 180°, it yields a red-coloured resin, and a compound, $C_{28}H_{22}O_5$. When benzylic acid is treated with dilute sulphuric acid and bichromate of potassa, water, carbonic acid, and benzophenon are formed—

$$\underbrace{C_{14}H_{12}O_3}_{\text{Benzylic acid.}} + O = H_2O + CO_2 + C_{13}H_{10}O.$$

Formation of Adipinic Acid from Mucic Acid.—M. L. Marquardt.—The author says—"Some time ago M. Bode succeeded in obtaining from the compound $C_6H_4Cl_2O_4$ (which compound is the result of the action of excess of phosphor-chloride upon mucic acid), by means of zinc or sodium-amalgam, a substance which he (M. Bode) called muconic acid, $C_6H_6O_4$; this acid only differs from adipinic acid by a deficiency of 2H. The author of this paper states that he has obtained, from muconic acid, pure adipinic acid, by treating the former, after having been moistened with water, with sodium-amalgam, and leaving this mixture standing for some hours in a warm place. The fluid, after having been removed from the mercury, is acidified with dilute SO_3, next shaken up with ether, and, on removal of that fluid, by distillation, adipinic acid remains behind.

Annalen der Chemie und Pharmacie, September, 1869.

This number opens with a series of three treatises on trimethyl benzol. The first of these papers treats on—

The Trimethylbenzol which is Formed by the Introduction of an Atom of Methyl into Xylol.—MM. R. Fittig and K. Laubinger.—In the introduction to this paper, the authors state that mesitylen is a peculiarly-modified trimethyl-benzol; and that the substance which, under the name of cumol, or pseudo-cumol, has been met with in coal-tar is also a modification of trimethyl-benzol, but different from mesitylen by its monobromide, $C_9H_{11}Br$, which is a crystalline substance, fusing at 73°. Pseudo-cumol has often been the subject of chemical researches; but the authors of this paper deny any value to these researches, since, according to them, pseudo-cumol, as applied to these researches and obtained from coal-tar, is and always remains, any rectifications and fractional distillations notwithstanding, a mixture of several hydrocarbons. The authors, therefore, have prepared pseudo-cumol synthetically, by introducing into xylol 1 atom of methyl. The fluid thus obtained was purified by distillation with sodium, and was found to boil constantly at 166°. *Products of substitution of pseudocumol.*—Mononitropseudocumol, $C_9H_{11}(NO_2)$, is a solid substance, crystallising in prisms, fusing at 71°, soluble in alcohol. It is distinguished from nitro-mesitylen by its point of fusion, and by its being soluble in cold fuming nitric acid without thereby undergoing any change. Dinitropseudocumol has not been obtained by the authors in pure state. Trinitropseudocumol, $C_9H_9(NO_2)_3$; also a solid substance fusing at 185°, and crystallising from its solution in benzol in large quadratic-shaped prisms. The authors then treat, under the following heads, the following subjects:—*Products of reduction from trinitropseudocumol; bromated products of substitution from pseudocumol; products of oxidation of pseudocumol.* Among the latter, xylylic acid, $C_9H_{10}O_2$, is found; also paraxylylic acid, and xylydinic acid, $C_8H_8O_4$, which are described at great length, as well as their salts.

The second treatise on this subject is headed—

On the Trimethylbenzol which is Generated when Two Atoms of Methyl are successively introduced into Toluol.—MM. Fittig and Jannasch.—The authors say they have proved, by researches made and published some time ago, that the methyltoluol prepared sythetically from toluol differs from xylol; a difference undoubtedly due to the unequal position of the atoms of methyl towards each other. The authors therefore argue that, if, synthetically, a third atom of methyl be added to the methyltoluol (dimethylbenzol), a trimethylbenzol, different from pseudocumol, will be obtained. In order to prove this hypothesis by experiment, they prepared from toluol a large quantity of methyltoluol; and, on treating that with bromine, obtained *monobromated methyltoluol*, $C_8H_8Br(CH_3)_2$, a liquid as clear and colourless as pure water, boiling at about from 204° to 206°. By means of iodide of methyl and sodium, trimethylbenzol was prepared from the liquid just alluded to. The result was the generation of a liquid boiling at 166°, and not differing in physical qualities from pseudocumol. In many of its chemical characters, this trimethylbenzol is not distinguished from pseudocumol. The greater part of this paper is devoted to a discussion of the relative position of atoms of CH towards other groups of polymers thereof; but since, without the introduction of some woodcuts annexed to the original, this rather abstruse subject cannot be clearly understood, we proceed to the third treatise:—

On the Trimethylbenzol contained in Coal-Tar.—MM. Fittig and Wackenroder.—The authors have prepared from the hydrocarbons of coal-tar (which have a high boiling point), by carefully-conducted, often-repeated, fractioned distillation, a hydrocarbon, the boiling point of which lay between 164° and 167°. This material has been converted into a trinitro-compound, which, after having been purified, yielded a solid crystalline body, fusing at 230°, soluble in alcohol, and yielding, after carefully-conducted elementary organic analysis, results leading to the formula $C_9H_9(NO_2)_3$. On dissolving this substance in warm benzol, the authors found that the body alluded to is not a simple compound, since the mother liquor of the solution in benzol yielded, on evaporation (after the previous separation of the crystalline compound just mentioned), a batch of prismatically-shaped crystals, entirely different from the needle-shaped body first obtained, which last crystalline body was found to fuse at 185°, and to possess all the properties of trinitropseudocumol. The researches of the authors, very exhaustively described, lead to the result that the trinitro-compound obtained from the hydrocarbon from coal-tar above alluded to is a mixture of trinitromesitylen and trinitropseudocumol; accordingly the hydrocarbon from coal-tar boiling at from 164° to 167° is a mixture of pseudocumol and mesitylen, which latter substance may even be prevalent in this fluid.

Electrolysis of Water in Contact with Silver.—Dr. Runspaden.—This monograph treats on the fact first observed by Prof. Wöhler—that when water acidified with sulphuric acid is decomposed by a galvanic current, and silver is applied as electrodes, peroxide of silver is deposited on the anode and metallic silver on the cathode. The two main questions answered by the author by a series of experiments are—What is the cause of the formation of peroxide of silver on the positive pole, and by what means does the metallic silver find its way from the positive to the negative pole? The treatise is too lengthy and too concisely abstracted already in this periodical [the treatise was published originally as a separate work] to admit of useful condensation. In an appendix, the author informs us that there is an error in all works treating on chemistry and physics, viz., the statement that gold (pure, of course) and platinum are the only two metals which are not oxidised at the positive pole when serving as electrodes. The author finds, and has confirmed by experiments carefully conducted, so as to exclude any source of error, that gold itself is oxidised to a very considerable extent, and that, during experiments as those alluded to, there is formed a definite oxide, $Au_2O_3,3H_2O$; percentically—gold, 79·47; oxygen, 9·62; water, 10·91.

On Chlorous Acid.—M. Brandau.—The author gives, in about twenty pages, a very complete and exhaustive treatise on the preparation and properties of chlorous acid, both as gas and as liquid. Since, however, the engravings added to this paper are absolutely required to understand a great part of it, we content ourselves by describing the properties of the liquid chlorous acid. It is a liquefied gas; colour of fluid, deep red-brown; very fluid. Even below 0°, the vapour of this liquid exerts a considerable pressure. Freshly prepared, the fluid boils about half a degree above 0°. If this fluid is suddenly brought to a temperature of about + 8° to 10°, it explodes with great violence. It cannot be kept without continuous and spontaneous decomposition for any length of time. The gas given off from this liquid exhibits the well-known greenish-yellow colour of chlorous acid. The specific gravity of the liquefied gas at 0°, referred to water at 4° (the point of greatest density of water), is 1·3298.

Preparation of Chlorate of Baryta.—M. Brandau.—The author makes a mixture of commercial sulphate of alumina, of sulphuric acid, water, and chlorate of potassa. The mixture should have the consistency of a thin magma, and be heated on a water-bath during half an hour, while it is frequently stirred up. The reaction which takes place is represented by the undermentioned formula:—

$$[Al_2(SO_4)_3] + SH_2O_4 + (ClKaO_3)_3 = [Al_2(SO_4)_3 + SKa_2O_4] + (ClHO_3)_2.$$

The product is a solution of hydrated chloric acid, alum, excess of sulphate of alumina, and excess of sulphuric acid. After the mixture has become quite cold, it is mixed with several times its bulk of alcohol, filtered, and washed with alcohol of 50 per cent. The alcoholic filtrate is neutralised with hydrate of baryta, whereby chlorate of baryta, sulphate of baryta, and some alumina are formed. The bulk of the alcohol is removed by evaporation. The aqueous solution of chlorate of baryta is next filtered, and the residue washed with water (distilled, of course). The liquid is next evaporated to crystallisation, yielding pure chlorate of baryta. A slight excess of sulphate of alumina and sulphuric acid should be applied, since, otherwise, some chlorate of potassa will remain mixed up with the chlorate of baryta.

The Brominated Products of Substitution of Dibenzyl.—Dr. Marquardt.—The author first refers to the researches made on this very same subject by MM. Fittig and Stelling, and then describes a series of identical compounds as those obtained by the parties just named, but prepared in a different manner. Chiefly the effect of a different temperature appears to be in play, in this instance, to produce compounds of different physical properties.

On some Products of Decomposition of Tribenzylamine.—M. W. Rohde.—This paper, being a critical review of M. Limpricht's labours on this subject, is not well suited for abstraction.

Determination of the Equivalent of Albumen.—M. Fuchs.—After briefly reviewing the researches made by Messrs. Schwarzenbach, Lieberkuhn, and others, on this subject, the author describes a series of his own experiments, the main result of which is that the precipitates formed by albuminous substances and platino-cyanide of potassium are substances of variable composition and decomposable by water. The author also found that the silver compound of albumen applied by M. Lieberkuhn for the determination of the albumen does not answer that purpose, since, on repeating, even up to seven times, the last-named author's experiments, he found the results to vary considerably, and, among themselves, to be different from those obtained by M. Lieberkuhn. On repeating M. Commaille's experiments on this subject, the author found that his very carefully-conducted experiments agreed with those of the last-named gentleman

very closely, and that, therefore, the compound obtained when chloride of platinum and a slightly acidified solution of albumen are mixed is the precipitate best suited for the determination of the equivalent of albumen.

Occurrence of Laurite in the Platinum Ore found in the Oregon Territory, U.S.—Prof. Wöhler.—Laurite is a mineral, first met with in the platinum ores found in Borneo, and composed of sulphide of ruthenium and sulphide of osmium. In the platinum ore here alluded to, this mineral is met with in such minute crystals that they are only distinguishable when magnified 50 diameters. Chemical tests, however, distinctly detected the laurite, which has been fully described some years ago by this eminent author.

Zeitschrift für Chemie von Beilstein, No. 15, 1869.

This number contains the following original papers:—

On Orthonitrodichlorophenol and an Isomeric Dichlorophenol.—M. O. Seifart.—Orthonitrodichlorophenol, $C_6H_2Cl_2NO_3OH$, is a solid substance, crystallising, from its ethereal solution, in rhombic-shaped crystals; soluble in ether, alcohol, and chloroform, but not in water; is not capable of being sublimed; fuses at 125°, but becomes decomposed at the same time. The author gives a catalogue of salts which this substance forms:—The ammonium salt, $C_6H_2Cl_2NO_3ONH_4+HO$, is a crystalline substance, readily soluble in hot water; orthoamidodichlorophenol is a solid substance, soluble in water, but far more readily in alcohol, and fuses at 166°; dichlorphenol, $C_6H_3Cl_2OH$, is a solid substance, difficultly soluble in water, readily soluble in alcohol and ether, fuses at 65°, and boils at 220°.

On Chloronitrophenols.—MM. Faust and Saame.—Chloronitrophenol, $C_6H_4Cl(NO_2)O$, is a solid body, exhibiting bright yellow-coloured, large sized crystals; it smells like saffron, fuses at 87°, is nearly insoluble in water, but readily soluble in alcohol and ether; it forms salts which crystallise, and are readily soluble in warm water. The authors give a lengthy catalogue (the name and formulæ) of a series of these salts, and distinguish α, β, and otherwise designated compounds, which, however, vary only in slight particulars from each other.

Decomposition of Acetate of Silver by Iodine at a High Temperature.—M. Birnbaum.—When a mixture of acetate of silver and iodine is submitted to heat, there ensues, at a comparatively low temperature, a very strong reaction, the products of which, partly vapours, and partly permanent gases, were, by suitable means, condensed and collected by the author. Among the condensable vapours, he found acetate of methylic ethyl, boiling at 55°, and hydrate of acetic acid. Among the gases, carbonic acid, acetylen, and, beside this, another carburetted hydrogen were found. The solid residue of the reaction consisted of iodide of silver and some carbonaceous matter. The author enters into a very lengthy discussion as to the origin of the different substances found, but we cannot follow him therein, since it would require the reproduction of an enormous series of formulæ. When acetate of silver is heated by itself, a very violent reaction ensues, which sometimes even comes to actual combustion. The reaction yields acetic acid, and, among the gaseous products, CO_2 and marsh gas. The residue in the retort was found to consist of metallic silver and carbon.

Definition of the Place to be Assigned to the Benzol Series.—M. V. von Richter.—A paper not suited for abstraction.

New Method of Formation of Ortho-Chlorobenzoic Acid.—M. Wroblevsky.—When sulpho-diazo-chlorotoluol is boiled with anhydrous alcohol, there is formed ortho-chlorotoluol, $O.C_6H_4Cl.CH_3$, a fluid boiling at 156°, and which, on being treated with chromic acid, yields ortho-chlorobenzoic acid, a solid substance, difficultly soluble in water, but readily so in alcohol, and fusing at 151°.

Behaviour of Toluidine towards Bromine.—W. Wroblevsky.—When, into an alcoholic solution of toluidine, a mixture of air and vapours of bromine are passed, a large quantity of dibromotoluidine, and only very little monobromotoluidine, is formed; the former precipitates, and is collected on a filter. After addition of water to the alcoholic solution, the filtrate is evaporated, and until after having ceased to give off acid vapours. Ammonia is then added, in order to precipitate monobromotoluidine. Dibromotoluidine—

$$C_6H_2Br_2(NH_2).CH_3,$$

is a solid body, crystalline, fusing at 73°, soluble in alcohol and ether, not in water.

On Ethyl-Phenol.—MM. Beilstein and Kuhlberg.—The authors state, first, that it is just possible that tyrosin may be equal to amidoethyl-para-oxybenzoic acid, $C_9H_{11}NO_3$, and they tried to obtain it (tyrosin) from ethyl-para-oxybenzoic acid, which latter acid may be made by acting upon ethyl-phenol with sodium and carbonic acid. The researches made by the authors, and described in this paper, are, as might be expected, of a very complex nature, their aim being the synthesis of tyrosin. We regret that the paper is not suited for further abstraction.

Moniteur Scientifique, No. 305, September 1, 1869.

This number contains, as usual, a series of very well written papers, but those which are original do not belong to the domain of chemistry. Among the *brévets d'invention*, we briefly notice that MM. Broenner and Gutzkow have obtained, in France, a patent for the manufacture of anthracen, by distilling the asphalte, employed for making street pavements, with super-heated steam, and a subsequent sublimation of the raw product obtained. The anthracen is converted into anthraquinon, by gently heating the former with twice its weight of nitric acid, sp. gr. 1·3 to 1·5, and washing with water the product obtained. The anthraquinon is converted into alizarine and purpurine (both are formed at the same time), by dissolving it in gently heated sulphuric acid, to which solution nitrate of protoxide of mercury is added. The material resulting from this reaction is dissolved in an alkali, filtered, and next precipitated by an acid, whereby variable quantities of alizarine and purpurine are obtained. This process of manufacture is already carried out, on the large scale, by MM. Meister, Lucius, and Co., at Hoechst, near Frankfort-on-the-Maine, and is a great improvement upon MM. Græbe and Liebermann's method. The editor of the French paper above named states that he received from the manufacturers just named a sample of a ¼ of a kilo. of this artificially-prepared alizarine.

No. 306, September 15, 1869.

This number contains only the following original communication:—

A Letter from MM. Meister, Lucius, and Co., at Hoechst, near Frankfort-on-the-Maine (dated September 10th last), wherein these parties state that they are not manufacturing artificial alizarine by the method for which MM. Broenner and Gutzkow have taken a French patent. They also desire it to be understood that, for some time already, they have manufactured a substance which they call *alizapurine*, by a process kept secret. M. Camille-Kœchlin, of Mulhouse, after having very carefully tested a sample of the substance made by the manufacturers above-named, states:—"The sample sent, though it is not truly an alizarine in the strictest sense, since it differs, in many respects, from genuine alizarine, as obtained from madder, or as that lately produced by artificial means, yields, however, in its application, colours superior to those obtained from madder and any of its commercially made products; and no doubt the material made by MM. Meister and Lucius will be the madder of the future." M. Kœchlin adds—"The paste, for in that state it is obtained, I experimented with has fully five times the tinctorial power of madder, and all the colours are more brilliant.

The other papers contained in this number are not original, and, excepting the *brévets d'inventions*, are already either published by us in full—as, for instance, Mr. Abel's paper on explosive substances—or have been abstracted by us from the original publications in which they appeared.

Revue Hebdomadaire de Chimie, September 9, 1869.

Apparatus for the Liquefaction of Protoxide of Nitrogen and other Gases.—M. Deleuil.—The apparatus, of which an excellent woodcut is given, is an improvement upon the very generally used and well-known apparatus of M. Natterer, of Vienna, and, in principle, the same—viz., a force-pump, to the piston of which an upwards and downwards movement is imparted by means of cranks and wheelwork. The recipient for the condensed gas, and the body of the pump, are surrounded by a strong freezing mixture, and the recipient is provided with properly constructed valves, whereby it is possible to make, with ease and comfort, and without danger, experiments with liquefied gases in a lecture-room; while the apparatus for condensing the gases is placed in a separate room by itself. Without reproducing the cut, we cannot enter into more details on this subject. The price of the apparatus complete is, at Paris, 1900 francs (£76).

Annales de Chimie et de Physique, August, 1869.

This number contains only one original paper, or, rather, a lengthy essay, on—

Interrupted Currents.—M. A. Cazin.—This essay is strictly of a mathematico-physical nature, and not suited for abstraction.

Bibliothèque Universelle et Revue Suisse.—Archives des Sciences Physiques et Naturelles, No. 140, August 15, 1869.

This number does not contain any original paper relating to chemistry or allied sciences.

TO CORRESPONDENTS.

J. Cox.—The subject of your query has already been fully discussed in these columns.

W. H. Hindmarsh.—We know of no analytical practice for disposal just now, or of a partnership in chemical works. By repeating the advertisement, you would probably hear of one. A Mr. G. Green, of 5, Sebbon Street, Islington, has written to us for your address, as he wishes to have his certificate returned.

W. R.—Chloride of iron can only be economically prepared on the large scale at chemical works, where hydrochloric acid can be had at a mere nominal cost. Your other questions can be better answered by a few practical experiments, than by written descriptions. The last of Dr. Angus Smith's articles, "On the Examination of Water for Organic Matter," appeared in No. 510.

Biggs, Holland, and Biggs.—We do not know the address of MM. Græbe and Liebermann, but a letter to the care of the publishers of the *Berichte der Deutschen Chemischen Gesellschaft zu Berlin* will probably reach them.

THE CHEMICAL NEWS.

VOL. XX. No. 516.

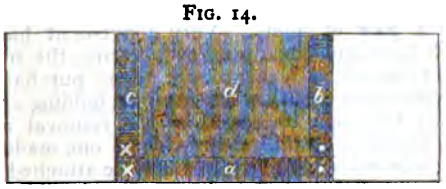
ON MICROSCOPICAL MANIPULATION.

By W. T. SUFFOLK, F.R.M.S.

(Continued from p. 171.)

A VERY useful trough for viewing objects in fluid can be made with a slight amount of trouble. Cut in half an ordinary 3 × 1 slide (Fig. 14, shaded portion in centre). From this cut off the strip *a*, then the pieces *b* and *c*, and reject the centre piece, *d*. Before cutting, it is well to mark the adjacent edges with ink, as indicated in the figure, to prevent any mistake in putting them together afterwards. The three pieces *a*, *b*, and *c* are to be cemented with marine glue on the middle of a slide, and, as the cut portions, if replaced as directed, fit each other accurately, there is no occasion for grinding. The trough is completed by fastening an oblong piece of thin cover-

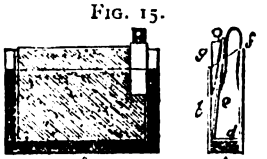
FIG. 14.



glass on the upper surface. For this purpose it is better not to use marine glue, as the cover frequently requires removal, as, from its thinness, it is liable to be broken in cleaning. It can be best secured by the use of the following, known as "electrical cement," from its having been used to fasten various portions of electrical apparatus together:—Melt together five parts rosin, one part bees'-wax, one part red-ochre, two parts Canada balsam; mix well, and pour into pill-boxes of convenient size. This cement is most conveniently used with a miniature soldering bit, which is rendered more comfortable to use by its being balanced with a plug of lead in the handle. With a little practice, a very neat joint can be made. The cement is also useful for many other purposes, of which notice will be taken in the proper place.

Larger troughs, having sides of plate-glass, can be made by those who will take the necessary trouble. In this case, the surfaces to be cemented must be

FIG. 15.



accurately ground. Such vessels are very useful in looking over the results of pond-hunting with a low power for the purpose of selecting such objects as may be required for more detailed observation. The troughs, of various shapes, can be purchased at most opticians.

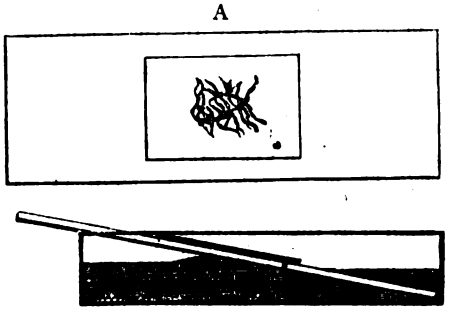
The form represented in Fig. 15 is particularly convenient, as by means of the whalebone spring, *f*, and the wedge, *g*, the space between the front glass, *b*, of the trough and the inclined plate, *c*, is capable of adjustment, so that an object can, when desired, be kept close to the front glass. These parts can be removed when a greater depth of water is required for larger objects.

A simple and useful contrivance, to be used as a growing-slide, has been described by Mr. C. J. Muller (*Monthly Microscopical Journal*, vol i., p. 174). The object of a growing-slide is to keep alive any minute water-plant or animal, the development of which it is wished to observe. Many plans have been devised for this purpose, but none equal in simplicity or efficiency that now to be described.

An ordinary 3 × 1 slide (Fig. 16, A) is pierced with a minute hole at about 3-10ths of an inch from the centre on one side. When an object under investigation is put upon it immersed in water, the thin glass cover is so placed as to include this hole, which should be near its margin. When it is desired to keep the specimen moist while off the stage of the microscope, the slide is placed in a small flat trough (B) in an oblique position, object uppermost, with one

FIG. 16.

A



B

end (that nearest the hole) resting against the bottom of the vessel on one side, and the other resting upon the edge of it. Sufficient water is put into the vessel to admit of the liquid reaching within a ¼ or ½ an inch of the glass cover on the uppermost side, when it will be found that the water on the under side reaches beyond the centre of the slide, and consequently beyond the hole with which it is pierced. In this state, the object will remain moist so long as the trough contains a sufficient quantity of water. When required to be placed on the stage of the microscope, the water is easily wiped off the slide, without any disturbance of the object.

Mr. Muller's original trough was made of tin-plate, but, as this material is liable to rust when long in use, Mr. F. W. Gay has had them made of pewter of an improved form, which has proved an effectual remedy for this defect. Thus constructed, they are to be obtained of Mr. C. Baker, Holborn.

The process of attaching cells to plates of glass has been given; but nothing has been said about the material of the rings forming the cells. When required of some considerable depth, rings made of slices cut from thick glass tubing answer admirably. If square or oblong cells are required, they can be

* The substance of a course of lectures delivered to the members of the Quekett Microscopical Club, January—April, 1869.

cut from tubes of suitable form. Very useful cells are now made by Mr. Collins of pure tin of various thicknesses, from that of thin writing-paper up to that of a thick tube cell: several sizes can also be procured in each thickness. Tin is not acted upon by any of the fluids used in preserving microscopical objects, and has the advantage of being much cheaper than glass, and at the same time equally efficient. Cells of unusual form can readily be cut from the sheet-tin with a penknife or pair of scissors, and circles can readily be punched. The adhesion of the cover-glass is improved, and the process of mounting in fluid much facilitated, by grinding the upper surface of the cell after it is attached to the slide with water upon a Water-of-Ayr stone, as suggested by Dr. Carpenter. This gives a beautiful surface, and ensures the perfect fit of the cover, and renders the closing of the cell a matter of greater certainty than it would be if the natural surface of the metal were used.

Some very useful aids to the examination of microscopical objects, and which can readily be made by the exercise of the smallest amount of mechanical ingenuity, are described by Mr. S. J. McIntire, in the *Transactions of the Quekett Microscopical Club*, vol. i., p. 69. One of these is of such general application that it will be well to describe it. A piece of sound sheet cork, about 2 in. by 3¼, or other convenient size, and of a thickness suited to the purpose for which it is intended, is perforated with an oval or circular hole; this may easily be cut with a penknife or sharp chisel, and the edges finished with a file. The cork is placed between two pieces of glass of similar size, the lower one being covered with a few layers of pink blotting paper, and the whole contrivance kept together with two india-rubber rings. The cell so constructed is used for keeping alive small insects that inhabit damp situations, such as *Podurœ*. The moisture is readily supplied by dipping the end of the slide into water, which is absorbed and retained by the blotting paper. The proper food of the insects can be placed in the cell. By the aid of this simple contrivance, Mr. McIntire has been enabled to make some most interesting observations on the habits of the *Podurœ*, which have been kept living in these cells for many months. This plan admits of modification to suit the object under observation. In the author's researches on the blow-fly, it was necessary to use thin glass, and to have the means of viewing the object on either side; this was accomplished by cutting a rectangular hole in a suitable piece of cork, placing the thin glass on either side, and securing it by bending on its edges strips of the sheet tin used for making cells which had been inserted in the cork, which effectually fastened the glass in a somewhat similar manner to that by which a stone is set by jewellers, and readily permitted its removal when required.

Among the tools employed by the microscopist, none are more generally in request than needles of various sizes and forms. They are frequently required of various curvatures; this bending can readily be performed by the microscopist himself. If a needle is heated to redness in the flame of a spirit-lamp, and allowed to cool, it can easily be bent or twisted into any required form. Steel so treated, if heated again to redness and suddenly cooled in water, becomes excessively hard and brittle; in this condition, it is capable of scratching glass, but is too fragile for dissecting instruments. The right temper for the dissecting needles is obtained by heating and cooling in tallow or oil; this, with needles, may be readily done in a common tallow (not composite or paraffin) candle. While the needle is soft, it may, by the exercise of a little dexterity, be hammered out so as to form a small knife, or lancet, which can then be hardened so as to take a cutting edge; many useful instruments can also be made out of small pieces of steel. Needles and cutting instruments are best sharpened upon a very hard, white stone, known at the tool shops as Arkansas oil-stone; it cuts very rapidly, and gives an extremely fine edge. Scissors, when blunt, may readily be sharpened on the oil-stone, by opening the blades and rubbing them on the stone, holding them nearly upright. The burr produced by this operation need not be ground off, as it is soon removed when the blades are worked together; the screw is to be tightened if required. For delicate dissections, the steadiest cutting instrument is a kind of scissors, made almost exactly like a minute pair of sheep shears, and known as the microtome; in use, it feels very much as if the fingers were extended and armed with cutting edges. There is hardly any other cutting instrument so much under the control of the operator.

The best handles for needles and other small instruments are made of cedar pen-holders into which the needle, with the eye broken of, is inserted with a pair of pliers. Very convenient handles, which have the advantage of allowing the needles to be removed at pleasure, are to be purchased at fancy warehouses; they are used for holding crochet hooks; they are improved by the removal of the ivory handle, and the substitution of one made of a cedar pen-holder, which can easily be attached to the metal socket with electrical cement, and will be found to be lighter and more pleasant in use.

(To be continued.)

A NEW AND ECONOMICAL METHOD FOR EFFECTING THE EXTRICATION AND CONDENSATION OF AMMONIA FROM GAS LIQUOR

FOR PURPOSES OF CHEAP CARRIAGE, AND FOR FACILITATING THE MANUFACTURE OF AMMONIACAL SALTS.*

By FREDERICK BRABY, F.G.S.

It is but a very few years since that the various bye-products obtained from the manufacture of coal gas were not merely a drug in the market, but proved an absolute nuisance to the manufacturer and to the general public.

Coal tar was even burnt under the retorts, or was introduced therein for the production of gas; and gas liquor was commonly given away to anyone whose ingenuity might enable him to turn it to a useful purpose.

But the progress of science in this, as in other cases, soon discovered applications where none were supposed to exist.

From coal tar are not only now obtained naphtha, benzol, carbolic acid, and other valuable derivatives, but also the brilliant and diversified colours of what are called aniline dyes are obtained from the same source. The ammoniacal liquor, too, to which, on the present occasion, I desire to be favoured with your attention, is now not only not given away in the Metropolitan and other districts, but, in certain localities, the greatest competition exists for its acquisition. It at present constitutes, in this country,

* Read before the British Association, Exeter meeting, Section B.

the principal source of ammonia, and, consequently, of the ammoniacal salts, which are so usefully and so successfully applied in the arts, and more especially to agriculture. In London and its neighbourhood, the purchase of the residuary products of the various gas companies is eagerly sought after, and it is now considered a privilege to be allowed permission to tender for them for the term of one, two, or more years, supply. Practically, the tar and gas liquor trade is in the hands of a few parties jealously desiring to exclude outsiders, who thus find it extremely difficult and often absolutely impossible to obtain even a few thousand gallons.

The object of the present communication is to show how the demand for gas liquor which so far exceeds the means of actual supply can be met. It is to show, moreover, that by condensation and reduction of bulk for transport, small and remote gas works may be enabled to utilise and export their residual products at a profit; and above all, how, by the introduction of certain improvements, the quantity of ammonia as produced and utilised from the manufacture of gas, may be practically increased from ten to fiftyfold.

The strength of gas liquor is commonly specified in the various tenders as technically 6 oz. The prefix, denoting the number of ounces, refers to each gallon of the liquor, and does not signify the number of ounces of ammonia that are present, but the number of ounces of sulphuric acid which would be required to neutralise the ammonia. Consequently a butt of 108 gallons of 6-oz. liquor implies, by calculation, that 108 times 6 ozs. or 40 lbs. of sulphuric acid are required to saturate the whole quantity. Now it is found in practice that, if we divide the quantity of sulphuric acid required by 3, we shall get at the quantity of ammonia actually present. This result closely agrees with theory, the equivalent of dry ammonia being 17, and that of monohydrated sulphuric acid (oil of vitriol) being 49; the proportion is very nearly 1 to 3, It follows, therefore, that, as 40 lbs. of sulphuric acid are required to saturate a butt of 6-oz. liquor, so one-third of this or little more than 13 lbs. of real ammonia are contained in this immense quantity of liquid and merchantable product, weighing as it does in the aggregate no less than 1107 lbs., or half a ton. On referring to the ordinary commercial standard, viz., of 6 ozs. to the gallon, 6 ozs. of sulphuric acid divided by 3 gives 2 ozs. of ammonia as the entire quantity present. Now a gallon of the gas liquor weighs 10 lbs. and, if the lbs. be multiplied by 16 to reduce them to ounces, we have a total of 160 ozs., containing only 2 ozs. of real ammonia or 1 oz. to 80 ozs. of water.

The result of this is, practically, to prohibit the transport of gas liquor over any but moderate distances, because, in its present form, for every ton of real ammonia carried by barge, tank-cart, or otherwise, no less than 80 tons of water must be carried for no other purpose but as a solvent. It must not be inferred, however, that the *whole* of these 80 tons of water is waste carriage. Ammonia in a free state cannot be conveniently carried, except when dissolved in a certain quantity of water. It would not be judicious to concentrate the ammonia to a higher degree than 0·900, since if, in course of carriage, it were subjected to any great degree of heat, the water at an elevated temperature would disengage some of the NH_3 held in solution, and such a disengagement of ammonia might be attended with dangerous results. A very useful and safe solution for all purposes of transit would be about one part by weight of ammonia to four parts of water; this would reduce the present cost of carriage for this important article to no less than twenty times, or, in other words, the transit of a certain quantity of ammonia over a certain distance costing now £20 would, if conveyed in the above concentrated form, be reduced to 20s. This scale of reduction would at once enable it to be carried by rail in petroleum or other barrels, or in tank-trucks, or otherwise, and would bring the numerous gas works which are scattered over the United Kingdom within economical transport of the centres of manufacturing industry, so that this important bye-product of gas-making might be utilised for the general good, and be not so extensively wasted as has been, and is now, frequently the case.

In order to effect this desirable object, I recently, in conjunction with Mr. Baggs, secured a patent for effecting the necessary concentration of ammonia by certain novel means, which promise in practice to prove far more rapid and economical than any hitherto employed. The process may be shortly described as follows:—To the common ammoniacal gas liquor a certain quantity of slaked lime is added. The liquor thus treated is placed in a capacious boiler or still containing from four to five thousand gallons. The whole is then heated and maintained at a temperature of from 100° to 200° F., the liquor being slowly but constantly stirred by means of an internal agitator, the spindle of which passes through a stuffing box in the end of the boiler. A powerful blast of air from a double-action force-pump actuated by a small steam-engine or otherwise, is blown continuously through the liquor. The air enters by two long perforated pipes placed near the bottom of the boiler, and in its upward passage it is compelled to pass through a horizontal diaphragm drilled with numerous small holes. The result of this arrangement being that the air, in its ascent, is subdivided into innumerable small sheaves and bubbles, to each and all of which, in accordance with well-known and recognised laws, the ammonia attaches itself and is carried away with only a very small proportion of aqueous vapour. An exit pipe is fixed to the top of the boiler, so as to carry away the mixture of air and ammonia, and the extremity of this pipe dips into a supply of water contained in a cold and suitable receiver, where the ammonia is immediately absorbed, and the air after thus effecting its removal in a separate state, escapes through the water and is permitted to pass off into the atmosphere. The condensers are generally arranged like a series of what are known as Woulfe's bottles, but for the purpose of obtaining great strength and purity, this arrangement may be superseded in the manner following.

The ammoniacal gas separated by the air is purified in a manner which will be afterwards described, and is then caused to pass into a vessel about three parts filled with broken lumps of pure block ice. From the well-known affinity of ammoniacal gas for cold water, the gas is arrested by the ice, which is rapidly liquefied, and a pure solution of ammonia of any required strength is obtained. It is advantageous to cool down the mixture of air and ammoniacal gas before it is allowed to enter the condenser; the air after having parted with the ammonia which has been dissolved by the liquefied ice, passes off into the atmosphere as in the former instance. The finest Norwegian transparent block-ice may, in the height of summer, be obtained at the London Docks at 23s. per ton, and even less, according to the number of tons required, the supply being constantly maintained by the arrival of fresh ships. Or ice may be obtained by one of Siebe's refrigerating machines almost as cheaply as that which is imported.

This patent process for separating the ammonia by blowing air through gas liquor, when at an elevated temperature, is so much more rapid in the operation than the process of merely boiling the gas liquor as hitherto conducted that, with a very moderate-sized apparatus, several thousand gallons of gas liquor can be treated in a single day, and the ammoniacal produce of the largest works may be continuously converted into a concentrated and more portable form without trouble or delay. Even in the smallest works, consuming not more than from ten to fifty tons of coal a week, the bulk and weight of the gas liquor may be quickly reduced, and the result will be of such standard value that a still containing from 20 to 100 gallons would, probably, in such cases, answer every desired purpose, and would be found to be remunerative. In many instances the gas liquor might be heated and the power supplied, if desirable, from the waste heat of the retorts.

By the adoption of this improved process the present trade in crude ammonia may be expected to expand and to become of higher importance than it now is.

The comparatively limited supply which is now available restricts its application. The commercial advantages which would be derived from the many technical purposes to which it is applicable would be considerable, and manufacturers being enabled to obtain cheap supplies from distant sources, the total quantity utilised would be immensely increased.

When, instead of producing caustic ammonia it is desired to manufacture ammoniacal salts, the ammoniacal gas in conjunction with the atmospheric air may be conducted into sulphuric or muriatic acid, or into a metallic or saline solution capable of appropriating the ammonia.

As the evaporative power of air increases with the absence of moisture therein, it is possible that, by drying the same artificially before introducing it into the liquor, it would take up a great quantity of ammonia. The removal of all moisture from air may be effected with comparatively little expense by the suction of the air required for the force-pump through sulphuric acid, and a close wooden box containing lumps of chalk. This method is well known in connection with other applications.

The blast of air may be hot or cold, and may be delivered in any manner adapted to increase and effect more intimate contact between the air and the liquid containing the ammonia.

By adopting what I call the atmospheric or blowing principle, nearly the whole of the ammonia can be liberated from the solution in which it is contained, without any fire or external heat applied to or under the still or boiler, but, if the liquor be heated, the solubility of the alkaline gas is diminished and its extraction is facilitated.

Gas liquor is, in this country, the most common, and at the same time the most economical, source of ammonia, and the system of extraction by forcing air would, of course, be equally applicable to ammoniacal bone liquor, or to any other chemical preparation in which the caustic ammonia is held in solution.

(To be continued).

NOTE ON THE EARLIER HISTORY OF THE SCIENCE OF HEAT.

By GEORGE FARRER RODWELL, F.C.S.

As a supplement to the lectures on "Heat" which have recently appeared in this journal, it will not, I think, be out of place to give a short account of some of the principal facts connected with the earlier history of the science of Heat. In doing this it will be impossible to preserve any great continuity, my object being rather to indicate some of the old scientific treatises in which experiments are detailed, and to supply the student with a means of reference which the foregoing lectures of necessity could not afford. The memoirs and the works of recent writers on Heat are so well known and so much at the command of all who desire to pursue the study, that it will be sufficient to mention the names only of Cazin, Clausius, Despretz, Franz, Guthrie, Helmholtz, Herschell, Hirn, Joule, Knoblauch, Kopp, Magnus, Mayer, Melloni, Pouillet, Regnault, Balfour Stewart, Tait, Thomson, Tyndall, and Wiedemann.

It is difficult to say when the science of Heat, properly so-called, first arose. It is certainly a younger science than Statics, Dynamics, Hydrostatics, Hydrodynamics. Pneumatics, Optics, Static Electricity, and Magnetism. I question whether Acoustics can be added to this list, although it has ever had the stimulating effect of the art of music, which, in its turn, had the stimulating effect of Church Ceremonial, and attained some perfection in the 16th century, and much perfection in the 18th. M. Libri very truly says "Les recherches des Pythagoriciens sur les vibrations des corps sont les plus anciennes expériences de physique qui soient parvenues jusqu'à nous,"* but we must bear in mind that the results of these experiments were applied to music as an art, rather than to sound as a science. Omitting, then, the question of the precedence of Acoustics, we yet perceive that Heat is amoung the younger of the sciences. This arises from the fact that, until late in the last century, heat was regarded as a chemical agent, and became merged more or less into chemistry proper. Separate treatises on Heat were unknown, but every chemical work devoted some chapters to the acts and operations of fire, "Car en effet," as Lemery remarks, "c'est par le moyen du feu qu'on vient à bout de presque toutes les opérations chimiques." Hence arose such expressions as "Chymick heat," "ye hete of ye chimists fornace," &c., to designate intense degrees of heat. Then, again, the theory of Phlogiston is essentially a heat theory in one sense, but it has ever been regarded as a chemical theory, because the action of heat is so closely associated with the majority of chemical operations that the scientific cared not to step aside to examine the nature of heat itself, preferring to leave the examination of the cause to study that of the ultimate effect. Boerhaave in his admirable *Elementa Chemiæ*, the most extensive chemical work which had up to that time (1732) appeared, devotes a good deal of space to the "instruments" of chemistry, "beginning," as he remarks, "with fire, by reason that no chemical operation ever was, or can be hereafter performed, to which fire does not contribute." (It may be remarked here that *fire* and *heat* were often used as almost synonymous terms by old writers; thus Boerhaave says "Fire expands even the hardest bodies.") I imagine that Francis Bacon's little treatise, *De Formâ Calidi*, was the first attempt to raise Heat into a separate science. It was an utter failure, yet the attempt is to be applauded, for it was the lack of observation and the paucity and obscurity of the knowledge possessed at that time by the world at large in regard to heat, that of necessity resulted in the failure. What are we to say to such an assertion as the following? "Omnino calor cælestium augetur tribus modis; videlicet ex perpendiculo, ex propinquitate sive perigæo, et ex conjunctione sive consortio stellarum." S'Gravesande in his excellent *Physices Elementa Mathematica*—one of the best illustrated works on Physics which has ever appeared, and which may even now be consulted with advantage,—gives 45 pages ("Editio tertia, duplo auctior," 1742) to heat, and 234 to light. He commences the "Liber de igne" with the very pertinent remark in his blunt rugged Latinity, "Pauca de igne norunt philosophi; multa ipsos latent," adding very sensibly (and it is to be wished that his example were more often followed) "Hypotheses non fingam; generaliora, quæ experimentis deduci posse mihi videntur, eo quo potero meliore ordine, dicam."

The production of fire by the refraction and reflection of the rays of the sun was well known to the ancients. The sacred fire of Vesta was re-kindled by the rays of the sun reflected from a metallic mirror, and, according to Pliny, the mirror was sometimes replaced by a glass globe filled with water. Aristophanes clearly alludes to the use of glass lenses as burning glasses in the Νεφελαι.

Lactantius, in his curious treatise, *De ira Dei*, mentions that a glass globe filled with water and placed in the rays of the sun, will kindle fire even in the coldest weather.† Baptista Porta in his ever new, ever interesting treatise, *Magiæ Naturalis*—which links the magic of Art of Eastern

* "Histoire des Sciences Mathématiques en Italie." 1838.

† Lactantius was born about A.D. 250; he died in 326. His works were amongst the first printed in Italy; the first edition issued from the press of the monastery of Subiaco as early as the year 1465, while a second issue appeared in Rome in 1468, in both cases it will be remembered before a single book had been printed in this Island. The passage alluded to above is taken from the tenth chapter, entitled "De mundi ortu, et rerum naturæ, et Dei providentia," and is as follows—"Omitto silicem, ac ferrum. Orbem vitreum plenum aquæ si tenueris in sole, de lumine, quod ab aqua refulget, ignis accenditur etiam in durissimo frigore."

civilisation with the magic of Nature of Western civilisation, Chaldæan mysticism and Theurgy with the Realism of the Renaissance,—Baptista Porta mentions the fact that heat, sound, and cold may be reflected by mirrors in the same manner that light is reflected. As a delicate instrument of observation in the case of the reflected cold, Porta placed his eye in the focus of the mirror, as, some two and a half centuries later, Dr. Tyndall placed his eye in a focus of dark heat rays in order to see whether any light accompanied the heat rays. Porta's account is interesting; it occurs in the seventeenth book, and is entitled "Calorem, frigus, et vocem speculo concavo reflectere." "Si quis candela in loco," he continues, "ubi spectabilis res locari debet apposuerit, accedet candela per aerem usque ad oculos, et illos calore et lumine offendet, hoc autem mirabilius erit, ut calor, ita frigus reflectitur, si eo loco nix objiciatur, si oculum tetigerit, quia sensibilis etiam frigus percipiet." Somewhat later Hamerus Poppius calcined antimony "per radios solares" with the use of a lens, in order to determine whence came the gain of weight. Bonaventure Cavalieri, the discoverer of infinitesimals, writing in 1632, states that he was able to inflame dry substances by reflecting the heat emitted by a charcoal fire by means of a spherical speculum; by using a parabolic reflector he produced the same effect at a distance of 5 feet, a small fire of wood being the source of heat. He recommends a hyperbolic reflector, and asserts that the impressions of heat, cold, sound, and scent move in straight lines.* Athanasius Kircher has also treated of reflection in his *Ars Magna Lucis et Umbræ*.

The term "radiant heat" was introduced by Scheele in his treatise entitled *Luft und Feuer*. Pictet in his celebrated *Essais Physiques sur le Feu* (1790) demonstrated the enormous velocity of propagation of radiant heat; he also treats of the absorption and reflection of heat, and of latent and specific heat. Prevost made known his "Theory of Exchanges" in 1791 through the medium of the *Journal de Physique*.

Black discovered "latent heat" about the year 1760; his pupil Irvine introduced the term "capacity for heat," while Gadolin replaced it in 1784 by the term "specific heat." In connection with the determination of the specific heats of various substances, the following names are most prominent:—Wilke, Lavoisier, Laplace, Kirwan, Dalton, Dulong, Petit, De la Rive, Regnault, Favre, Silbermann, Bérard, De la Prevostaye, and Desains.

As regards the air thermometer I am inclined to think that Galileo invented it about the year 1597; some attribute it to Sanctorio of Padua, others to Cornelius Drebbel of Alcmaer, while others, again, maintain that it was discovered by each of these men independently of each other. Some of the members of the Accademia de Cimento first constructed a fluid thermometer in 1655 or 1656. Edmund Halley introduced mercury in the place of alcohol. Otto von Guericke was the first to take the freezing of water as the lowest limit of the scale, while Renaldini, in 1694, proposed the boiling and the freezing points of water as the opposite limits of the thermometric scale. A kind of rude differential air thermometer is mentioned by Sturmius in his *Collegium Experimentale sive Curiosum* (1676). Sir John Leslie described the differential air thermometer which bears his name, in 1804 in his "Experimental Enquiry into the Nature and Propagation of Heat."

Leslie's principal work is his "Essay on Heat" in which he described the radiative and absorptive power of various substances, and determined the laws which regulate the radiation of heat. He maintained, however, that air is as essential to radiation as it is to convection.

The subject of the conduction of heat was discussed at some length by Lambert in his "Pyrometrie" published in 1779, but the earlier mathematical treatment of the subject is due to Fourier, and is detailed in a paper entitled "Thèorie Analytique de la Chaleur," communicated to the Academie des Sciences in 1807. His definition of conductivity is extremely lucid, and he has treated of the cooling of an uniformly heated sphere with great ingenuity and elaboration. Poisson and Carnot have also applied the higher mathematics to the elucidation of various questions connected with the science of heat, and in our day Helmholtz, Clausius, and Thomson.

Mariotte and Hooke observed that glass cuts off many of the rays of radiant heat. M. De la Roche discovered in 1812 that radiant heat which has passed through glass has lost the rays which glass most readily intercepts, and that, as the temperature of the radiating source rises, so does the readiness of the radiant heat to pass through glass increase. Nobili and Melloni worked together on the subject of radiant heat. The former invented the thermopile, while the latter made the important discovery that rock-salt is very transparent to all kinds of heat, and that, by using lenses and prisms of rock-salt, dark heat rays may be refracted exactly in the same manner that light is refracted by glass. These results were published in the celebrated treatise entitled "La Thermochrose, ou la Coloration Calorifique," and were at first received with some credulity by the Parisian *savans*.

The most notable experiments in connection with the polarisation of heat were made by Bérard in 1812 (*Memoires d'Arcueil*, vol. 3), and later by Forbes.

The Abbé Rochon endeavoured to determine the comparative heating effects of the various coloured rays of the spectrum as early as the year 1776; he employed a flint-glass prism and an air thermometer, and reckoned the heating power of the red rays to be about eight times greater than that of the violet. In 1798 Leslie (?), by using a differential air thermometer, found the calorific energies of blue, green, yellow, and red to be as 1 : 4 : 9 : and 16. In 1800, Sir William Herschell employed a small mercurial thermometer for the same purpose, and arrived at the conclusion that the hottest part of the spectrum is beyond the red rays. A detail account of recent research on this subject (specially of the "long spectrum of the electric light") will be found in Tyndall's work "On Heat treated as a Mode of Motion."

The history of heat theories has not been alluded to above because the history of the kinetic theory was discussed at some length in the first of the foregoing lectures,* and I have elsewhere† treated of one of the phases of the material theory. Bergman's *De Materia Caloris* may also be consulted by those who are interested in this part of the subject. Of recent works on Heat I would specially mention Clausius "On the Mechanical Theory of Heat;" the treatise of Tait "On Thermodynamics;" the *Thèorie De la Chaleur* of M. Desains, and the *Thermodynamique*, of M. Bertin ‡

It is hoped that the above facts—desultory though they be—may be of interest to those who desire to follow the literature of the science of Heat in greater detail than is possible in lectures, which are rather for purposes of demonstration than for the discussion of facts connected with the history of a science.

International Exhibition of Amsterdam.—Professor Pepper is now giving an instructive lecture at the Royal Polytechnic on the "Tentoonstelling." While speaking highly of the inhabitants, the lecturer refers at length to their industrial pursuits, and illustrates the lecture with enlarged views of the Exhibition as well as some curious costumes worn by the Netherlanders. The lecture occupies less than an hour in delivery, and gives a very clear idea of the country and its people.

---

* Cavalieri was born in Milan in 1598; he died in 1647. The above is extracted from a work entitled "Lo specchio Ustorio: onero trattato delle settioni Coniche et alcuni loro mirabili effetti intorno al lume, caldo, freddo, suono, et moto ancora." Bologna, 1632.

* CHEMICAL NEWS, vol. xx., p. 13.

† "On the Theory of Phlogiston," *Philosophical Magazine* for January, 1868.

‡ The last two treatises are published in the *Recueil de Rapports sur l'état des Lettres et les Progrès de Sciences en France*, a series of which it would be difficult to speak too highly.

THE LATE DR. THOMAS GRAHAM, MASTER OF THE MINT.*

On Thursday, September 23rd, the remains of this distinguished man, attended by a number of his sorrowing relatives and personal friends (among the former of whom were his sister, her husband, and family), were conveyed to their last resting place in the High Church Burying Ground, Glasgow.

But few persons were privileged to any intimate acquaintance with Dr. Graham. He was never strong enough physically to allow him to mix much with society; he was always, or with rare exception, strong enough to toil in the field of science. Even scientific men, owing to his retiring habits, have not seen so fully the bearing of his labours, as they have seen of that of others in kindred pursuits, which will have much less influence. The reason of this will be at once apparent when we consider that he never pursued a merely popular or fashionable subject of investigation, and that he never sought a fashionable assembly in which to disclose the results of his labours, nor did he ever leave his own field of inquiry, although all the highways around him were bustling and busy, and if any person occasionally ventured near him it was only to find that there was nothing to be seen till he pointed something out. We do not pretend to be able to see and appreciate the entire significance of his scientific life—it would for this require much more study than we have given to it—and it will probably require many years for scientific men to develop the ideas originated by him. We can only endeavour to picture to ourselves the scene as he found it, and again as he left it touched by his master hand. Picturing in this connection is scarcely the right word—slight sketching is a phrase too strong for all that we can here attempt.

The general mind of the time has not yet arrived at a right apprehension of chemistry proper. The prevailing notions on the subject, even among well-educated persons, relate to the chemistry of a byegone time, and belong rather to the end of the last century than to the science of the present day. In that earlier time, the elements or simple bodies had been increased in number, and it was that there existed numerous bodies hitherto unsuspected. England had proved the existence of many of these elements, France had arranged them, adding more, and giving a theory of their action, and making a preliminary science from the materials thus created. Lavoisier saw first the qualities of combinations made by metals and other solid bodies with gases, and gave us a definite and clear nomenclature for the science. Wenzel and Richter tried long to make it clear that the constituents of substances must be proportionate and definite, but it did not appear possible to perceive by what innate process these proportions could be produced, and the whole question seemed to involve an inpenetrable natural mystery. Dalton, in the simplicity of his mind, looked on matter as composed of exceedingly small bodies, probably round in form, like those conjectured by his great predecessors, from Leucippus to Newton, and thought that if we have one substance represented by black marbles, and another substance by white marbles, neither of which could be broken or divided, we cannot help forming definite compounds in chemically uniting them. That great idea of Dalton has been at the root of all advance in the science, and if any analysis is in contradiction to it, we at once deem it incorrect. When Dalton was publishing his opinions Graham was born, and it seems that from very early manhood it had been his desire to know more of the movements of these atoms. In a paper by him as early as 1829, he showed that diffusion of gases takes place among ultimate particles or atoms, and not between sensible masses. This, then, was a new step. Dalton had shown why they combined in definite proportions, Graham showed that there was another property, a distinct movement—a vitality, so to speak, among the atoms. If, as Graham found, gases diffused through porous substances, such as he operated with, they were not driven forward mechanically, so that the mixture should pass like water, but the diffusion volumes are inversely as the square root of the densities of the gases employed in the experiment. If the gases were pressed out or expelled from the containing membrane, no air would return to supply their place; but it was found there was always an interchange of gases—for example, when hydrogen (contained in a tubular glass vessel having its open ends closed with stucco plugs), spontaneously passed through the stucco, air passed in with a velocity denoted by 1277; if carbonic acid were used it passed out, whilst air passed in with a velocity of 623 only. Chlorine being used, the air passed in with a velocity equal to 302. From these results Graham was led to believe in Dalton's idea that gases were as *vacua* to each other—an imperfect explanation of the phenomena—although it was empirically correct. In 1831 he said—"The law at which we have arrived, which is merely a description of the appearances, and involves, I believe, nothing hypothetical, is certainly not in accordance with the corpuscular philosophy of the day, and is altogether so extraordinary that I may be excused for not speculating further upon its cause till its various bearings and collateral subjects be fully investigated." Graham leant, however, to the belief that the cause was the existence of an attraction of the particles of one gas for the particles of another, an attraction existing on the surface of the gaseous molecules. This idea led him to study the diffusion of liquids. In this inquiry he came to the conclusion that "diffusion" is a property of a fundamental character upon which the properties depend, such as the volatility of substances. Liquid diffusion thus supplies the densities of a new kind of molecules. "The fact that the relations in diffusion of different substances refer to equal weights of these substances and not to their atomic weight or equivalents is one which reaches to the very basis of modern chemistry. In liquid diffusion we deal no longer with chemical equivalents or the Daltonian atoms, but with masses even more simply related to each other in weight than the former. Holding still by the chemical atoms we may suppose that they can group together in such numbers as to form new and large molecules of equal weight, or of weights which have a simple relation to each other. It is this new class of molecules which appeared to play a part in solubility and liquid diffusion, and not the atoms of chemical combinations." The vast importance of this conclusion, resting upon experimental evidence, every chemist will at once understand.

It will thus be seen that, after a struggle of twenty years, Graham was able to speak of chemical movements not essentially connected with the atomic theory of Dalton. Still, it must be remembered, that these are movements, not combinations. They had, however, an important bearing on decompositions produced by liquid diffusion.

It was in examining this question that he observed the low diffusive power of albumen compared to common salt, for example, and conceived a mode of proximate analysis for mixed animal fluids. Strange to say, he found this diffusive power of liquids was closely allied to volatility. This is due to a cause about the last that even cultivated people generally would have imagined. Diffusion, as practised, was simply the passage through a thin membrane of gelatinous matter, or, as we may say, of parchment-paper as the material used. By observing this, he was able to divide bodies in solution into two classes, severally called by him "Colloids" and "Crystalloids." If a liquid containing examples of these two bodies were placed in a vessel, one side of which is of parchment-paper, whilst on the other or outside of it there was water, it was found that the crystalloid substance passed through the paper into the water, whilst the colloid substance remained. In his earlier papers on

* Communicated.

the diffusion of gases, he had shown that it was only in the hypothesis of self-motion that we could account for the motion of the air within the smaller vessels of the lungs, as they could not be inflated or filled by the action of the chest and diaphragm, which removed only about 20 cubic inches of air at a time, while there were 300 cubic inches of air to he filled and emptied. In this paper on diffusion, the passages of saline fluids through membranes are explained; and the separation of bodies in solution is also shown by a similar self-acting process. We cannot follow him further into his ideas respecting colloid substances, which, he says, possess *energia*. He regards these latter as being matter in a dynamical state, whilst crystalloids are matter in a statical or rest condition. Ever, we should observe, does Graham look at the ultimate properties of bodies; he keeps the atom in view, or, at least, the fundamental matter, and always finding some new property regarding it, freed from the thousand years of exhausted speculation, but illuminated by experiment and answers obtained by such acute cross-questioning of Nature as no one before him, in that department, at least, ever equalled. We may say, further, without fear of contradiction, no one has succeeded, by such original paths, in obtaining an entrance into the domain of Nature. In speaking of diffusion through membranes, he makes it quite clear that the latter does not act as a filter. The substance is mechanically impenetrable: molecules pass through it, not masses. These molecules are moved by the power of diffusion. It was when examining the action of a septum of caoutchouc separating gases that his attention seems to have been called to the surprising passage of gases through the homogeneous substance of a plate of fused platinum, or of iron at a red heat, as discovered by MM. St. Claire Deville and Troost. He enquired if this had any relation to liquefaction, and concluded that such a term could only be applied in a vague way to bodies so elastic and volatile at an elevated temperature as the gases are, and hydrogen in particular. Still, since dissolving and liquefying must be allowed, with such a fact before us as silver retaining twenty volumes of oxygen at a red heat, Graham also believed that the absorption of gases by a liquid (such as carbonic acid by water) is not a purely physical effect. It appears to involve some relation in composition. In the composition of the bodies, he adds—"May a similar analogy be looked for of hydrogen to liquid on colloid bodies of the metallic class?" It was in following up this idea that he came to the conclusion that hydrogen might pass into metals, and form with them an alloy. This alloy he succeeded in making, and a medal of palladium and hydrogenium was struck in his honour. The hydrogen in this condition and connection was called hydrogenium, in order that the name might have a termination like the names of the metals which it resembled. The palladium contains nine hundred volumes of a substance so light as hydrogen, and so many thousand times lighter than itself. This brilliant discovery had other results. Iron was found to absorb gases when cooling; and it was, therefore, possible to know in what gas iron did cool by finding the gas shut up or included in it. The technical value of this may still be very great; but Graham cared little for such results. He sought cosmic truth; and he had a wonderful proof of his own correctness by the examination of cosmic phenomena. He found that the gas which was shut up in iron made by man was carbonic oxide, but the iron from space, or meteoric iron, contained hydrogen. This gas he took for us out of the meteoric iron, and burnt it. It was hydrogen. Strange that at that time a small star had increased in brilliancy, and become a large one. The spectroscopist found, by the evidence of the spectrum lines, that hydrogen was burning. Graham's quiet and, to all appearance, uninteresting, unimportant, and even dull, experiments, that nobody cared to share with him, had at last resulted in two of the most brilliant facts, which even cultivated minds must long wonder at and admire. Reference to one of his latest speculations must finish our present notice of this distinguished man. That gases have initial movements as one of their original properties, and that the speed of these movements severally may be their main distinction. This would take them out of the region of chemistry proper, and bring them into physics; but physics and chemistry are, after all, fundamentally one. A new field is unfolded to us; new work must be done, and new workers are required. Who among us will give up all the ordinary gratifications and amusements of life to work in this field like Graham? Who among his fellow chemists will do work worthy of being placed beside his? We may freely say that such another will not soon arise, and, if our country produces such a man in a century, she does her duty well, even if the rest are only of average powers.

We cannot go into the detail of the labours of Graham. We have left out his enquiries into the action of water, basic and constitutional, in chemical compounds; his able papers on the arseniates and phosphates; and we have said nothing of osmotic force by name; neither have we done justice to his enquiries on effusion and transpiration; but we have hastily, after his funeral, tried to remember the main points of a great scientific life, and we trust they will be more closely studied than heretofore by all scientific men. We are almost ashamed to allow such a meagre account to stand as representative of the labours of such a man; but it is only for a little, as a longer and more detailed life must soon be written by men who will give much time, care, and competent thought to every portion of the publication. We need scarcely speak of Graham in private. Such enquiries will always have one result in showing that he was pure-minded, just, generous, and kind-hearted to the uttermost. Humble he was, quiet, and as simple-minded to the last as if he were always the same hoping, trusting youth that he seemed to be when he first began to lecture in the Andersonian Institution thirty-nine years ago. By his death, Scotland has lost, at a somewhat early age, one of her brightest scientific names, and Great Britain and the world one of the greatest chemists of the present or of any period.

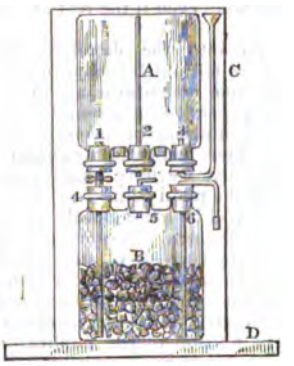
LABORATORY NOTES.

ON A CONVENIENT FORM OF SULPHURETTED HYDROGEN APPARATUS FOR LABORATORY USE.

Of the many forms of apparatus that have been proposed for the generation of sulphuretted hydrogen, very few allow themselves to be changed so as, at a moment's notice, to give a steady and constant stream of the gas without a slight but continuous escape taking place. In large laboratories, where many analyses are being carried on at the same time, and a large amount of the reagent used, the form described by Fresenius in his "Qualitative Analysis," similar to the hydrogen apparatus used in making sulphuric acid chambers, is all that can be desired. Lead, however, is scarcely a suitable material for smaller apparatus, and glass must be substituted. The old form, with three bulbs, is sometimes used, but these are expensive, and objectionable, inasmuch as, when charged, but not in use, the acid is only prevented from falling and acting on the sulphide by the volume of gas below, so that a variation in the temperature, or very slight leak in the connections, or even the porosity of many varieties of india-rubber tubing, is sufficient to keep up a constant action. The form to be described combines, on a small scale, the advantages of both.

In the figure, A and B are two Woulf's bottles, each furnished with three necks, one held over the other by

means of two wooden supports, passing between the necks, and so shaped as to fit the bottle, firmly secured to a backboard, C, which, again, is strongly fixed to the base-board, D. A may be rendered more secure by further connecting it with the backboard at the top. Each of the necks is fitted with a good cork. A short and rather broad tube is inserted in cork No. 1. No. 4, opposite to it, is furnished with a tube of equal size, reaching to the bottom of B. These tubes are connected by means of a piece of india-rubber tubing, with sufficient space free to allow of the latter being closed by a Mohr's pinch-cock. Through No. 2 passes a small tube, reaching to the top of A and terminating immediately below the cork. In No. 3 is inserted an acid-funnel, the tube reaching on the



inside just above the cork, and bent upwards outside so that the funnel shall be on a level with the top of the apparatus. Through No. 6 passes a tube long enough to reach to the bottom of B: the outside end of this is bent downwards, and terminates in a small piece of india-rubber tubing, which can be plugged with a piece of glass rod. The central neck is furnished with an exit-tube for the gas, the stream from which must be regulated by means of an india-rubber tube and screw-clamp. About one-third of the lower bottle is filled with small pieces of flint, and on this the sulphide of iron is placed.

To charge the apparatus, the tube at No. 6 is closed, and sufficient acid poured down the funnel to cover the sulphide. When the egress of the gas is stopped, the liquid passes up through No. 4 to A, the air in the latter escaping through the small tube at No. 2. When all the liquid has ascended, the connecting tube at No. 4 is closed by means of the pinch-cock, and the lower bottle relieved from the pressure. When the acid becomes exhausted, it may be drawn off by removing the stopper at No. 6, when, if the liquid is in the upper vessel, it will at once run off; if, however, the exhausted solution is in the lower vessel, it must be removed by blowing in at No. 5. The outside limb of No. 6 may be made long enough to act as a syphon, when the necessity of blowing would be avoided: it would then, however, be easily broken.

E. W. Parnell.

Runcorn, Sept. 25th, 1869.

MISCELLANEOUS.

The Proposed New Chair in the Andersonian Institution.—In our Students' Number we stated that Mr. Young's new chair of technical chemistry had been accepted by Mr. W. H. Perkin; and, as the appointment had received the sanction of the trustees, we were justified in making the announcement. We are, however, now informed that the managers have asked the trustees to cancel the entire arrangement, and we accordingly hasten to notice this fact, especially as the present Professor of Chemistry in the Institution considers our announcement detrimental to his interests. We have received two pamphlets, one being Dr. Penny's remonstrance and appeal against the appointment of an additional Professor of Chemistry, and the other Dr. Adams's reasons of protest; from these we gather that, as Dr. Penny has always instructed his pupils in technical chemistry, and as his income is derived from class-teaching, the new chair would greatly interfere with his interests. Dr. Penny has expressed his willingness to consider any arrangement for carrying out Mr. Young's intentions, provided his titles, rights, &c., are preserved; or, for the actual progress of the Institution, he is willing to vacate his chair on condition of receiving a reasonable compensation for his apparatus and the loss he would sustain. We have no doubt that Mr. Young will adopt some means of carrying out his munificent endowment, without that injury to present interests which it would certainly cause if the original scheme were to be adopted without considerable modifications.

Irrespirable Air of the Wine-Must Fermenting Tubs.—M. Saintpierre.—It is a well-known fact that the four Departments of the South of France, named l'Hérault du Gard, l'Aude, and Pyrénées-Orientales, produce, year after year, about 12,000,000 hectolitres (every hectolitre is rather more than 22 gallons) of wine; every hectolitre of must gives off an average 2500 litres of carbonic acid gas, and, since the size of the fermenting tubs is such that each one contains with ease 400 hectolitres of liquid, one may readily imagine what a quantity of carbonic acid there will be disengaged, considering that, during the short space of from 2 to 3 weeks, from 500 to 1000 hectolitres of must are ready for fermentation in confined localities, generally of no more cubic capacity than 1000 cubic metres (rather more than 35,600 cubic feet). The gas given off during the fermentation has a rather high temperature, and is, moreover, charged with the vapours of various ethers and alcohols, simultaneously the products of the fermentation. Even to those accustomed to this sort of atmosphere its effect upon the system is very marked. Quicklime is very commonly placed in the cellars wherein the fermenting tubs are placed, and a good ventilation kept up. The author of this paper has found, however, that nitrogen is among the products of fermentation; he states that, in 1868, he found that the atmosphere of a large tub could not support the combustion of a candle, although the empty tub (the must and dregs had been removed from it for fully 24 hours before his visit) contained a large quantity of quicklime, and no indication was found of carbonic acid. On analysis of the air contained in this tub it proved to consist, in 100 parts, of:—Oxygen, 11·85; and nitrogen, 88·15. Only the best possible ventilation and plentiful use of lime and lime-water can make cellars wherein these fermenting tubs are placed fit for work-people.—*Journal de Pharmacie et Chimie.*

CHEMICAL NOTICES FROM FOREIGN SOURCES.

In accordance with the generally expressed wishes of our friends and readers, we have effected arrangements to enable us to give, under the above heading, notices of every chemical paper in the world, *as soon as possible after publication. Whenever possible, these notices will appear in the form of carefully prepared, although necessarily brief, abstracts; as respects papers either too long or too abstruse to render condensation possible, their titles will be chronicled; and in all cases accurate reference will be made to the original publication. The two half-yearly volumes of the* Chemical News, *with their copious indices, will therefore be equivalent to an English edition of the "Jahresberichte," with the additional advantage of keeping the readers week by week on a level with the latest advances of science.*

Note. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus des Séances de l'Académie des Sciences, October 4. 1869.

A great portion of this number is devoted to lengthy discussions upon the manner in which the metrical system has been obtained. Those who have a desire to impugn its accuracy have brought forward several alleged facts relating to inaccuracies committed during the geodesical surveys which preceded the introduction of the *metre*. It is satisfactory, however, to find that these inaccuracies are only imaginary, and the discussions here alluded to fully bring out the important fact that those who desired to detract from the value of the work of the committee of 1790 are mistaken, even so much so as to confuse works of far later date (1808) with those done in 1789 and 1790.

Artificially-Crystallised Silver Amalgam.—M. E. Dumas.—It appears that at the Mint at Bordeaux (France now keeps up three

mint establishments—one at Paris and one at Strasbourg), there has been left standing, in an iron mercury bottle, a quantity of about 10 kilos. of that metal, which had been used to extract the silver out of some refuse residues. On filtering through chamois leather, there were left upon the filter a certain number of well-defined crystals, which, on analysis, were found to contain, in 100 parts:—Silver, 27·4; quicksilver, 72·6; and traces of gold. The native amalgam of these two metals contains, in 100 parts, silver, 36, and quicksilver, 64, corresponding with the formula $AgHg_4$. The crystals above alluded to correspond to the formula, $AgHg_8$.

Disappearance of the Acids of the Grape and their Probable Conversion into Sugar.—M. Petit.—The author states that the ripening of grapes is accompanied by the disappearance of a large quantity of acid. Green, unripe grapes yield, on an average, 36 grms. of acid to the litre. When the grapes ripen, they double in bulk, and ought, if only water had been added during the process of ripening, to have yielded 18 grms. of acid to the litre, while only from 5 to 6 grms. is detected by analysis. It should be stated that this result is not due to the saturation of the acid by bases, since the ripe grape contains less base than the ripe grape does.

Constitution of Pseudotoluidine.—M. Rosenstiehl.—The author gives the following *resumé* of his paper on this subject:—"I wish to acknowledge an error formerly made, to point out that the constitution of pseudotoluidine is not yet accurately known and well established." Lastly, the author states that he does not intend to pursue studies on this subject any further. The paper is chiefly a critical review of the labours of others on this subject as compared with those of the author.

Cosmos, October 2, 1869.

Manufacturing Manure from Offal of Wool.—M. Pichelin.—Fifty kilos. of this offal are mixed with 33 kilos. of concentrated sulphuric acid and 35 kilos. of nitric acid, sp. gr., 1·321. This mixture is well stirred up for about ten minutes, and next mixed with some native phosphate, coprolites, for instance, in the proportion of 100 kilos. of the acid mixture to 200 kilos. of very finely ground up phosphates. This manure becomes, in forty-eight hours, as hard and dry as rock, so that it has to be ground up again under mill-stones.

Conservation of Wood by Solutions of Salts of Copper.—M. Morin states that he has in his possession wooden water-wheels which have been in use for more than 1500 years for the evacuation of water from a copper mine. These wheels have a diameter of 6 metres; and, on a portion of the wood being analysed by M. Payen, it was found to be perfectly sound, and to be partly converted into a compound of cellulose and copper, precisely similar to that which is formed in Boucherie's process for the preservation of wood by sulphate of copper.

Tanned Cotton, also called cotton-leather, is prepared by treating cotton fabrics in a similar manner to that in which skins and hides are treated for the manufacture of leather. Cotton hereby acquires greater strength, and is more enabled to resist the effects of moisture and disintegrating efforts.

Zeitschrift für Chemie von Beilstein, No. 16, 1869.

We find in this number the following original papers:—

Test for Arsenic and the Preparation of Hydrochloric Acid free from Arsenic.—M. Bettendorff.—When arsenious or arsenic acid is dissolved in fuming hydrochloric acid, and there is added thereto a solution of protochloride of tin dissolved in hydrochloric acid, a brown-coloured very bulky precipitate, which rapidly settles down, is formed, which precipitate, after having been collected on a filter and washed, first with hydrochloric acid, next with water, to remove the latter entirely, constitutes, after having been dried over sulphuric acid *in vacuo*, a greyish coloured powder, of metallic aspect; this, on being rubbed in an agate mortar, exhibits metallic lustre, and is volatile on being heated, while oxide of tin, in the shape of a very light powder, is left. On being analysed, the precipitate was found to consist of from 98·46 to 95·86 per cent of metallic arsenic, according as to its preparation, arsenious acid, arsenic acid, or arseniate of ammonia and magnesia had been applied. The precipitate could never be obtained quite free from tin. The author further states that when the hydrochloric acid employed has a sp. gr. of 1·115, the arsenious or arsenic acids dissolved therein become, if not entirely, at least for the major part, converted into chloride of arsenic; and the reaction described, therefore, takes place between that chloride and protochloride of tin. When the hydrochloric acid has a sp. gr. of 1·100, the arsenious acid is not converted into chloride of arsenic, but is dissolved as arsenious acid; chloride of tin does not act upon combinations of antimony under the same conditions. The author advises that crude hydrochloric acid, sp. gr. 1·164, should, in order to eliminate all arsenic from it, be treated with a strong solution of protochloride of tin in pure HCl, left standing for twenty-four hours, the precipitate removed by filtration, and the acid next placed in a retort, the first 1-10th of the distillate kept separately, and the remainder distilled off to dryness, when that portion will be found absolutely free from arsenic; the first 1-10th might, in some cases, retain 0·02 per cent of that metal.

Orthoxylol, a New Modification of Dimethyl-Benzol.—MM. Bieber and Fittig.—The authors have discovered a new hydrocarbon, C_8H_{10}, which differs from isoxylol and methyl-toluol, and has been named by them *orthoxylol*. It is a fluid body, and boils at 141°; it is distinguished from other substances of isomeric composition by the difficulty wherewith it yields nitro-combinations, and, also, by the slow action which a mixture of chromate of potassa and sulphuric acid exerts upon this substance.

On Bromotoluol, Bromotoluol-Sulpho Acid, and Isomeric Sulpho-Hydrate of Toluol.—MM. Hübner and Wallach.—This rather lengthy paper is not at all suited for any useful abstraction with due justice to the labour of the authors.

Action of Sulphurous Acid upon Chlorids of Platinum.—M. Birnbaum.—The author reviews, at some length, the labours of other investigators on this subject, and then states that, when ammonio-chloride of platinum is placed in a concentrated aqueous solution of sulphurous acid, and the mixture heated on a water-bath, care being taken to keep excess of sulphurous acid, a yellow solution is obtained; this solution was evaporated to dryness, again some aqueous SO_3 added to it, and dried over SO_3. A compound was obtained in crystalline state, which contained platinum, ammonium, chlorine, and sulphurous acid—$Pt:3Cl:SO_3:2NH_4$. When the strongly acid solution of ammonio-chloride of platinum in sulphurous acid was saturated with carbonate of potassa, a salt was obtained wherein the different component bodies were contained in the proportion expressed by $Pt:3Cl:SO_3:2NH_4:K$. This salt is the potassa salt of the acid first obtained by the action of SO_3 upon ammonio-chloride of platinum in combination at the same time with chloride of ammonium. The formula of the acid just alluded to is—

$$Pt\left\{\begin{matrix}Cl\\HSO_3\end{matrix}\right\}+2NH_4Cl.$$

The author succeeded, by means of a complicated set of experiments, in substituting, for both atoms of chlorine of the chloride of platinum, the radical HSO_3, and thus obtained a crystalline compound—

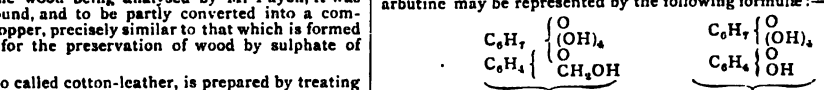
$$Pt\left\{\begin{matrix}HSO_3\\HSO_3\end{matrix}\right\}+2NH_4Cl+H_2O.$$

No. 17, 1869.

This number contains the following original papers:—

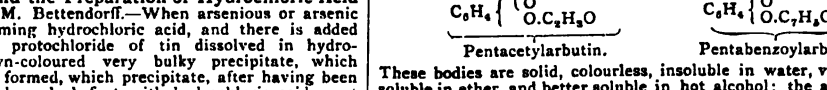
Contribution to our Knowledge of Isomerism in the Benzoic Acid Series.—M. Hübner.—This memoir is a critical review of the labours of M. V. von Richter on the subject above named; and the author defends his own experiments on this subject, and proves that M. V. von Richter has made several mistakes. The paper is not suited for abstraction.

On Arbutine.—M. A. Schiff.—Just in the same manner as salicine can be split up into glycose and saligenin, arbutine is split up into glucose and hydrochinon. The relation between salicine and arbutine may be represented by the following formulæ:—



Salicine — Glycosalicyl-alcohol. Arbutine — Glycohydrochinon.

Benzoyl-arbutine is prepared by means of chloride of benzoyl; the acetyl-arbutine is prepared by the action either of acetyl-chloride or of acetic anhydride. The final products of these reactions contain five acid radicals, and are made up according to the following formulæ:—



Pentacetylarbutin. Pentabenzoylarbutin.

These bodies are solid, colourless, insoluble in water, very slightly soluble in ether, and better soluble in hot alcohol; the acid radicals can be removed by boiling with weak bases. The author's paper is full of a series of formulæ similar to those here quoted; he states that an aqueous solution of arbutine reduces freshly precipitated oxide of silver readily at a low temperature. A solution of arbutine yields, with solution of perchloride of iron, a deep blue colouration, which gradually disappears; but the derivatives obtained from arbutine do not do so.

Isomeric Nitrotoluols and Toluidines.—MM. Beilstein and Kuhlberg.—After referring to the experiments made on this subject by M. Rosenstiehl, the authors state that the party just named did not enter into any particulars as regards the splitting up of nitrotoluol ihto its different components—that is to say, all of them nitrotoluols differing from each other by slightly modified properties, the various bodies being distinguished by the prefixes *a*, *β*, and so on. The paper is rather a catalogue of formulæ, and is divided into five sections, treating of the sulpho-acids; toluidines and para-toluidines; aceto-toluides; toluidine derived from xylol; and *β* chlorotoluol, $C_6H_4Cl.CH_3$. The authors, moreover, state that this paper is intended only as a general survey of the subject, and that they continue their researches thereon.

Isomeric Nitro-Ethyl-Benzol and Xylidine.—MM. Beilstein and Kuhlberg.—*a* nitro-ethyl-benzol boils at 246°, has a specific gravity of 1·124 at 25°, and is a yellow-coloured fluid; *β* nitro-ethyl-benzol is also a liquid, boils at 227°, sp. gr. 1·126 at 24°. The *a* compound is capable of yielding acids; not so the *β* compound. *Xylidine*, $C_6H_3.C_2H_5.NH_2$, corresponding to the *a* nitro-toluol, *boils 214°*, is a limpid liquid which becomes readily brown-coloured on exposure to air; sp. gr. 0·975. The *β* xylidine boils at 210°. Acetoxylide, $C_6H_3.NH(C_2H_3O)$; the *a* compound boils at 317°, fuses at 94°, and is somewhat soluble in hot water; the *β* compound is readily soluble in hot water, and boils at 305°; both are solid bodies.

On Dichloric and Trichloric Benzoic Acid.—MM. Beilstein and Kuhlberg.

Derivatives of Benzol obtained from Toluol.—MM. Beilstein and Kuhlberg.—These papers are not well suited for abstraction.

On Paratoluidine.—MM. Hübner and Wallach.—Paratoluidine is a liquid which in pure state resists a cold of −21° without becoming solid, is very readily soluble in alcohol and ether, and rather soluble in water; with acids, it yields salts which crystallise. Sulphate of paratoluidine, $(C_6H_4NH_2.CH_3)2SO_4H_2$, is very readily soluble in water. Acetoparatoluide, $C_6H_4.CH_3.NH.C_2H_3O$, is a solid body exhibiting needle-shaped crystals, fusing at 105°, soluble in alcohol and ether, but not readily soluble in water.

Solubility of Nitrates in Nitric Acid; Separation of the Nitrates of Potassa and Soda from each other.—M. C. Schultz.—Nitric acid does not form acid salts. Several nitrates which are readily soluble in water are difficultly soluble in nitric acid; and this fact explains why silver, lead, and iron are not readily acted upon by very concentrated nitric acid. One part, by weight, of the undermentioned salts require for their solution in—

	The First Hydrate of Nitric Acid, HNO_3.	Hydrated Nitric Acid, $2HNO_3+3H_2O$.	
		(At 20°.)	(At 123°.)
	Parts.	Parts.	Parts.
KNO_3	1·4	3·8	1
$NaNO_3$ ..	66·0	32·0	4
$LiNO_3$ ..	200·0	—	—
$AgNO_3$ ..	500·0	30·0	6

The nitrates of baryta, strontia, and lead are as insoluble in both the above-named nitric acids as the sulphates of these metals are in water. The nitrates of potassa, rubidium, and ammonia are readily soluble in hydrated nitric acid. The author is of opinion that the by far greater solubility of nitrate of soda than nitrate of potassa in nitric acid might be applied to the separation of these salts from each other; but the author very properly observes, also, that working with nitric acid, especially on the large scale, is, in many instances, impracticable. For analytical purposes, this plan is not suitable, since chloride of sodium is rather insoluble in nitric acid.

No. 18, 1869.

This number contains the following original communications:—

Researches on the Sulpho-Acids of Benzol.—M. Ross Garrick.—This paper contains an enumeration of the most prominent salts of the three following acids:—From benzolsulpho acid, C_6H_4Br,SO_4HO; isobromobenzolic acid, $C_6H_4BrSO_3HO$; benzoldisulpho acid—

$$C_6H_4\begin{cases}SO_3HO\\SO_3HO\end{cases}$$

Without reproducing a very lengthy series of formulæ, the chief contents of this paper, we do not find therein anything worth much notice, and therefore abstain from further quotation of its contents.

New Method of Converting Fatty Acids into their Alcohols.—Dr. Saytzeff.—This is simply a preliminary notice, *pour prendre date*, written from Kasan. The author says that, when sodium amalgam is suffered to act upon a mixture of fatty acids and their anhydrous chlorides, the alcohols belonging thereunto are obtained; for instance, acetic acid and acetyl-chloride yield ethylic alcohol. The author promises full and complete details in a future paper.

Formation of Aniline from Bromide of Benzol.—MM. Hübner and Alsberg.—This paper is also marked "preliminary notice." It is written with the object of elucidating the question, Whether the atoms of hydrogen contained in benzol do all occupy the same rank? In order to settle this point, the authors have set to work to obtain, from different bromated and chlorinated benzols, anilines, and to compare these mutually. For this purpose, bromide of benzol was nitrified, with the result that two varieties of bromonitrobenzol were obtained; one of these compounds, evidently, is the same as that described by M. Couper; the other compound is a monobromonitrobenzol, fusing at about 38°, and yielding, on being amidised, two bromoamido compounds. The bromonitrobenzol (Couper's) fuses at 125°, and yields, on being treated with tin and hydrochloric acid, an amido compound, $C_6H_6BrNH_2$; this, on being first treated, while in alcoholic solution, with sodium, and next with chloracetyl, yielded an acetanilide, fusing at about 116°, soluble in water, and more readily soluble in alcohol and ether. The authors promise full details on this subject afterwards.

Thihydrobenzoic Acid.—MM. Hübner and Upman.—A short "preliminary notice." When sulphobenzoic chloride is brought into an apparatus wherein hydrogen gas is briskly evolved from tin and HCl, a white substance is separated, which, on being collected on a filter, washed with water, dissolved in ammonia and re-precipitated by HCl, and boiled in alcohol to which HCl is added, there is obtained a solid crystalline substance, a compound which, on being submitted to elementary analysis, was proved to consist of $C_6H_4.SH.COOH$; this body the authors have named thihydrobenzoic acid; it fuses at 242°, is difficultly soluble in alcohol, and insoluble in water.

Jahrbuch der Kaiserlich-Königlichen Geologischen Reichsanstalt. First two numbers for 1869.

Of this periodical, published by the Austrian government, one number is published at the end of each quarter of the year. Very frequently these papers contain the results of chemical researches and analyses, and these we briefly abstract:—

Phosphatic Nodules from the Chalk Formation of Russian Podolia.—Dr. Alth.—Leaving the purely geological portion of this paper, and the discussion on the origin of the phosphatic nodules in general, and especially of the variety here alluded to, the author states that the result of the analysis for this mineral is, for 100 parts:—Water, 0·65; silica, 14·18; lime, 26·12; fluorine, 11·69; alumina, 0·99; phosphoric acid, 23·50; iron (*eisen*), put down as metal, 9·23; cobalt, 4·60; manganese, 1·40; sulphuric acid, 2·10; magnesia, 3·52; potassa, 1·20; loss, 0·82.

Analyses of Several Kinds of Common Salt from Galicia.—M. A. von Kripps.—This paper is sub-divided into several sections. The average composition of rock-salt from Stebnik is, in 100 parts:—Chloride of sodium, 90·281; chloride of potassium, a trace; chloride of magnesium, 0·286; chloride of calcium, 0·508; sulphate of lime, 8·245; water, driven off at 160°, 0·680. Rock-salt from Kossow contains, in 100 parts:—Chloride of sodium, 98·0; alumina, 1·7; loss by heat (water driven off at 160°), 0·2. We have only selected a couple of samples from among a number of about one hundred. It appears that Galicia is very well provided with deposits of rock-salt, which is wrought out by mining processes, and that, by boring, saline springs of sufficient strength to admit of boiling down and obtaining salt thereby, are found in large number.

Researches on the Mineral Water of Rajec-Toplitz.—M. E. Glasel.—In a remote portion of the Comitate of Trentschin, near Sillein, a mineral spring is met with, the water of which is the subject of this memoir. The temperature of this water varies from 26·5° R. to 20·4° R. The water is colourless, devoid of smell, has a saline astringent taste, and exhibits, in its natural state, alkaline reaction. In 100 parts, the composition of the dry saline residue is quoted as follows:—Calcium, 52·63; magnesium, 33·29; sodium, 9·21; potassium, 2·83; aluminium, 2·02; oxide of iron, a mere trace; carbonic acid, 82·17; sulphuric acid, 16·57; chlorine, 1·31; silica, 0·80; phosphoric acid and iodine, a trace; free carbonic acid, 7·05; sp. gr., 1·000768.

Bulletin de l'Académie Royale des Sciences, des Lettres et des Beaux Arts de Belgique, No. 7, 1869.

This number contains only one paper relating to chemistry:—

Presence of Chloride of Sodium in the Water and Rocks of the Coal Formation of Luijk (Liège).—M. R. Malherbes.—The paper here quoted is not the original work of the author, but two reports on his paper, one of which is written by the well-known M. Omalius D'Halloy, the other by M. Dewalgue. Both these gentlemen differ from the author above-named, as regards his opinion that the formation of coal should have taken place in salt-water ponds; but they also state that it is difficult to explain why some samples of sandstone of the locality above named should contain 0·101 per cent of chlorine, while in other samples of the same stone, and in the same locality, no chlorine is found at all. Some of the schistose rocks contain 0·085 per cent of chlorine; others, again, none of this element, notwithstanding they are found close by each other and evidently belong to the same geological formation.

Journal de Pharmacie et de Chimie, September, 1869.

This number contains the following original articles:—

Laws which Regulate the Part any Substance Plays between Two Solvents.—MM. Berthelot and Jungfleisch.—A paper on this subject, recording researches of the same nature, was published by these authors, and noted by us from the *Comptes Rendus*, therefore we do not further allude to it here.

Purifying of Bromide of Potassium.—MM. Bobierre and Herbelin.—The authors state that when bromide of potassium is adulterated, or mixed with iodide of potassium, it is, in order to detect this, only necessary to place a few grains of the salt in question on paper previously impregnated with starch paste, to moisten it, and admit a small quantity of chlorine gas, whereby the iodine is set free and the paper coloured blue. A better test, given by the authors, is the use of bromine, added to the salt after it has been placed under benzol; if the latter becomes red-coloured, iodine is present. The title given to this paper should have been "On the Detection of Iodine in Bromide of Sodium."

Preservation of Eggs.—M. Violette.—The main results of this paper are the already long known facts that eggs may be kept in perfectly fresh state by varnishing them over with a so-called drying oil, linseed oil being preferred on account of its cheapness; poppy-seed oil also answers this purpose perfectly well.

Bayerisches Industrie und Gewerbeblatt, July and August, 1869.

These two numbers, published together, contain, among the officially-published material, most excellently drawn-up and well-digested law, and police regulations, for the management and traffic of the railways of the Kingdom of Bavaria. The duties, as well as the rights, of the officials thereby employed, as well as of the travelling public, are clearly and distinctly defined, and every care and precaution is taken to insure the safety and comfort of all concerned. Even in a technical point of view, this document deserves the notice of all who have anything to do with, or authority over, railways, which, as evidenced also in Bavaria, are better managed, and with more profit to the nation at large, by the State than by private companies.

Ceramic Industry of Krönningen, Lower Bavaria.—Dr. Wimmer.—The kingdom of Bavaria is rich in various qualities of

clay fit for the most varied kinds of pottery, from the finest china, made near Nymphenburg, to the coarse but highly refractory clay which is made up in so-called Passau melting pots. The clay referred to in this paper, after having been dried at 100° (whereby it lost 21 per cent of water), gave, on being analysed, the following results for 100 parts:—Water, and trace of organic matter (lost by ignition), 2·02; alumina, 27·42; oxide of iron, and traces of oxide of manganese, 6·88; lime, 5·60; magnesia, 0·20; potassa, 0·18; silica, in combination, 19·20; sand and free silica, 38·40. No traces, even, of sulphuric and phosphoric acids, chlorine, and carbonic acid could be detected. This clay is fit only for very coarse pottery.

Schools for Brewing in Bavaria.—Dr. Zingerle.—It appears from this paper that there exist, at Munich and Augsberg, excellently arranged schools wherein everything which relates to the brewing of beer is taught practically and theoretically; and, from the enumeration of the students who attend, they being natives from various European countries, as well as from America, this instruction seems to be highly valued.

Polytechnisches Journal von Dingler, first number for August, 1869.

This number contains the following original papers relating to chemistry:—

Manner in which the Nitrogenous Substances are Divided in the Potatoes.—M. Dietzel.—This lengthy paper contains researches made by the author with the view to determine what portion of the tuber of the potato is richest in protein compounds; and since, according to this author, there exists a peculiar relation between the quantity of the fatty matter contained in this, as well as in other vegetables, he concludes that, where the largest quantity of fat is there also is relatively the largest quantity of protein. The results are quoted as follows:—The layer nearest the skin contains—Proteinoid, 14·16; fat, 0·66; quantity of proteinoid for one part by weight of fat, 21·45. Interior of tuber contains—Proteinoid, 9·50; fat 0·38; quantity of proteinoid for one part, by weight, 25·00.

Use of a Vacuum in Brewing.—M. Jicinsky.—This paper is so entirely of a practical nature that it is not exactly suited for our pages; but the author certainly proves the great benefits brewers would gain by adopting the use of vacuum apparatus.

Second number for August, 1869.

Among the original papers relating to chemistry, we find in this number:—

Peculiar Steam-Boiler Incrustation.—M. Reichardt.—On visiting a manufactory situated on the higher portion of the Thuringian river Saale, the author noticed a boiler incrustation, which, from its very dark brown colour, appeared almost to consist of an oxide of iron containing manganese. The analysis gave the following results:—Water, driven off at 100°, 2·10 per cent; insoluble in hydrochloric acid, 17·12; soluble therein, 80·78 per cent. Full analysis, in 100 parts:—Water, at 100°, 2·10; white clay and sand, 8·87; oil and pitch, 8·25; sulphate of lime, 1·80; peroxide of iron, 1·20; protoxide of iron, 0·22; carbonate of lime, 68·52; carbonate of magnesia, 9·60. The dark colour is due, not to the oxide of iron, but to the organic matter, oil, and fat, partly decomposed by the high temperature, and converted into a kind of pitch.

Chemical Investigation of Tablettes de Bouillon Russes.—M. Reichardt.—The substance here alluded to is not in commerce in the western parts of Europe, and is manufactured from the meat, not only of cattle, but also that obtained from game, which latter is very plentiful in the less inhabited portions of Poland and Russia. The researches of the author, who obtained the genuine material from a friend of his who resides in Russia, yielded the following results for 100 parts:—Water, at 180° (without any decomposition), 21·7; fatty matter, 0·22; nitrogen, 10·57; ash, 4·75; soluble in alcohol, 38·09 per cent. The author, having purposely compared these meat lozenges (for so they may be called) with Liebig's extract of meat, comes to the conclusion that the extract is superior in every respect, but that this is counterbalanced by the relative cheapness of the lozenges, and their very convenient portability and non-liability to decay.

Neues Jahrbuch für Pharmacie, von Dr. F. Vorwerk, July, 1869.

This number contains the following original communications and papers:—

Researches on those Resins Derived from the Convolvulaceæ, which Act as Drastic Purgatives.—MM. Köhler and Zwicke.—This paper contains an historical review of the discovery and older analysis of *Scammonium jalappa*, and other substances less generally known and now obsolete in Europe, formerly used as physic, and produced by plants belonging to the natural order above named. The chemical researches of the authors are confined to convolvuline and jalapine; the former expressed by the formula $C_{72}H_{50}O_{32}$, the latter by $C_{68}H_{54}O_{32}$. These two substances behave with reagents in the following manner:—

Convolvuline is not soluble in ether, and is precipitated by it from its alcoholic solution; is entirely insoluble in benzol; when evaporated to dryness along with nitric acid, convolvuline becomes violet red-coloured upon the addition of SO_3. The acid solution of convolvuline is precipitated by alum solution. The alcoholic solution of convolvuline is not precipitated by a solution of nitrate of protoxide of mercury. Nitrate of silver produces, in solutions of convolvuline, a pulverulent, non-adhesive precipitate, immediately becoming black-coloured.

Jalapine is perfectly soluble in alcohol and ether; is soluble in benzol, but rather difficultly; but is readily taken up by benzol from its alkaline solutions when these are shaken up with benzol. Jalapine, treated as described, is not coloured at all. Acid solution of jalapine remains quite clear and undisturbed on being treated by alum solution; alcoholic solution of jalapine is precipitated by nitrate of protoxide of mercury, yielding a bulky, caseous precipitate, insoluble, also, on heat being applied. Nitrate of silver produces a bulky, caseous, whitish grey, clotted precipitate in solutions of jalapine, and this precipitate is only slowly changed by the action of the light.

These reactions may serve to distinguish between genuine resin of jalap, and between scammony and its resin.

Description of a Practical Chlorine-Water Apparatus.—Dr. Duflos.—There is added to this paper a woodcut, and, without reproducing it, it is not an easy matter to make this apparatus understood. The chief point is that the pressure of the gas escaping from a mixture of 2 ounces of dry bichromate of potassa, and 11 ounces of commercial hydrochloric acid, is made to saturate, with chlorine gas, 8 lbs. of water, by making the gas to force, by pressure, this quantity of water from one Woulf's bottle into another.

Detection of Wheaten Starch among Arrow-root, and of Wheaten Flour among Starch.—Prof. Boettger.—Take 1 grm. of the material to be tested, put it in a porcelain dish, and add 180 c.c. of distilled water; apply heat, and boil the mixture briskly while stirring continuously and briskly with a glass rod. Any starch which is quite free from gluten—for instance, pure potato starch, or pure arrow-root—will not exhibit, when treated in this way, any foam on the surface of the liquid as soon as the stirring is discontinued; but when the starch happens to contain the slightest trace of gluten, in other words, flour, there will appear on the boiling liquid, during the stirring up, a strong foam, which is so strong that it often resembles the foam on soap-suds.

August, 1869.

This number contains the following original papers:—

Gelatinæ Medicatæ in Lamellis.—Dr. Huseman.—This paper treats on the preparation of a peculiar kind of lozenges, pills, and gelatinous capsules fit to serve as vehicles for either very strong pharmaceutical preparations, which can only be given in very minutely small doses, such as as atropine, strychnine, and the like, or substances which are very disagreeable to the taste, as *balsamus copaivæ*, cod-liver oil, &c. The paper is strictly a pharmaceutico-technical one, and we therefore allude no further to it.

Preparation of Pure Hydrochloric Acid.—Dr. Rieckher.—The author mixes crude hydrochloric acid, sp. gr. 1·170, (containing 34·25 per cent real HCl), and sulphuric acid, sp. gr. 1·830 (containing 93 per cent of monohydrated acid), in the proportion of 100 parts, by weight, of the latter acid and 40 parts of the former (HCl), leaving, after distillation, whereby the HCl is volatilised, a sulphuric acid of 1·650 sp. gr. The loss of HCl in this operation amounts to about 3·5 per cent.

Cultivation of Opium in Germany.—M. Jobst.—This paper is altogether of a botanico-technical nature, treating on the mode and commercial advantages of cultivating the *Papaver somniferum* for the purpose of obtaining opium of good quality, which appears to be perfectly possible in some parts of Southern Germany.

Detection of Alcohol in Chloroform.—M. Blacher.—Add to the suspected chloroform a small piece of caustic potassa, and leave the fluid at rest for a few minutes; then add distilled water, and shake the chloroform therewith. Decant the water, and add a solution of a salt of copper to the aqueous fluid; if a precipitate ensues, the chloroform contains alcohol. Another, and perhaps more reliable, plan to detect alcohol in chloroform is to add to the latter a small piece of quite dry caustic potassa and a piece of reddened litmus-paper; if the latter becomes blue on being shaken up with the chloroform, it is sure to contain alcohol, provided always that it is quite anhydrous.

Revue Hebdomadaire de Chimie, September 16, 1869.

Names Given to Spirituous (Alcoholic) Liquids.—M. Mené.—It frequently happens that some industrial, or commercially-adopted, term for an alcoholic fluid is not properly understood, and this especially is the case with what, in and out of France, is known as *trois six*, 3-6. All alcoholic liquids are designated according to their strength, as indicated by Cartier's areometer for spirituous liquids. Liquids from 16° to 20° are called *eau de vie*, strictly translated water of life, or life-giving. Holland proof is spirit of 19° Cartier, strong *eau de vie*, brandy marks 21° or 22°. Above that degree, the fluids are named *esprits*, *spiritus*, and, by means of certain cypher figures, written as fractions, the greater or smaller quantity of water which these fluids require, in order to be reduced to the state of ordinary *eau de vie* of 19°, is expressed; for instance, *trois six*, 3-6, is an alcohol of 33°, three parts of which, by bulk, produce six parts of *eau de vie*. The *trois sept*., 3-7, is alcohol at 35°, three volumes of which form seven volumes of *eau de vie* at 19°. The word brandy is, no doubt, a contraction for *brantwein*, meaning, literally, burnt wine, since real genuine brandy is obtained by the distillation of certain wines, not as such fit for beverage.

Les Mondes, September 16, 1869.

Another Successful Artesian Well.—The well-known M. Say, the owner of the most extensive sugar refinery in France, situated on the Boulevard de la Gare, at Paris, has just got completed, at his manufacturing premises, the boring of an artesian well. At 562 metres

below the surface, a water layer has been reached, yielding 7000 litres of water per minute. The water, which has a temperature of 28° above zero, on reaching the surface rises to a height of between 20 and 30 metres above the end of the bore-hole at surface level. The cost has been 300,000 francs, and the work has been completed within four years, by the successors to the celebrated MM. Mulot, St. Just-Dru.

Comparative Review of the Composition of Milk from Various Mammiferæ.—In 1000 parts of milk, the undermentioned quantities of the following substances are contained in the milk of the animals respectively quoted:—

	Water.	Butter.	Caseine.	Sugar.	Inorganic matter.
Women	889·08	26·66	30·30	43·68	1·30
Cows	864·20	31·30	45·30	47·70	6·00
She Goats	844·90	56·87	35·14	36·91	6·18
Ewes	832·32	51·31	09·78	39·43	7·16
Mares	004·30	24·36	53·35	32·76	5·23
Asses	890·12	18·53	35·65	50·46	5·24
Sows	818·00	60·00	52·00	60·70	8·30

September 30, 1869.

Strengthening and Rendering Woven Tissues Impermeable to Water.—M. Neuman.—A sulphuric acid bath is made containing acid varying in strength from 40° to 66° Beaumé (specific gravities 1·384 and 1·850), and kept at a temperature of 57°. The woven tissues, cotton or linen, are rapidly passed through this bath, being only left in contact with the acid for from ten seconds to two minutes, according to the nature of the tissue, which is immediately after passed through very cold water, and next submitted to a thorough washing process. The effect of the action of the acid is an incipient dissolution, and formation of a varnish-like matter, which, especially after it has been regularly spread over the fabric, and incorporated therewith by hot-pressing and calendering, greatly increases the strength of the fabric, rendering it simultaneously impervious to water.

Annales de Chimie et de Physique, September, 1869.

This number is entirely filled up with a lengthy monograph, which bears the title—

New Researches on Thermo-Chemistry.—M. Berthelot.—We confine our abstraction to the headings of the different parts and sections of this paper. *Endothermic and exothermic reactions*:—Combinations formed with absorption of heat; on double decompositions; formation and decomposition of formic acid; fermentations and constitution of sugar; on compounds which develope heat when becoming decomposed and in nascent state; formation of protoxide of nitrogen and the decomposition of nitrate of ammonia; chemical action of light; on action by contact; on isomeric transformations; on the influence and effects of pressure upon chemical phenomena; changes of temperature produced by the mixing of divers fluids; general principle involved in all chemical reactions. *On pyrogenetic equilibrium*:—Decomposition of organic substances by heat. This memoir will be continued in another number of this periodical.

Journal für Gasbeleuchtung, August, 1869.

Among the original papers contained in this number we notice:—

What is Cheap Gas?—Dr. Schilling.—The contents of this paper, which is written with an evidently large amount of technical and commercial knowledge on this subject, might be very advantageously translated by our excellent contemporary, the *Journal of Gaslighting*. The idea of cheap gas is, indeed, a very relative one, since it is possible, by those well acquainted with all the *minutiæ*, of gas-making, to manufacture gas which, though nominally cheap, may, by want of "durability," and even with a high illuminating power, be very expensive to the consumer.

Photometrical Studies.—M. Elster.—This paper, and the following—

Purification of Coal-Gas—M. Buhe—are excellent treatises on the subjects, but, unfortunately, too lengthy to admit of any useful abstraction. As regards the purification of gas, it is quite clear, from the manner in which this subject has been taken up abroad that it deserves deeper looking into than is generally done at gas-works.

Monatsberichte der Königlich Preussischen Akademie der Wissenschaften zu Berlin, May, 1869.

This number does not contain any papers at all relating to chemistry or sciences allied thereto.

June, 1869.

This number contains the following original papers relating to chemistry and allied sciences:—

Preparation of Silicic Acid in Crystalline Shape by the Dry Way.—M. Rose.—The paper is identical with that which appeared on this subject, written by the same author, in the *Berichte der Deutschen Chemischen Gesellschaft*, No. 14, 1869, from which it has been abstracted.

Relation of Chloral and Trichloracetic Acid to the Animal Organism.—Dr. Liebreich.—This paper relates a series of physiological experiments aided by chemical reactions. It appears that hydrate of chloral may become a very useful and safe anæsthetic.

Emission and Absorption of Heat Radiated at Lower Temperatures.—M. Magnus.—The author states—"Different bodies heated to 150° emit, by radiation, different kinds of heat; some bodies only emit one kind of heat. Rock salt belongs to those substances which, if it is quite pure, emit different kinds of heat. The author then enters into discussions on diathermancy, and the power of absorption for certain rays of heat; but the paper is too concisely written to admit of any further useful abstraction.

Moniteur Scientifique, October, 1869.

This number opens with a short paper on—

Artificial Alizarine.—M. Kœchlin.—To this paper is added a set of printed-calico patterns, dyed in five different species of colours, viz., black, puce, scarlet, pink, and violet, respectively produced by the artificial alizarine of Messrs. Meister and Lucius, as made by them at Hoechst, near Frankfort—madder, garancine, alizarine from madder, and purpurine from madder, both sublimed. From the author's paper, it appears that the substance made by the firm just alluded to is neither artificial alizarine nor purpurine, but a new compound, superior to both these substances. Alizarine, indigotine, and luteoline are correlated by the property of being crystallisable by sublimation. Purpurine does not yield solid colours until after it has been sublimed.

Test for Detecting Very Minute Quantities of Iodine.—M. Alfraise.—Take water, 100 grms., starch, 1 grm., nitrite of potassa, 1 grm.; boil this mixture during five minutes, and, after cooling, pour it in a bottle, wherein it keeps for years without deterioration. When required for use, take 10 c.c., add one single drop of hydrochloric acid. Take as much as a pin's head in size of the dry salt to be tested for iodine, place it in a clean porcelain capsule, and add one drop of the test-fluid last mentioned. When no iodine is present, no coloration ensues; but the least trace of iodine gives rise to the formation of a well-defined blue colour. The liquid test-fluid, after addition of HCl, keeps quite well in a properly-stoppered small bottle.

NOTES AND QUERIES.

Carbonic Acid.—Can any of your readers give me some practical information respecting the manufacture of the above by Harrison Blair's process, viz., the passage of common or superheated steam over red-hot limestone enclosed in fire-clay retorts?—CO_2.

Spectrum of Sirius.—In the hydrogen line, F, of the spectrum of Sirius, that line is not exactly coincident with the solar line, F. If, then, this deviation exists in that line, should not the like condition occur with respect to the lines of sodium, iron, &c., which I do not understand Mr. Huggins to state?—W. P.

Magic Lantern Light.—I require a powerful light to show to an audience the microscopic image enlarged upon a white sheet in a darkened room, and would take it kind if any of your readers could tell me—(1) Will the magnesium lamp do (the room is a comparatively small one); (2) whether is Solomon's or Larkin's powder-lamp best, and (3) where can I obtain or hear of Larkin's lamp (mentioned in the CHEMICAL NEWS, vol. xv., p. 323)?—C. HUNTER.

Detection of Artificially-Coloured Red Wine.—Dr. Wittstein.—The author states that he was desirous to try whether the statement of M. Facen that peroxide of manganese has the property of decolorising naturally red-coloured wine, but leaving the colour of artificially red-coloured wines untouched when, after having been simply for some time in contact with the peroxide, it is filtered off from that material again. The author had some genuine good red wine, the produce of his own vineyard, and also experimented upon some samples obtained from wholesale houses: and he found that, after treatment with peroxide of manganese, all these samples lost their red colour; and, according to Facen's statement, there might be assumed that none of these samples of wine were artificially coloured. The author then added to a genuine red wine about 1-25th part of its weight of mallow flowers (Flores Malvæ arboreæ), which are largely used for colouring wine; and, at the same time, the author repeated this experiment with a very faintly straw-yellow-coloured white wine, obtaining thus beautifully red-coloured wines. On shaking these up with peroxide of manganese, the artificially-coloured samples were, however, found as readily decoloured after filtration as the genuine red wines had been; therefore M. Facen's test does not hold good.—*Polytechnisches Centralblatt*.

TO CORRESPONDENTS.

Ferrum.—Send us sample, with full particulars, as we know o several who use it.

Amatta.—You will find particulars for making sympathetic ink in Cooley's "Cyclopædia of Practical Receipts."

THE CHEMICAL NEWS.

Vol. XX. No. 517.

ON MICROSCOPICAL MANIPULATION.*

By W. T. SUFFOLK, F.R.M.S.

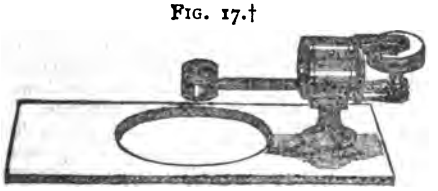
(Continued from p. 182.)

The processes connected with the preparation and preservation of microscopical objects have always occupied a considerable space in nearly every work on the use of the instrument. The subject is one of general interest, and the importance of being able to preserve specimens for future reference can scarcely be overrated.

The simplest of these processes, and also the oldest, is that known as "dry-mounting."

The objects suitable for mounting dry are those which can be preserved in air and are capable of being dried without injury to their structure. The ways of mounting are extremely numerous, and are principally means of protection from the great enemies of all natural history preparations—damp and dust. One of the oldest ways of mounting objects was upon discs punched from a compound sheet of card and wash-leather, through which a pin was run for convenience of holding in the stage forceps and keeping in a cork-bottomed drawer. This plan of mounting was abandoned when the lieberkuhn fell into disuse, but it has since been revived in a new form by the late Richard Beck, who invented a very ingenious instrument for holding the small

Fig. 17.†



discs of metal and turning them into any required position. This is an extremely useful piece of apparatus, as it is often required to turn an object into several positions for the thorough examination of its structure. So perfectly is this accomplished, that five out of the six sides of a cube may be examined by means of the revolving disc-holder. This instrument has supplied a want created by the introduction of the binocular microscope, as the greater focal depth and stereoscopic effect given by it has rendered advantageous frequent changes of the position of objects, for which this contrivance most effectually provides. For the keeping of the discs from the influence of dust and damp, he contrived a close-fitting screw-box, having suitable arrangements for the reception of twenty-four discs.

Great use has also been made by some observers of open cells. These consist of a hole bored in a 3 × 1 slide of wood, with a piece of card-board glued to the bottom, the objects being fastened with a little gum. This answers very well with objects not liable to injury from exposure, such as shells; but, for most purposes, it is necessary to close up the object, and this, in many instances, is done in a manner very detrimental to its preservation. Wherever paper and paste or gum are used, various fungi and confervæ are nearly sure to make their appearance, unless special precautions, such as saturating the paper with, and mixing in the gum, a small quantity of corrosive sublimate. The microscopical fungi are doubtless interesting plants, but, when they grow over valuable preparations, we feel them to be a nuisance, and decidedly in the way.

Some microscopists, avoiding the use of paste, gum, and paper for securing the cover to the slide, have made use of varnishes of several kinds These generally have the defect, if thin, of running in between the glass and cover and spoiling the object, and, if thickened with a solid substance, such as lamp-black or vermillion, of becoming porous after a time. Some of the fluid medium of the varnish, also, is liable, in drying, to rise in vapour within the cell, and condense on the cover, interfering with the distinct view of the object. The vapour of turpentine or naphtha, however, is in no way otherwise detrimental, as it tends rather to the preservation than the destruction of tissues.

The electrical cement previously described (Chemical News, vol. xx., p. 181) is free from this defect, and furnishes a means of rapidly mounting objects either with or without a cell. If the object is very thin and flat, it may be placed upon a slide, and a thin glass cover put over it. Both having been carefully cleaned, one of the spring clips made of wire and cork (which are to be procured of most opticians) can be used to hold the cover in place while the cement is being run round it with the little brass bit. The bit should not be made too hot, or it will not hold the cement. After the cover has been fastened down, the rough cement can be smoothed by passing over it a clean bit, heated rather more than is required for laying on the cement. The bit is easily cleaned by wiping while hot upon a piece of blotting-paper. The first attempts, no doubt, will be far from elegant in appearance; but, after a little practice, great neatness may be attained. This process is also available for attaching the cover to cells of metal or glass, which must be used with dry-mounted objects whenever their thickness is such as to require it. This mode was formerly much employed, but was abandoned on account of the brittleness of the cement. This may be remedied by varnishing, when the cement has become hard, with gold-size, which is remarkable for the tenacity with which it adheres to glass and its toughness and non-liability to crack. Respecting the properties of this varnish, more will be said in the chapters relating to fluid-mounting. This system of compound cementing answers perfectly; the electrical cement having, in the first instance, no tendency to run in, and the gold-size effectually keeping it from separating from the glass. If the natural red colour of the electrical cement is objected to, a black finish can best be obtained by the use of lamp-black as prepared for water-colour painting. The best form is that in tubes. A little of this is pressed from the tube, and, if too thick, a small quantity of water added. With this the varnished surface is thickly painted, and, when dry, a few coats of gold-size will

* The substance of a course of lectures delivered to the members of the Quekett Microscopical Club, January—April, 1869.

† This, with several other woodcuts, have been kindly lent by Messrs. R. and J. Beck, of Cornhill.

keep it from being washed off. The result is a dense, lustrous black, very superior in effect and durability to that produced by a black varnish. This finish is equally available for fluid and balsam mountings.

If the object cannot be kept in its place by the pressure of the cover glass, it will require fastening. If the object will bear a slight amount of heat, a small spot of electrical cement may be placed on the glass, melted by holding over a lamp, and, while soft, the object fixed. Or the thick varnish composed of shellac and wood-naphtha, sold at most varnish-shops as liquid glue or "patent knotting varnish," will be found useful for this and other purposes to be mentioned hereafter. Care must be taken to allow the naphtha time to evaporate, or its vapour will obscure the cover. While this drying is taking place, the slide may be turned face downwards over a large pill-box, or the cover put on, and kept in place with a spot or two of electrical cement, deferring the completion until the varnish has dried.

It is not necessary to employ any kind of black background for opaque objects, the best background being that of the dark-well beneath the stage, formed by bringing round that part of the diaphragm-plate which has no hole, and so closing up the aperture. If a black patch is used, it prevents advantage being taken of various kinds of illumination from beneath, which are often of great service, while the mounting on clear glass is in no way detrimental to the view of an object lighted from above.

It is necessary that the object to be mounted should be perfectly dry before it is placed in the cell, otherwise moisture will, sooner or later, make itself apparent.

Most objects can be dried by the application of a moderate heat. If wrapped up in a piece of paper, and placed inside the fender, in an hour or so they will be found to be effectually dried. A Seidlitz-powder box answers extremely well for this kind of drying: it can be still more effectually accomplished by means of the well-known hot-water oven.

There are cases, however, where heat is inadmissible, especially with delicate tissues. The desiccation of these is best accomplished in a vacuum. The substance to be dried is placed under the receiver of an air-pump; the air is exhausted, and, under these conditions, it will give off vapour at a much lower temperature than under ordinary atmospheric pressure. It is only necessary to provide some means of absorbing the watery vapour as fast as it is given off—such as concentrated sulphuric acid or dry lime.

Another, and very effectual mode of drying delicate tissues without heat, is the process described in the CHEMICAL NEWS (vol. xiii., p. 122), translated from *Zeitsch. fur Anal. Chemie.* This process, which is quite new so far as its application to microscopical purposes is concerned, consists in immersing the substance to be dried in ether in the presence of dry chloride of calcium. The apparatus employed is simple, consisting of a wide-mouthed stoppered-bottle, at the bottom of which is placed some chloride of calcium. A slice from the bowl of a tobacco-pipe forms a support for a Berlin crucible and cover, in which the substance to be dried is placed. The whole is then covered with ether (the methylated answers very well for the purpose), and the mouth of the bottle closed. The ether absorbs water from the tissue, which is again absorbed by the chloride of calcium, and the process goes on without attention until the chloride of calcium ceases to absorb. The results, as far as at present ascertained, have been very satisfactory. Cellular tissue (fresh potatoe) has been dried without any contraction. Flies' heads have contracted less than by drying in air; the eyes were in very perfect condition, and gave good results upon a section being cut; the striation on the muscular fibre was perfectly preserved. A small spider, treated by this process, was dried without any shrinking of the abdomen. Those substances which are injuriously acted upon by ether cannot, of course, be dried by this process; but it is evidently a very valuable addition to the microscopist's resources.

When the object is removed from the drying apparatus, the ether dries off in a few seconds. If it is required to preserve the object in balsam, it can either be mounted at once, wet, with ether, or transferred to benzole or turpentine.

(To be continued.)

A NEW AND ECONOMICAL METHOD FOR EFFECTING THE EXTRICATION AND CONDENSATION OF AMMONIA FROM GAS LIQUOR FOR PURPOSES OF CHEAP CARRIAGE, AND FOR FACILITATING THE MANUFACTURE OF AMMONIACAL SALTS.*

By FREDERICK BRABY, F.G.S.

(Concluded from p. 184).

The principles already indicated may, perhaps, be illustrated with advantage by a brief description of a working-plant actually constructed at Deptford for the purpose of extracting ammonia. An excavation has been made in which is sunk a reservoir for containing the gas liquor, and having the following dimensions:—namely, 35 feet long, 7 feet wide, and 6 feet deep. The bottom is formed of 1 foot of concrete, two courses of bricks, and of two courses of red flat tiles; the sides are of 14-inch brick-work, two courses with tiles in conjunction with concrete.

The wrought-iron still is set in brick-work, so that flame may play more than half round its external surface. It is 30 feet long by 6 feet in diameter. About 4000 gallons of gas liquor are pumped into it from the reservoir for the purpose of being operated upon.

Heat is applied by means of a fire underneath, but a coil of hot air or steam pipes placed in the interior of the still or boiler would be equally efficacious. Two cast-iron 3-inch air-pipes, which are attached to the ammonia generator, extend along its whole length, and are situated one on either side, and nearly at the bottom. They are perforated with holes increasing in size as they extend from the inlet. Into these pipes, and from them into the gas liquor, is driven atmospheric air by means of a pair of cast-iron force-pumps. These are 20 inches in diameter, 1 foot 8 inches stroke, with rods and slings, wrought-iron connecting rod and crank, and a cast-iron beam 6 feet long. On the entry of the streams of air they are caught and agitated by the twelve iron fans of a stirrer, making about 80 revolutions per minute.

The air, together with the lime and the various constituents of the gas liquor (viz., water, ammonia, carbonic dioxide, sulphuretted hydrogen, sulpho-cyanides, &c.) are thus brought continuously into intimate contact. The air loaded with the volatile alkali which has become eliminated from the solution passes upwards into the steam chest and through a branch pipe into the purifier or washer. This is a small wooden vessel of the capacity of 350 gallons, containing lime and being about one-third full

* Read before the British Association, Exeter meeting, Section B.

of water. It has a tight head and a stout perforated elm false bottom, the holes being concentric and increasing in number and dimension as they radiate from the inlet, which is brought below the false bottom.

This purifying vessel is furnished with a small agitator having two blades, one revolving above and the other below the false bottom. There are two trial or test taps at appropriate heights, to test for gas or for water, and there is also a pipe sealed at one end, rather less than half way from the bottom, for the purpose of leading away any excess of liquid that may accumulate owing to the condensation of aqueous vapour which may pass over with the volatile alkali. There is a long straight tube or safety pipe from the washer, and the bent pipe from the ammonia generator is also provided with a safety valve and a vacuum valve. In the washer the ammonia is deprived of any remaining hydrosulphuric acid or other impurity that may have escaped being fixed in the generator. About half a bushel of finely sifted slaked chalk lime is found to be a suitable charge for the washer, and when this becomes saturated or impure, it is renewed by means of a pipe and tap placed at the bottom of the vessel. The washer being a close vessel soon becomes full of air and gas, which are forced by the pressure through a pipe opening into the top and leading to a coil or worm placed in a cold water cistern, and terminating in a deep close vessel about one-third full of pure cold water, which has been condensed from the waste steam from the engine. A portion of the ammonia becomes absorbed by the water, but the residue, together with all the air, after bubbling up through the liquid, is conducted by a bent pipe to nearly the bottom of a second similar receiver, and thence in the same way to a third, but which is opened at the top,

The air, having fulfilled its function, is now permitted to escape into the atmosphere, the whole of the ammonia having, however, been arrested.

This last receiver, instead of water, contains a strong solution of chloride of iron, which being denser and possessing a higher specific gravity than water, offers a greater pressure and resistance to the passage of the gas. The iron salt is, of course, decomposed, with formation of muriate of ammonia in solution, with deposition of a green mud containing sesquioxide of iron, which, after having been calcined, is found to constitute an excellent pigment for rough iron or wood-work.

After the whole of the ammonia has been extracted from the gas liquor, the contents of the still are run off into a draining pit, from which the clear solution finds its way into the sewers, and the solid inodorous lime compounds may be carted away.

This draining pit is constructed of 1¼ inch deal boards together with sand and brick-work. It is 4 feet 9 inches wide, 5 feet 4 inches deep, and 10 feet long. There are fillets whereon to rest three perforated shelves or platforms. The bottom is formed of perforated deals with 6 inches of sand, also with gravel, and cement. There are channels and small drain pipes leading into a large central earthenware pipe, and from thence into the sewer. The sharp sand, &c., under the perforated boards can be removed at will, and be replaced by fresh materials whenever required.

Care must be taken that the large pipe from the boiler to the washer be sufficiently high to guard against any back pressure. The vacuum valve opens and admits air when the fire of the still is withdrawn and the steam becomes condensed.

In order to ascertain the exact state of the contents of the boiler at any required height, and to avoid tapping the upper portion of the boiler at too many places, the following simple contrivance is adopted:—There is one tap at the lower end, to which is attached a short pipe inside the still working easily on an elbow. To this pipe is connected a copper wire having its outlet just above the external surface of the boiler, and by which wire the short pipe may have its orifice presented at any required height, at which it is desired to ascertain the state of the contents of the vessel. For instance, supposing the fire to be withdrawn, and the agitators to be quiescent, if the end of the tube were pulled up by the wire and the tap opened, a clear liquid would issue, which could be tested in order to ascertain whether the whole of the ammoniacal gas had been removed. On the other hand, if the short tube were allowed to lay along the bottom of the still, the opened cock would allow the green sulphocalcareous mud to escape. It is stated in Dr. Miller's "Elements of Chemistry" that, at a temperature of 32°, water takes up about 1050 times its volume of ammonia; at 59°, 727 times, and at 78°, 586 times its volume. Water saturated with ammonia at 60° contains more than one-third of its weight of the gas, increasing in bulk from 1·0 to 1·5, and becoming specifically lighter.

Hence the receiver should be not more than one-third or one-half full of water to allow for the increase in bulk caused by the solution of the ammonia.

In July, 1867, valuable papers upon the utilisation of the waste products of the manufacture of coal gas were read before that important body, the British Association of Gas Managers, by two of our first authorities on this subject, Dr. Letheby and W. Esson, Esq. Dr. Letheby declares that it is so manifestly of the greatest importance that the liquor should be sent away to the gas works as strong as possible; it ought, in fact, never to be under 6° Twaddle, or of less than 12 ounces strength, and with proper condensation and judicious washing there should be from 29 to 30 gallons of such liquor produced from every ton of coals. The price in London is 2s. per butt, 8-oz., with an increase of 4d. per oz. on every additional ounce of acid strength. Below 3° of Twaddle or 5 ounces of acid it does not pay for working, whereas at 10° or 11° of Twaddle it is a valuable product. Both Dr. Letheby and Mr. Esson emphatically insist upon the importance of the strength of the ammoniacal liquor. So rapidly does the commercial value augment, in relation to its concentration that, whereas a butt of 108 gallons of gas liquor is worth 4s., the same quantity of caustic ammonia of specific gravity 0·900 is worth from £15 to £20. A lower strength of gas liquor than 6-ounce has not hitherto been thought worth working, but one advantage in Braby's system of extraction and concentration consists in the fact that a high strength is not indispensable. Even 2 ounces would in practice yield a profit.

As an evidence of the importance of an increased supply of ammonia and of its large demand, it may be mentioned that a firm with which the writer is connected recently offered 4s. per butt of 6-ounce liquor, and yet was unable to obtain a supply, showing that the value has doubled in the short space of two years. Mr. Esson describes an economical arrangement for the extraction of ammonia from gas liquor with the assistance of steam, and by an apparatus similar to a Coffey's still, but which is subject to the disadvantage that the noxious gas (sulphuretted hydrogen) is not simultaneously fixed or disposed of, and that at least 15 per cent of ammonia is left in the liquor, which has afterwards to undergo the supplementary process of distillation with lime. The present ordinary method of making liquor ammonia is, as far as I am acquainted, from sulphate or muriate of ammonia, which is itself obtained from gas water. By Braby's process, liquor ammonia may be obtained much more quickly and economically from gas-liquor direct.

There are many gas-works where ammoniacal salts are now manufactured; but it is suggested that, in new works, or at those where the gas-liquor is not at present utilised, it would be preferable, in the event of the adoption of the principle herein advocated, that the ammonia, after concentration, should be sent to the sulphuric or muriatic acid works, rather than that the acids should be sent to the gas-works. In metallurgy, it is found more advantageous to transport the calcined or partly-prepared ores to the coal districts for smelting, rather than to take the fuel to the mines.

Barges fitted with tanks ordinarily employed in the conveyance of gas-liquor contain from 3000 to 8000

gallons. A land journey of 12 miles with two horses for a load of 500 gallons in a tank-van now costs £1. By rail, the cost of freight is 1d. per ton per mile.

The advantages of the above-described system may be summed up as effecting a considerable economy in labour, time, and occupation of plant, together with the facility of extracting the whole of the ammonia from the gas-liquor in a pure condition. A manufactory, previously consuming 10,000 gallons of gas-liquor per week, may now utilise 24,000 gallons, and at about half the expense of fuel of that formerly incurred.

The great interest of this subject in a chemical point of view, its high importance to the metallurgist and manufacturer, and the increasing value of ammonia to the farmer (with whom it is almost another name for fertility and abundance), must constitute my apology for having engaged so much valuable time in its consideration.

A CHEMICAL METHOD OF TREATING THE EXCRETA OF TOWNS.*

By EDWARD C. C. STANFORD, F.C.S.

THIS paper is intended as a continuation of two former papers read before the Glasgow Philosophical Society, and published together in the CHEMICAL NEWS, under the title of "A Chemist's View of the Sewage Question."

In these papers, I have endeavoured to show that the water-closet system of disposing of human excreta, unless it undergoes some great modification, can never be regarded as the perfect system of the future. I have strongly urged the general adoption of the dry-closet, as avoiding all the great evils which are apparently inseparable from the use of water as a vehicle; and pointed out the use of charcoal, by which its application to towns and cities is simple and easy. Since these papers were published, further experiments have been made, which strongly confirm the opinions already advanced, and form the subject of this paper.

Amongst other objections to the use of water as a carrier, I have specified—

1. The enormous cost of the works required, in proportion to the small amount of noxious material to be removed.

2. The large annual outlay required to keep the closets in order. Experience, in large cities, has shown that, on this account, these closets are quite unsuitable for the dwellings of the poor.

3. The enormous amount of water employed (estimated at 365 times the weight of the excreta), where, as in many towns, there is much difficulty in obtaining it.

4. That it results in a subterranean flood of filthy water, which must flow somewhere; and, wherever it flows, it pollutes the region, thus disseminating and distributing the evil.

5. This material, worth about 30s. per ton, has its value reduced, by dilution, to 1d. per ton, which it is impossible, by any known chemical method, to extract with profit.

6. The large generation of noxious gases in the sewers, which constantly escape into our streets and houses.

In reference to the latter, Dr. Gairdner speaks strongly of almost all sewers, as "diffusing poison upwards and downwards," and too often "carrying backwards, into the very heart of the dwelling, the reflux gases, the produce of the decomposition of the impurities of a whole neighbourhood."

Dr. Fergus characterises the sewers as "a gigantic laboratory under our dwellings," from which noxious gases escape, by gully holes into our streets and pipes into our houses.

He has furnished me with a number of extracts from eminent medical authorities, which conclusively show the highly dangerous character of the miasma occasioned by the infiltration of sewage water and the evolution of sewer gas.

Of these I shall only make two quotations, which should be sufficient to convince any one of the important bearing of this question on the national health:—

EXTRACT No. I.

Mr. SIMMS'S *Second Report* (1860) *of* Dr. GREENHORN'S *Investigations in Several Towns in England.*

Pages 59 and 60.—"*Diarrhœal diseases* are increasing in this country; they vary, in different districts, from 4 to 663 per 100,000 persons. If the diarrhœal death-rate of England generally were only ten times the minimum diarrhœal death-rate, there would be an annual saving in England of nearly 20,000 lives."

"In the districts which suffer the high diarrhœal death-rates, the population either breathes or drinks a large amount of putrefying animal refuse."

Page 61.—"If the diarrhœal death-rate of England is reduced to that which prevails among the healthier parts of the population, typhoid fever (now, probably, the cause of at least 15,000 annual deaths) will be reduced in more than equal measure; and in proportion as infantile diarrhœa is reduced, the convulsive disorders and respiratory inflammations of infancy (which now cause fully 60,000 annual deaths) will also show a large, if not equal, reduction of death-rate."

Page 64.—"The excess of mortality has, in all cases, been coincident with one or other of two local circumstances—(*a*). *The tainting of the atmosphere with the products of organic decomposition, especially of human excrement;* or (*b*), *the habitual drinking of impure water.*"

EXTRACT No. II.

From Mr. SIMON'S *Ninth Report to the Privy Council.*

Pages 32, 33, and 34.—"*Cholera* derives all its epidemic destructiveness from filth, and especially from excremental uncleanliness."

"It cannot be too distinctly understood that the person who contracts cholera in this country is, *ipso facto*, demonstrated with almost absolute certainty to have been exposed to excremental pollution; that what gave him cholera was, mediately or immediately, cholera contagion discharged from another's bowels; that, in short, this diffusion of cholera among us depends entirely on the numberless filthy facilities which are let exist, and especially in our larger towns, for the fouling of earth, and air, and water, and thus, secondarily, for the infection of man with whatever contagion may be contained in the miscellaneous outflowings of the population. Excrement sodden earth, excrement reeking air, excrement tainted water; these are, for us, the causes of cholera. Cholera ravaging here at long intervals is not Nature's only retribution for our neglect in such matters as are in question. *Typhoid fever and much endemic diarrhœa are, as I have often reported, incessant witnesses to the same deleterious influence. Typhoid fever, which annually kills some* 15,000 *to* 20,000 *of our population; and diarrhœa, which kills many thousands besides.*"

Dr. Fergus has drawn attention to a remarkable but very common and fruitful cause of the escape of sewer gas into houses. He frequently noticed, when attending patients suffering from gastric fever, a peculiarly sickly and offensive odour, and in all cases traced it to the leaden syphons and soil-pipes of the water-closet. On examination, these were generally found to be perforated with holes, sometimes of considerable size, through which the sewer gases freely escaped into the house. The evil exists to an extent which will scarcely be credited by those who have not specially investigated the subject. A long length of soil-pipe will often be found bulged outwards in little swellings, each of which, sooner or later, open, and present apertures for the escape of sewer gas.

* Read before the British Association, Exeter Meeting, Section B.

If the pipe be laid, as it often is, under a bed-room floor, this may go on for years, until at last the pipe is taken up in a perfect honeycomb of deterioration; and we may pretty safely predict the sanitary condition of that bed-room and of its occupants. I have been informed by plumbers that it occurs most quickly where chloride of lime has been used; but the necessity for the use of this shows that the evil had existed before its application. The pipe becomes covered in the interior with a whitish-brown powder, of which four specimens were examined; the composition is shown below:—

	I.	II.	III.	IV.
Carbonate of lead	2·70	86·00	91·00	92·90
Carbonate of lime	80·63	2·50	2·10	2·90
Water	0·45	1·20	1·00	0·50
Lead insoluble as oxide ..	—	3·50	1·50	1·45
Silica	1·35	2·80	1·00	1·60
Organic matter	14·87	4·00	3·40	0·65
	100·00	100·00	100·00	100·00

The lead put down as insoluble is combined, apparently, with a kind of fatty acid, represented as organic matter. In No. 1, chloride of lime has evidently been recently used. The pipes are all taken from different closets, and arranged in an increasing order of deterioration. The action is probably caused by the carbonic acid, aided by the other gases of decomposition, and the fatty matter of the excreta producing carbonate of lead under somewhat similar conditions to those which obtain in its manufacture on the large scale; the carbonate of lime being derived from the solid excreta. This view requires confirmation; but one fact is obvious (and it is sufficient to show that the water-closet has been introduced before we have studied its effects)—that leaden pipes so much condemned for carriage of water for drinking purposes are even more unsuitable for house drainage; and the reason given explains, to a certain extent, what is generally admitted—that the common earthenware syphon forms the cleanest water-closet.

None of the disadvantages enumerated attend the use of the dry-closet; still less can any of these gigantic malaria evils result from its general adoption. It meets every sanitary requirement, which, after all, is the main desideratum. Moreover, its machinery is simple and inexpensive. It effects at once a great saving of water; and it enables us to secure the whole of the value of the excreta. I have pointed out the only objections which can be urged against its application in large cities to be, when dry earth is used; the large amount required (three and a half times the weight of the excreta), the difficulty of obtaining such a supply, and the large cartage necessary: three and a half times the weight to be removed into the city, and four and a half times the weight to be carried out.

Now, by using charcoal, these objections are entirely removed; for it only requires one-fourth the quantity as compared to earth, and, by re-burning the charcoal, the supply is provided from the excreta itself; and the cartage is reduced to the weight of the material carried into the city, and twice its weight carried out. The quantity per diem for a population of 500,000 is calculated at 385 tons in, and 770 tons out; a quantity about the same in Glasgow as the city ashes.

Moreover, charcoal has other advantages over earth. It is a powerful deodoriser, and its employment guarantees a perfect immunity from odour quite unattainable by any water-closet; and it blackens and conceals the excreta so perfectly that no one seeing the product from the closets for the first time would have the least notion from its appearance what it was. As, also, the dust would always be sifted out for sale as manure, the charcoal used in the closets would always be of proper size, and no dust could be projected in the working of the closet. Such a closet could be kept in every bed-room without the possibility of becoming a nuisance, if only attended to; but, in houses constructed for the purposes, the closets on the several floors would be over one another, and the product from each fall through a 12-inch pipe to a small cesspit below the house, and this need only be emptied once a year. The small size of this pit may be imagined when it is mentioned that 1 cwt. of charcoal per month will be sufficient for each closet if used by six persons daily, and one cart load per annum will empty the pit.

Use of Charcoal in Latrines.—I have shown, in a former paper, how the use of seaweed charcoal in latrines effects its composition, by converting the carbonate of lime it contains into phosphate. The results published were from experiments with ten, twenty, fifty, and one hundred times its weight of urine evaporated down. I found that, though in all cases there appeared to be no appreciable loss of ammonia in drying, when the last product was re-burned alone, only half the nitrogen came over as ammonia, though the whole was obtained by soda lime. As, however, I propose for latrines the charcoal should be used ten times before re-burning, I have undertaken a complete series of experiments, the results of which are given in Tables A, B, and C, showing the composition of the chars after each re-burning, up to ten re-burnings and one hundred uses. The results are as regular as can be expected from the variable composition of the substance operated on. It will be seen that the residual chars rise, after five or six re-burnings, to about 25 per cent phosphate of lime, while the carbonate is reduced to 2 per cent. After having attained this composition at which it becomes regular, it would be advisable to add a certain proportion of fresh seaweed char, to prevent the phosphoric acid remaining soluble, of which a trace now appears, and to secure a regular supply of a good sugar-refiners' charcoal, which would add a considerable value to it. In any case, the phosphate of lime thus gradually deposited is quite equal to a soluble phosphate for agriculture on account of its finely divided condition. The average yield of ammonia by simple re-burning is about equal to the calculated amount, and shows clearly that neither in the drying nor in the distillation has any been lost. The total yield is 3·16 per cent on the char, or 31·6 per cent for each re-burning. The total increase of char is 183 per cent, or 18·3 per cent for each re-burning.

The density of the char has increased 131 per cent in the ten re-burnings, the increase being mostly in the first five re-burnings. The ammonia only was estimated in the destructive distillation. The increments of potash and phosphoric acid are pretty regular, that of sulphuric acid remarkably irregular. The commercial result of this process for latrines would be as follows:—Supposing the char sold as a manure after ten uses, 1 ton would produce, allowing 15 per cent for moisture, 30 cwts. of manure, containing nitrogen equal to 20 per cent sulphate ammonia, 7 per cent phosphate lime, and 5 per cent sulphate potash, and worth at least £5 per ton, or equal £7 10s., whilst it would have cost £2 for the char, 30s. for cartage, reckoned at 10 tons carted in and 20 tons carted out at 1s. per ton, or a profit of 8os. on each ton of char used. If, again, the char be used fifty times, and re-burned five times, its cost will be increased by cartage to £9 10s., and, by five re-burnings at 3s. 6d., to £10 7s. 6d., and in quantity, allowing 11 per cent for moisture, to 2 tons, the cost being thus £5 3s. 9d. per ton, and its value, containing 12 per cent phosphate lime, reckoned as soluble, and 15 per cent sulphate of potash, is £5 per ton, in addition to which nearly 30 cwts. of sulphate of ammonia are yielded in the five re-burnings, worth, at 16s. per cwt., the sum of £24 less the cost of acid. If, however, the char be as good a sugar refiner as I suppose, its value will be much above that stated. In this case, however, the char would have to be washed, and the amount would be less by the amount of soluble matter it contains from which the potash could be separated. It would be easy, of course, to increase the soluble phosphate for some crops by the addition of mineral phosphate rendered soluble.

Use of Charcoal in Closets.—The experiments, the results of which are given in Tables D and E, were made with one of Smith's self-acting dry-closets, used by several lads.
